The third work, *Objective Analysis of Meteorological Fields*, is, by contrast, a valuable monograph on a limited theme, and prompts a little digression. The post-war application of basic fluid physics to atmospheric motions of weather systems on the largest scale and to the general circulation is particularly important and interesting because of its direct relevance to routine weather forecasting, more or less familiar to everyone. The techniques in use hitherto depended on the charting of weather patterns and particularly of barometric pressure patterns drawn freehand and extrapolated into the future by expert judgment—a highly subjective process. It should

perhaps be kept in mind that the same procedures are still in use almost everywhere in the world, and that the new mathematical techniques have as yet been introduced into routine practice only at a few weather centres in spite of 20 years' steady progress in a few leading countries.

The topic of L. S. Gandin's monograph is just one facet of the whole complex, and is concerned with methods whereby the raw data of meteorological observations received over telecommunication networks from all parts of the world may be fed directly into the high-speed computer to define the initial conditions of the dynamical problem without the need for expert analysis. The difficulties that arise are mainly specific to the problem and derive from the unevenness, sparsity and errors of the observations coupled with real variability on scales smaller than that of the problem. Where data are sparse (especially over the oceans), linear interpolation is hopelessly inaccurate; where data are numerous, smoothing is essential. For these reasons, there is no ready definition of a 'best fit', and quite elaborate techniques combining interpolation, smoothing and weighting have been developed and justified empirically. The main purpose of Gandin's book is to present a system of 'optimum interpolation'. It is essentially a method of least squares to determine grid-point values of the variables in terms of the data and the structure functions and correlation functions of the fields, statistical quantities much more familiar in turbulence theory than in world-scale dynamics. The book touches on a number of other problems which arise in weather analysis and, as a rare example of academic elegance and clarity applied to this field, will be welcome not only to research workers but also to teachers who struggle to provide students with an insight into what is now a rapidly developing technology. The bibliography, comprehensively covering 'western' as well as Russian literature, will be really useful, and the introductory chapter which gives an account of the non-Russian work is equally helpful.

In this monograph, structure functions and correlation functions are introduced as statistical concepts to be applied to a statistical problem, but the formal discussion is welcome, as their application to large-scale dynamics is of growing importance. Their value in the theory of smaller scale turbulence, including the atmospheric boundary layer, is, of course, well known, but we need look no further than a paper by Smirnov, included in Prof. Blinova's book, to find evidence of special complications. This paper shows the geographical patterns of covariance of pressure between selected positions and all other positions in the northern hemisphere. The inhomogeneous nature of large-scale turbulence is clearly shown and confirms that the climate of the real Earth, however it may be disguised, differs from place to place with longitude as well as with latitude, a geographical fact which some geophysicists still find uncongenial.

ROCK METAMORPHISM

Controls of Metamorphism

Edited by Wallace S. Pitcher and Glenys W. Flinn. (A Symposium held under the auspices of The Liverpool Geological Society.) Pp. 368. (Edinburgh and London: Oliver and Boyd, Ltd., 1965.) 84*s*. net.

CONTROLS of Metamorphism is the proceedings of a symposium held in the Department of Geology at the University of Liverpool early in 1964, called to provide an opportunity for assessment of present understanding of the geological factors which bring about metamorphic changes in rocks and of the conditions in which such changes are effected. In the course of a re-examination of many familiar text-book statements concerning the significance of temperature, of pressure (both hydrostatic and non-hydrostatic) and of chemical environment, some time-honoured concepts were subjected to renewed and exacting scrutiny.

In an opening generalized survey J. Sutton adopts at once the view that regional metamorphism is essentially a thermal phenomenon. He holds that unusually great accessions of heat, in conditions which are geologically abnormal, are maintained for variable long periods, although such conditions are not widely developed at any one time. Other writers concur, but not all. M. P. Atherton examines the chemical significance of isograds and writes that recent work seems to indicate that pressure is relatively unimportant compared with temperature in relation to the definition of an isograd as a line joining points of similar pressure/temperature values. E. D. Lacy uses some striking examples of the interplay of temperature and activation energy factors to emphasize the importance of temperature in determining reaction rates. The view that there has been a tendency to minimize the importance of pressure relative to temperature is put forward by R. W. Rutland, who points out that recent experimental work at high pressures has emphasized a number of reactions which may properly be described as pressure-dependent. Harker's concept of stress minerals is rejected, the real importance of non-hydrostatic stress probably lying in its effect on the kinetics of reactions and the promotion of metastable growth. Rutland is mainly concerned with the problem posed by the often striking lack of agreement between geological estimates of depths of formation of some metamorphic minerals and the depths which seem to be indicated by experimental work. Likely tectonic overpressures appear inadequate to bridge the gap, and a chemical explanation (including the possibility of metastable growth) must be considered.

The textures of metamorphic rocks receive detailed attention from D. Flinn and N. Rast—many petrologists will fully endorse the opinion of the latter that preoccupation with the study of metamorphic facies has led to widespread disregard of textural patterns. Both these authors make frequent reference to the literature of solid-state physics, particularly metallurgy, and their contributions are followed by a helpful account of the science of metamorphism in metals presented by D. McLean, who applies the present development of these theories to a consideration of metamorphism in rocks. With the very different amounts of time available and very different temperatures prevailing, small variations in composition of a mineral may have a profound effect on equilibrium relationships—one example of many references to the way in which such relationships may come to depend a great deal on the particular composition of the rock in which a mineral is developed. Inherent in several contributions which are concerned with problems of host-rock composition and the chemistry of component minerals is the question whether chemical equilibrium is in fact commonly attained. Atherton, in his discussion of isograds, believes that in general it is. It has, of course, been recognized from the time of the earliest applications of the concept of index minerals that their conditions of genesis and their composition are often closely related to the bulk composition of the rock, and some "reversals" may thus be explained. Systematic variations in composition of micas, which are closely related in this way to the host-rock, are demonstrated by B. C. M. Butler, who points out that this situation may give rise to some difficulty in the determination of grade; and B. E. Leake reports similarly that over a wide range of temperatures and pressures it is the rock composition which mainly controls the composition of calciferous amphiboles.

Metasomatic metamorphism and the origin of migmatites provided yet another field for exploration. Discussions, opened by invited speakers, followed the presentation of the papers but are not recorded in full, though

there are frequent references to them in a general introduction to the volume by W. S. Pitcher. The reader is, in fact, occasionally tantalized by a remark such as "It is of interest to note that the validity of the basic assumptions [in isotopic dating procedures] could still be the subject of a vigorous debate". True to the original derivation of the word 'symposium', the meeting at Liverpool provided a feast of ideas (not all of which we have been able to mention here) as varied as the courses at a banquet and differing as widely in flavour and in nutritional value. They make a significant addition to the literature of metamorphism. The volume is described as *Geological Journal Special Issue No.* 1; we are encouraged to look forward to future special issues of similar quality.

F. C. PHILLIPS

ULTRASONICS IN MEDICINE AND BIOLOGY

Ultrasonic Energy

Biological Investigations and Medical Applications. Edited by Elizabeth Kelly. Pp. 387. (Urbana, Ill.: University of Illinois Press, 1965.) 12.50 dollars.

ULTRASONIC Energy brings together summaries of achievement and research in most aspects of ultrasonic technology as applied to medicine and the biological sciences, and is a good description of the subject as it stood three years ago. It is largely, if not entirely, the proceedings of the symposium on "Ultrasound in Medicine and Biology", held in the University of Illinois in June 1962. It is a very well produced book with excellently prepared diagrams, photographs and microphotographs, many in good colour.

In medical and biological research to-day, ultrasonics is providing useful assistance toward diagnosis by the delineation of structures as an alternative to X-rays for soft tissues or where radiation damage might be dangerous, for example, in the diagnosis of pregnancy. It is also being used therapeutically for producing discrete brain and nerve lesions, and in smaller doses for treatments in physical medicine. In biology it assists investigations of cell structure, helps to identify proteins and augments the destructive effects of X-rays on malignant tumours. It has the advantage that it can be focused and directed into the body with considerable precision.

Ultrasonic Energy will bring many aspects of the subject to the attention of workers whose main study is limited to a particular branch. Medical readers will find much of interest and ideas worth further study.

There are twenty-six sections or articles, each prepared by an expert research worker. Eight of these sections are on diagnostic techniques (for the eye, brain, heart and abdomen) by the pulse-echo technique; four are on surgical uses of high-intensity ultrasound, two on the effects of ultrasound on malignant cells, two on the neuromuscular system, one on the liver with emphasis on cellular effects, one on the effects on the ear and one is an abstract of work on physical medicine. There are five good articles on the action of ultrasound in biological tissues at different intensities and analysis of the effects of cavitation, of gas bubbles and streaming of cell protoplasm.

Practically the entire contents of the book can be found elsewhere by searching the technical and medical literature, but there is convenience in their concentration in a single volume. The expert reader should, however, be reminded that the book has scarcely been re-edited since the conference and, of the copious references, only four are dated after 1962. The article on physical medicine is given in a half-page abstract because the writer could not attend the conference; surely his full manuscript might have been obtained in the succeeding three years, especially as the book, in its title, does not purport to be a record of the conference but a text-book of the art. It contains verbatim reports of the discussions which followed each paper, even about films which the reader cannot see. As is usual in discussions in a large symposium, many of the remarks and questions are wide of the mark.

It surprises me that, with so much apparently known of the value of ultrasound coupled with X-rays for the destruction of malignant cells, this application has no advocates in the clinical field.

The contributors are from Europe and Japan as well as from many parts of the United States and it is internationally a comprehensive book.

C. N. SMYTH

FROM LIGHT TO SIGHT: THE METABOLIC BASIS

Biochemistry of the Retina

Edited by Clive N. Graymore. (1st International Symposium, London, September 1964.) Pp. xiv+172. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1965.) 60*s*.

VISION is a complex process involving a multitude of phenomena ranging from the relatively simple refraction of light to the interpretation of the nervous impulses in the brain. *Biochemistry of the Retina* is concerned with some of the intervening processes by which quantum energy is transformed into chemical and electrical signals, how this highly specialized tissue is maintained in a functional state and how diabetes, retinal degeneration and retinotoxic substances which each disturb metabolism and function may give a better understanding of normal processes.

Twenty papers were presented at the first international symposium on this subject and, although the approach and emphasis were extremely varied, the conclusions reached are entirely complementary. Discussion followed each paper, thus allowing alternative interpretations to be suggested and correlations with other findings to be emphasized. By including these, the editor has welded the individual reports into a coherent and valuable book.

Three papers deserve special mention, and a fourth, on the limitations in the use of tetrazolium salts for the histochemical localization of dehydrogenases, is important in view of the widespread use of this method in studying the retina. W. K. Noell examines the relationship between metabolism, light-evoked potentials (electroretinogram) and morphology of the retina, comparing normal animals, those with hereditary retinal degeneration and those with experimentally damaged visual cells. He concludes that the particular vulnerability of the visual cells to X-rays, hyperbaric oxygen, high light intensity and iodoacetic acid may be due to the presence of a light-activated energy transfer system which is highly susceptible to detrimental oxidations. A note at the end of the symposium on the role of ubiquinone is particularly relevant to this thesis. A defect in protective mechanisms could be a crucial factor in the genetic disease. L. Cohen, in conjunction with Noell, uses similar findings as a springboard for speculation on the molecular mechanism of the initial events of vision. Not all the facts fit the theory (or vice versa) but it is a worth-while exercise with stimulating ideas and a framework for new thought. Finally, M. Keen and C. Chlouverakis present an interesting hypothesis on the mechanism of diabetic retinopathy which evoked considerable discussion and approval.

Poor proof-reading of one paper detracts from the otherwise very high standard of editing and presentation, and two contributors have submitted inferior photomicrographs. It would have helped the wide range of non-retinal biochemists whom the book will surely interest if a consistent labelling of retinal sections had been adopted. Nevertheless the book begins to fill, most

admirably, a large gap in our knowledge of visual processes; it will be invaluable to the specialist and of absorbing interest to those with time to wonder.

M. V. RILEY

THE WORLD'S RICEBOWL

Rice

By D. H. Grist. Fourth edition. (Tropical Agriculture Series.) Pp. xxiii+548+74 photographs. (London: Longmans, Green and Co., Ltd., 1965.) 75*s*. net

THE importance of rice as a staple diet for many millions, particularly in the Far East, is underlined by the fact that nearly nine-tenths of the world production is in this area. Rice is also predominantly a peasant crop; only 6 million out of a total annual production of about 160 million tons enter world trade; much rice is consumed by the grower and most of the remainder in the country of production. This also highlights one of the difficulties in increasing yields per acre because, following the introduction of improved varieties, the chief means of doing this are by better water control and by the increased use of fertilizers, herbicides and pesticides. These improvements require a change from subsistence farming towards cash cropping. The heavily indebted peasant populations do not have the necessary money, so that social and financial as well as technical changes are involved in this very urgent struggle to increase world food supplies.

The present edition of the valuable book, *Rice*, by D. H. Grist will prove helpful to those engaged on all aspects of rice production—plant breeding, paddy growing, and rice processing and marketing. The book has been divided into three parts: 1, "*Oryza sativa* Linn.: The Plant"; 2, "Paddy Production"; and 3, "Rice: The Product". The arrangement of chapters between the parts does not appear entirely logical, because Part 1 contains chapters dealing with climate and soils, and water supply and control, and Part 3 covers the very wide range of subjects from milling and storage to production statistics and conditions of land tenure. The titles to the parts indicate the scope of the text, which occupies 463 pages. In Part 1, Mr. Grist starts with a short history of rice, digresses to soils and water supply and returns to his main theme with descriptions of the plant, and of varieties, and concludes this section with chapters on the genetics and breeding of rice. Part 2 covers the many facets of paddy production—methods of cultivation, fertilizers, weeds, diseases, and pests, and a useful description of fish farming in paddy fields. Part 3 describes the storage and milling of rice, factors affecting the nutritional value of rice, and finishes with chapters on the statistics of production and consumption and on economic conditions. Following the main text, there are three short sections: (i) seven appendixes relating to topics in seed testing, terminology and rice breeding; (ii) a bibliography with more than 700 entries, which are arranged alphabetically and numbered, so that reference to a particular author is easy and text references are exact; titles are also given, which is valuable in such a large and varied bibliography; (iii) the book concludes with a good index.

Mr. Grist has drawn his material from several standard works, from reports of the Food and Agriculture Organization and elsewhere, as well as from original work published throughout the world. He has quoted much that is not available to the normal literature searcher and therefore performs a most useful service. Unfortunately, his style tends to be indirect and at times slightly wordy, so that continuous reading of the book is something of an effort. There are one or two minor inconsistencies; for example, the columns in Table 2 do not have uniform units, and some of the headings do not allow the exact compound to be identified. The photographs and line drawings (which have been little altered since the first edition) complement the text admirably. There are very few misprints (and those noted are only single letters wrong). When reviewing the third edition of this book, the late Dr. H. Greene wrote a short article describing the current ideas on oxidation-reduction in paddy soils, and quoted some results by workers at the West African Rice Research Station (*Nature*, 186, 511; 1960). One would have liked to have seen Mr. Grist use these ideas and expand them with the work published between 1960 and 1964 for the present chapter on soils. However, these points are less criticisms of the present book than suggestions for any future revisions. There is no doubt that Mr. Grist's book has become a standard work on rice and is invaluable to anyone seeking a balanced opinion on any topic connected with the crop, or a guide to the original literature. At the price, the book represents good value for money and individuals as well as libraries should be able to afford to buy it.

J. K. R. GASSER

FINGERPRINT SCIENCE

Finger Prints

By Francis Galton. Pp. xxiii+xvi+216+15 plates. (New York: Da Capo Press, 1965. Originally published 1892.) 6.95 dollars.

THE scientific study of the dermal ridge patterns on the finger-tips has three aspects. First, it leads to a method of personal identification, secondly it forms the basis for genetical and anthropological investigations and, thirdly, it has significance in relation to certain malformations and growth disturbances. The most notable pioneer in the first and second fields was Francis Galton, whose chief work on the subject, *Finger Prints*, was originally published in 1892. This delightful book contains not only a very full description of the anatomy of variations in finger ridge patterns but it also gives some account of the historical background and initiates hereditary enquiries.

The main emphasis in Galton's work, however, is on the matter of personal identification. This application of dermatoglyphic science transcends all others in its scope and it chiefly concerns the small details of the ridge formations which seem to be chance variations rather than hereditary characters. As Galton says, "For instance, it would be totally impossible to fail to distinguish between the finger prints of twins, who in other respects appeared exactly alike". He explains how a system of identification by finger prints would be vastly more efficient than that proposed by Bertillon using an assortment of physical measurements and body markings. One great advantage of ridge configurations is that they do not alter with age—at least, their relations do not alter. "The pattern grows simultaneously with the finger, and its proportions vary with its fatness, leanness, usage, gouty deformation, or age. But, though the pattern as a whole may become considerably altered in length or breadth, the number of ridges, their embranchments, and other minutiae remain unchanged." On the general question of the use of these methods, Galton says that "in civilized lands and in peaceable times, the chief use of a sure means of identification is to benefit society by detecting rogues, rather than to establish the identity of men who are honest".

The reprint by the Da Capo Press is most welcome, since very few copies of the original are now to be found. An enlightening introduction is aptly supplied by the anatomist, Dr. Harold Cummins of Tulane University, who has been the pioneer in researches in the third field of dermatoglyphic studies, namely, their pathological applications. This addition amplifies considerably Galton's own historical account and directs attention to the world of Faulds, which was surprisingly neglected by Galton. Galton's failure to mention Nehemiah Grew might also have been

noted and perhaps the remarkable translation from Purkinje's paper might have been commented on.

Galton's ample illustrations are not so well reproduced as might have been desired. For example, Figs. 7 and 15 are too heavily printed and Figs. 9 and 19 seem to be fading away. Otherwise the new book is well produced. At the present time, when many new data are becoming available on chromosomal aberrations associated with deformities which include alterations in papillary ridge patterns, it will be particularly useful to have this classical work easily available. L. S. PENROSE

MODERN SURFACE COATINGS

Modern Surface Coatings

A Textbook of the Chemistry and Technology of Paints, Varnishes, and Lacquers. By Paul Nylén and Edward Sunderland. Pp. xiv+750. (London and New York: Interscience Publishers, a Division of John Wiley and Sons, 1965.) 147*s*.

A GOOD index of the rate of development of a branch of science or technology is provided by the number of books published on it. There has been a great flowering of books dealing with surface coatings, especially paints, in the past five years or so, rightly reflecting the active technological development and the growing orientation towards a systematic and science-based approach to the subject. In addition to specialist monographs on specific subjects, there have also been several general treatments of the field, and *Modern Surface Coatings* must be judged in relation to these, as well as on its own merits.

The important part in surface coatings played by developments in raw materials is illustrated by the allocation of space in the present book; there are 275 pages on polymers and polymerization, 50 on solvents and plasticizers and 170 on pigments—almost 500 in all on raw materials, compared with 120 pages on pigment dispersion, film properties and paint application, and 80 pages on specific types of paint. While accepting the importance of raw materials, one would have liked to see fuller treatment of the problems specifically related to paint making and using, the sections on surface preparation and application methods being particularly limited.

This having been said, it is difficult to find fault with the book as a general introduction to paint science and technology, and it should prove invaluable to students everywhere; the sound approach doubtless owes much to the first-hand experience of the authors in teaching the subject at the Royal Institute of Technology in Stockholm. Emphasis throughout is placed on the scientific principles behind the subject, and the authors have—rightly—little time for empiricism and the development of complicated formulations. As they say (p. 609) regarding the case of defects: "a thorough investigation and the use of a little physico-chemical imagination are much more likely to lead to a satisfactory and lasting solution". Readers need not expect, therefore, to find specific paint formulations in this book.

The general approach is to provide a balanced, critical and up-to-date survey; also a much more international outlook than usual is provided, with references to publications and standards drawn freely from the major contributory countries—mainly the United States, Germany and Britain, supplemented by specific Scandinavian contributors where appropriate. Another refreshing and useful feature is the use made of trade names and references to trade literature, whenever this seems the best source of information.

Minor omissions are the absence of any reference to polyvinyl fluoride polymers, and the curious omission of zinc silicates in the sections on inorganic and anti-corrosive paints, their treatment being restricted to anti-fouling paints. Only minor errors of fact were noted, and the whole book reads extremely well. References are numerous and up to date, one for 1965 being noted.

A better title would have been "Principles of Surface Coating Technology", but this was already pre-empted by the book by Parker from the same publishers; indeed, as Parker's book deals much more soundly with formulations than with principles, it is a pity the titles could not be reversed!

To sum up, *Modern Surface Coatings* should be of great value to students, lecturers and newcomers to the industry, and perhaps be educative even to established technologists. It is the best single-volume treatment of paint science and technology available to-day. L. VALENTINE

RUSSIAN FOR SCIENTISTS AND OTHERS

Complete Russian Course for Scientists

By M. Beresford. Pp. xvii+227. (Oxford: Clarendon Press; London: Oxford University Press, 1965.) 25*s* net.

COMPLETE Russian Course for Scientists is an excellent book and the key to its excellence lies in the fact that the title could easily have been "Complete Russian Course for Scientists and Others". There are a number of books in existence which claim to purvey Russian for scientists, and in most of them there is little or no attempt to teach the language. The books are useful—in a very limited way—for the particular scientists the authors have in mind (chemists, physicists, geneticists, etc.). They are rarely helpful to scientists in general.

The book under review is a very different affair—"a rapid, intensive course, designed to enable beginners to master the essentials of Russian for reading purposes". The author, obviously interested in philology, has produced a book which can be used not only by scientists and technologists, but by all students of Russian. It concentrates on the main features of Russian grammar and introduces scientific jargon gradually and progressively into the exercises, at first in the form of isolated phrases and then, in moderation, in the form of short texts.

The book contains twenty lessons (pp. 1–167), a supplement (pp. 171–193) containing eight divisions, including declension tables, tables of verbs, metric-English equivalents and a most useful list of Russian abbreviations, and finally (pp. 195–224) a select Russian–English vocabulary.

For the benefit of potential users of this book, here are a few notes on the contents of certain chapters. Lesson 1, as one would expect, deals with the Russian alphabet and includes numerous exercises. Lesson 2 deals in a masterly fashion with pronunciation, a most important feature of the Russian alphabet, with hard and soft vowels, stressed vowels and consonants and like topics. Lesson 3 deals with the structure and derivation of words. Lessons 4–12 cover the cases of nouns and the tenses and aspects of verbs. Lessons 13–20 deal with an important selection of topics—Russian names, pronouns, particles, participles, numerals, fractions, gerunds, compound words, suffixes and roots.

It will be clear from this brief review of the contents that this book gives all the grammar necessary to provide an adequate background for a reading knowledge of the language, and this is supplemented by appropriate exercises. Two final points for the reader who wants to get full value from the book—the Russian alphabet is very necessary for constant reference during the early stages of the course. A spare copy on a card, which could easily be moved from page to page, would facilitate such reference. The second point is in the nature of a warning. This is not a book to be read through. It calls for hard work and determination, but the author has done his best to make such hard work and determination a good investment.

S. I. TOMKEIEFF

EUROPEAN LAUNCHER DEVELOPMENT ORGANIZATION—BEGINNING AND END

THE European Launcher Development Organization (ELDO) began with the abandonment by the United Kingdom Government of the development of the *Blue Streak* military rocket in April 1960. The rocket, which had been intended as a ballistic weapon with a range of 2,000 nautical miles, was built around two rocket engines of a type similar to that used in the American *Thor* and *Jupiter* rockets, but constructed and developed in the United Kingdom by Rolls-Royce, Ltd.

Before the decision to abandon *Blue Streak* was announced, studies had already begun of the potential usefulness of *Blue Streak* for civilian purposes. In September 1960, the United Kingdom, after suitable diplomatic preparation, invited a number of European countries to participate in an organization for launching satellites. The conference met in Strasbourg on January 30, 1961, and was attended by ministers from the United Kingdom, France, Belgium, Denmark, Germany, Italy, the Netherlands, Norway, Spain, Sweden and Switzerland. Observers attended from Austria, Canada, Greece and Turkey.

At this time the British Government was separately concerned in discussions with members of the European Economic Community about the feasibility of British entry into the Common Market. At the same time, too, initiatives were being taken to establish a European organization for launching scientific satellites (ESRO) the existence of which was not affected by the discussions on the future of ELDO.

At the Strasbourg conference in 1961 it was agreed that if a European organization for launching satellites were created, the first programme would be the development of a three-stage rocket based on British and French experience. The first stage of the rocket would be built by the United Kingdom, the second by France, the third stage and any satellites to be launched by other European countries. Tests of the complete vehicle would be carried out at Woomera in Australia.

It was also agreed at Strasbourg that any organization would be exclusively pacific and that all technical information arising out of the developments would be placed freely at the disposal of member governments. The British and French Governments agreed that their own experience would be placed at the disposal of the joint organization. (This raised the question, which has never been cleared up, of whether the British Government was entitled to place at the disposal of other European Governments information acquired under bilateral military agreements with the United States.)

At the first meeting it was also agreed that the estimated cost of the first programme—£70 million—would be spread over five years and would be shared between the participating countries on the basis of a third share by the United Kingdom and a division of financial responsibility among other countries in proportion to national income.

The Strasbourg conference was followed by a meeting in London in October 1961 at which Australia joined the participants. By this time it had been agreed that the organization should undertake a study of other possibilities than those based on the *Blue Streak* rocket. At this early stage it was plain that the estimated cost of £70 million for the first programme might not be realistic. It was further agreed that any expenditures exceeding this estimate would be divided among the member countries of any organization set up on a basis which might have to be negotiated within the organization at a later stage.

The formal convention of ELDO was opened for signature on April 30, 1962, and was promptly signed by Australia, Belgium and France, West Germany, Italy, the Netherlands, and the United Kingdom. Technical and administrative committees were established as were headquarters in Paris. A number of legal difficulties arising from the lack of definition of the powers in international law of the preparatory committee was eventually overcome. Throughout 1963 plans were drawn up for an initial programme and finally it was agreed that the convention should become binding on its signatories on March 1, 1964. Because by this time it was plain that the Scandinavian countries, together with Austria, Spain and Switzerland, would not sign the convention, it was agreed that the financial responsibility of those countries would be shared between France, West Germany and the United Kingdom (which increased the British share of the total cost to 38·79 per cent, compared with 24 per cent for France and 22 per cent for West Germany).

By the beginning of 1965 it was plain that the original estimate of cost of £70 million would have to be exceeded. For one thing, the original plans were acknowledged to be over-optimistic, and in April 1965 it was recognized that expenditure of some £22 million more than the original estimate would probably be necessary. At the same time it was argued by the technical working group that the initial programme based on *Blue Streak* and upper stages with conventional fuel would have to be replaced by a programme called ELDO *B*, involving liquid hydrogen fuel, if desirable objectives were to be attained. It was estimated that the cost of this programme, in 1965, would bring the total to more than £140 million. Further refinements of the system suggested more recently by working parties of the organization would have involved costs rising to perhaps three or more times the original estimate of £70 million.

The implementation of the initial programme has involved so far the launching of one first-stage rocket (*Blue Streak*) from Woomera. The first launching of a rocket complete with upper stages had been planned for the end of 1967 at the earliest. The chances that the programme of satellite development and launching originally conceived could be completed within the five years set aside for the ELDO agreement have become increasingly remote.

British dissatisfaction with the rising cost of ELDO has been expressed openly in ministerial circles for at least eighteen months. It has also been pointed out that the time is long since past when the ELDO development could be usefully thought of as a basis for a European communications satellite system. The first ELDO ministerial meeting since the signature of the convention, held in Paris at the beginning of May 1966, ended inconclusively with a decision to allow a period for further consideration of proposed refinements of the ELDO system intended to increase the launching capability of the system, and for further consideration of the cost thereof. The British Government's decision to withdraw from the current ELDO programmes derives directly from that first ministerial meeting.

According to British sources, there is no reason why other European countries should be surprised at the British decision, which is expressed in the following form of words:

"For some time the Government has had serious doubts about whether or not it should continue to participate in the ELDO programmes. These doubts were centred on financial, technical and economic assessments of the initial programme.

"The Government has concluded after a very careful and detailed consideration of all the factors involved that the latest proposals for modifying the initial programme still do not constitute a sufficient basis for continuing United Kingdom participation in the activities of the Organisation, and it has so informed its partners."

THE FRANKS REPORT—AN INSIDE VIEW

By Prof. R. E. RICHARDS
Physical Chemistry Laboratory, University of Oxford

[This comment on the Franks Report by Prof. R. E. Richards, Dr. Lee's professor of physical chemistry at Oxford, differs in part from that which appeared in *Nature* on May 14 (**210**, pp. 667–8), particularly on admissions policy and balance between humanists and scientists. Its publication here should not be taken to indicate anything but a belief that public discussion of the Franks Report is in the public interest—or at least in the interests of the University of Oxford]

THE report of the Franks Commission on the University of Oxford was published on May 12, after 2 years of intensive work [*Nature*, 210, 661, 667; 1966]. Hasty judgments on the complicated issues raised in the report are not likely to be of much value, but the following personal impressions concern some of the matters raised and the preliminary reactions they have produced.

The character of a university is bound to be strongly influenced by its admissions policy, and the procedure at Oxford has been widely criticized on various, sometimes incompatible, grounds. Before 1945, most who had suitable qualifications and could pay the fees could come to Oxford. After the 1944 Education Act, however, applications for admission increased very rapidly and far exceeded the capacity of the colleges. For many years the colleges had been setting an examination for the election of Scholars and Exhibitioners, and this well-tried system soon came to be used for the selection of nearly all candidates for admission. The examination has proved to be very effective at selecting promising young men, and those who have had a third year in the sixth form have been at a great advantage over others. It has thus been responsible to some extent for the criticisms often made simultaneously that Oxford takes too much of the cream of talent among university entrants and at the same time favours the independent schools.

The Commission has recommended that the examination should be retained, but with special questions only for those who are in the second year of sixth-form work. This proposal has already been anticipated by the scientists, who are setting a special paper in the next examination, which may be taken only by those who are in their second year after Ordinary Level. It is hoped that this proposal will accelerate still more the trend towards a greater proportion of candidates from maintained schools (only 19 per cent of those admitted in 1938–9 as against 47 per cent in 1965). It is interesting to note that almost the same proportions of those applying from maintained schools, from direct grant schools and from independent schools were admitted in 1965.

The proposal to abolish closed awards will also be generally welcomed. Their origin is historical and they are anomalies at the present time; 45 per cent of the closed awards in 1965 were made to candidates from independent boarding schools. Opinion among university teachers and school teachers is divided on the value of Open Scholarships and Exhibitions. Some think that the incentive to study for an examination without a restricted syllabus is valuable, others that it distorts the school curriculum. The weight of evidence to the Commission strongly supported the view that the present Advanced Level Examination, rather than the Oxford Scholarship Examination, is the main cause of undue specialization in the sixth form. The report recommends that the number of scholarships should not exceed 10 per cent of those admitted, thereby saving about £100,000 a year for other educational purposes. On this basis a small college might be able to offer only five or six scholarships a year, so that comparison might have to be made between very different subjects. The choice between, say, a physicist and a historian is often likely to be a rather arbitrary one, and for this reason many tutors would prefer to see scholarships for undergraduates abolished altogether. One compromise might be to award scholarships for one year only, and then to re-allocate them each year on the basis of progress made that year. This is open to the objection that it depends only on the personal judgment of a tutor.

The award of scholarships to postgraduates by colleges is recommended, and many recommendations are also made on the admissions of postgraduates, but these seem to be more applicable to the arts than to the sciences.

The size of the University is discussed at some length. As expected, the Commission has concluded that the collegiate system has so many advantages that the University of Oxford should not be allowed to grow so much as to undermine this important feature. Furthermore, the essentially democratic constitution of the University is easier to maintain than it would be if numbers were allowed to rise by a large factor. The suggestion is that the present population of 9,800 should be allowed to grow gradually to about 13,000 during the next 15–20 years. Much of this growth is expected to be among postgraduates, whose numbers will rise from 2,200 to 3,500–4,000. The report recommends that the number of women should be increased by seven hundred. These increases in numbers must, of course, be accompanied by increases in accommodation and this is inevitably a slow process. There is already a desperate shortage of lodgings in Oxford and it would be foolish to imagine that these increases can be accepted without further building.

On the distribution among subjects, the report recommends that much of the growth in numbers should occur in the applied sciences; an undergraduate school of about five hundred engineers is envisaged. A major expansion in the pure sciences and social studies is also recommended and, because of the limitation of total numbers, a compensating contraction must occur in other subjects, within an agreed programme of development. Many exciting new developments in pure and applied science have already been planned and we all welcome the encouragement of the Commission.

The teaching in Oxford has traditionally depended on the tutorial, and although the Franks Commission heard some criticisms of this method, I am sure that the great majority of teachers have no doubt about its value. The Commission quite rightly points out that few undergraduates can prepare themselves adequately in one week for more than one tutorial, and it recommends that the tendency in some subjects to multiply tutorials and to use them as a means of "handing out" information

should be stopped. Among the interesting statistics on the tutorial is the fact that 90 per cent of all tutorials in science are given by Fellows or lecturers and only 6 per cent by graduate students.

The report makes it clear that "research, in the broadest sense, is not something which academics do in the spare time they have left over from teaching, but that it is the first priority in their lives, giving meaning to the rest of their activities". One of the most common complaints from the academic staff was lack of sufficient time for their research, and the detailed survey by the Commission clearly shows that the reason for this is the very heavy burden of teaching borne by the academic staff. For example, the ratio of students to teachers, weighted according to the formula of the University Grants Committee for science at Oxford, was 13·5 in 1964–65. In other British universities, excluding Oxford, Cambridge and six new universities, the average was 9·8. The report recommends that the ratio at Oxford should be brought down to the national average "as a first step". This would involve the appointment of 124 more senior academic staff in science alone, and it is plain that this could only be done over a prolonged period. If it took 20 years, it would correspond to an increase at the same average rate as in the period 1922–65. It is not enough to find the men and the salaries to pay them; laboratories and equipment would also be needed. The report points out that the Holford Plan for the science area could provide an additional 1,000,000 sq. ft. of buildings. This would be enough to cope with the expansion, but on even the most optimistic estimate it could only be developed over a period of 10–20 years. The first step must therefore inevitably be a slow one.

The solution offered by the Commission is to reduce the hours of contact with pupils (including research students) to 14 per week, which is still much higher than the national average. Even this seems a pipe-dream to some scientists at present, many of whom teach for an average of 18 h per week, not including graduate supervision.

Some feel that in the sciences it is unreal to separate personal research from that carried on in collaboration with research students, and that research students need not be included in "contact-hours". Within limits, graduate students provide a stimulating influence on research, and an original and imaginative supervisor can easily provide enough ideas to keep several research students busy; their interaction with him can often provide a remarkable spur to further work. I think it is a mistake arbitrarily to limit the number of research students and that it would be best to discount them altogether from teaching hours, thereby giving scope to the more energetic research workers, without requiring the load of undergraduate-teaching to be unequally shared among lecturers. The maximum flexibility should be retained, and as the student/teacher ratio is reduced over the next 10–20 years, the teaching load will decrease and adjust itself, provided the numbers of undergraduates are kept within the planned figure.

Despite the very adverse ratio of students to teachers, Table 330 shows that the average total number of publications of the academic staff at Oxford (and at Cambridge, which is about the same) is higher than at any other university in Great Britain and at Berkeley, California. Table 331 gives a comparison, for certain science subjects for the year 1962–63, relating publications to staff at lecturer level and above at Oxford, Manchester and University College, London. The average number of publications at Oxford was 40–60 per cent higher than at either of the other two universities. We all know that the number of publications is not necessarily a good indication of excellence, but the evidence does not support the view that the heavy teaching load has been allowed to interfere seriously with research.

The question of academic salaries has received much publicity. The total bill for academic salaries at Oxford in 1964–65 was found to be about 15 per cent higher than the average total bill for other British universities. However, the staff at Oxford are considerably older than those at other universities, and if allowance for this is made, it turns out that the average salaries at Oxford are only 4 per cent greater than the national average.

A not inconsiderable part of the income of many Fellow-lecturers at Oxford is derived from what the Franks Report refers to as "piece rate" teaching. In the sciences this arose in the 'fifties when Oxford responded very quickly to a national demand for more university places. For example, whereas the number of men taking finals in the physical sciences was 250 in the period 1951–54, in 1957 the number was 494, and in 1965, 644. Unfortunately this increase was not accompanied by a corresponding increase in staff. Everyone was therefore required to teach more, and teaching over the normal limit, which may vary from 14 to 18 h in different Colleges, was paid for "piece rate". The Franks Commission proposes that these payments should be abolished, and states that "Our proposals must be considered together with those which we make for restricting the amount of tutorial teaching given to each undergraduate, with those for limiting the total teaching load on the staff of Oxford, and that for bringing up the staff-student ratio to the national average". However, it expects the new arrangement to be implemented in 3–5 years, although there seems to be little hope of improving the staff situation for 10–20 years. Most Fellow-lecturers would expect their income to be cut only as their teaching burdens are reduced to something approaching the national average.

The most radical reforms proposed by the Commission are concerned with the administrative structure. The truly democratic nature of Oxford has often been the envy of members of other universities for the freedom enjoyed by the academic staff in the organizing of their research and teaching. Most of the power resides in the faculties, so that in a real sense the University is controlled by the whole academic staff. The present complicated structure of the administration is, however, in dire need of overhaul, and the Commission proposes a complete revision of the present system. There is to be an interlocking system of elected bodies, headed by Council, which is to have considerably greater powers than in the past to plan and act decisively and quickly when necessary. The system will have to be studied in great detail, however, and the many objections weighed up, before it is fully implemented. Certainly the proposal to elect the vice-chancellor, who is to be given greater responsibilities and a longer term of office, will be welcomed.

In the science departments, formal committees will be established, with six members and the head of department as Chairman, to evolve general policy on teaching, appointments, buildings, and allocation of facilities. Such committees already operate in most departments, but the formalization of this arrangement will be welcomed. It provides the academic staff of a department with an opportunity to take part in its government and would make possible the occasional relief of the head from his administrative duties.

These are only some aspects of the conclusions given in this very impressive document. It is easy to seize on particular recommendations and criticize them out of context of the report, but intensive study will be required during the coming months to evaluate its conclusions fully. No doubt the University will implement the recommendations, or modifications of them, when they have been adequately debated. It seems likely that some of the issues which have been raised may prove helpful to other universities, and it is also clear that some of the weaknesses which have been uncovered are the result of rather haphazard growth which is not entirely the fault of Oxford itself.

NATURAL LEVELS OF LEAD-210, POLONIUM-210 AND RADIUM-226 IN HUMANS AND BIOTA OF THE ARCTIC

By DR. RICHARD B. HOLTZMAN
Radiological Physics Division, Argonne National Laboratory

RELATIVELY high concentrations of some fission products in humans and biota from Lapland and Alaska have been reported[1–5]. These have been attributed to the continual accumulation of these products on the long-lived, slow-growing Arctic lichens and sedges. Such plants are an important source of forage for reindeer and caribou, the meat of which, in turn, constitutes a substantial portion of the diets of Laplanders and Eskimos. These high levels of fall-out suggest, together with the proposed mechanism of uptake and the similarities to strontium-90 in atmospheric distribution[6] and biochemistry, that in Arctic biota the naturally occurring airborne nuclides lead-210 and its decay product, polonium-210, may also be present in high concentration. This phenomenon has, in fact, been reported by me[7] and more recently by Hill[8].

These naturally occurring 'fall-out' activities are of special interest in studies of aerosol precipitation mechanisms because their levels are independent of bomb tests and consequently they have been constant over the years. Because of this constancy and the high energy of the particles emitted by the lead-210 series (a 5·3-MeV α-particle from polonium-210 and a 0·4-MeV [average energy] β-particle from bismuth-210 compared with β-rays with average energies of 0·4 MeV from caesium-137 and 1·1 MeV from strontium-90 [yttrium-90][9]), the radiation dose to Arctic biota from this source may be quite significant relative to that from artificial ones.

Samples and Experimental Procedures

In order to elucidate some of the properties and mechanisms related to the accumulation of the airborne activities, data are presented on the concentrations of ^{210}Pb, ^{210}Po and ^{226}Ra (the long-lived precursor of the ^{210}Pb) in specimens of the human food chain from Arctic regions. Specifically, these are: lichens, caribou muscle, bone and rumen (mainly lichens), and human soft tissues (placenta) from Alaska; lichens, fodder (horsetail, *Equisetum flaviatile*), and reindeer muscle and bone from Finnish Lapland; and lamb bone from Iceland. For comparison, some related plant materials from non-Arctic regions were included—grass from Chicago and lichens from New Hampshire (north-eastern United States). The origins and descriptions of the specimens are presented in Table 1.

The contents of ^{210}Pb and of ^{210}Po in the samples were determined by a previously described method[10]. The sample was first wet-ashed (1–10 g of bone, or plant material, or 10–100 g of dried soft tissue) in concentrated nitric acid until nearly complete dissolution. About 10 ml. perchloric acid was added and the mixture heated until it fumed. When the sample became colourless, concentrated hydrochloric acid was added and it was fumed again. This fuming procedure was repeated three more times to remove residual nitrate, after which the solution was diluted to about 200 ml., the *p*H adjusted to 0·3 and a portion taken for calcium analysis. The ^{210}Po was then plated on to a silver disk and counted in an internal flow proportional alpha counter. Subsequent replating of the sample after a delay of three or more months to allow grow-in of the ^{210}Po then made it possible to estimate both the ^{210}Pb and ^{210}Po in the sample at the time of collection.

The ^{226}Ra was determined by the emanation technique of Lucas[11].

Results and Discussion

The results are presented in Table 2. In order to facilitate the dosimetry *in vivo*, the specific activities in the soft tissues are given in picocuries per gram of wet tissue. However, because of the difficulties in defining a standard *in vivo* state for bone[12], antler and plants, the units are in picocuries per gram ash for bone and antler, and picocuries per gram dry material (at 100° C) for the plants. The overall uncertainties from counting statistics, chemistry, and handling are about 15 per cent, at the 90 per cent confidence level, except where specific values of uncertainties are given.

It was not possible to estimate the initial quantity of polonium in the Alaskan lichen samples because these samples had previously been dry-ashed at 425° C, a temperature at which this element volatilizes.

Vegetation. The lichens and rumen (composed mainly of lichens) contain specific activities of ^{210}Pb and ^{210}Po that are very high relative to those in the horsetails and grass. The Alaskan lichens, in turn, contain greater concentrations than those from Finland and New Hampshire. The rumen are lower than the other Alaskan samples, possibly because of contamination from other plant materials and stomach fluids.

Although the concentrations of ^{210}Pb and ^{210}Po in lichens are high relative to those in the grasses measured here, they are comparable with those in a number of grass samples observed by Hill which range up to 23 pc. ^{210}Po/g dry[13]. That these latter values are inconsistent with the relatively small amounts of ^{210}Pb–^{210}Po acquired by cattle[14,15], as compared with those observed in reindeer

Table 1. DATA ON SAMPLES

Sample	Region	Description
Vegetation		
Lichens	Inari, Finland	Species. *Cladonia alpestris*, March 1961
Horsetails	Inari, Finland	Species: *Equisetum flaviatile*, Sept. 1961
Lichens I	Chariot Site, Cape Thompson, Alaska	Species: predominantly *Cladonia sylvatica*, June 1961
Lichens II	Chariot Site, Cape Thompson, Alaska	Species: predominantly *Cornicularia divergens* Ach., *Alectoria nigricans* Ach. Myl., *Alectoria ochrolecua* (Ehrh.) Mass, and small amounts of other species, June 1961
Lichens III	Chariot Site, Cape Thompson, Alaska	Species: same as above, June 1961
Lichens IV	Lebanon, New Hampshire	Species: *Cladonia*, July 1965
Grass	Chicago, Illinois	Species: Kentucky blue grass, May 1962
Animals		
Reindeer	Finland	2–4-yr-old animals, female, composite of ten animals. Muscle: shoulder. Bone, marrow-free. Date of death: March 14, 1961
Caribou I	Denali Highway, Alaska	2-yr-old, male. Muscle: hind quarter. Bone: femur shaft. Rumen, antler. Date of death: Dec. 6, 1962
Caribou II	Denali Highway, Alaska	3–7-yr-old, male. Muscle: hind quarter. Bone: femur shaft. Rumen, antler. Date of death: Dec 6, 1962
Lamb	Iceland	Commercial lamb obtained in Chicago
Human being, Eskimo placentae		
Subject I	Barrow, Alaska	23-yr-old; date of parturition: June 1963
Subject II	Barrow, Alaska	39-yr-old; date of parturition: June 1963
Subject III	Barrow, Alaska	16-yr-old; date of parturition: June 1963

and caribou (*vide infra*), may be due to the possibility that the grass measured by Hill is not representative of that consumed by the cattle. These samples were collected in December at which time they may have been growing slowly or have been dormant, so that, with a constant rate of ^{210}Pb fall-out, the concentration of this nuclide would increase at a constant rate. On the other hand, during the growing season, the quantity of grass would also have increased, thereby preventing increases in the concentrations of ^{210}Pb. Hill has recently demonstrated this phenomenon by comparing new with old grass from the same locations[8].

A similar phenomenon has been found in the Chicago grass collected in the spring as shown in Table 2. The average concentration was only 0·3 pc./g dry grass, in spite of the fair amount of precipitation (25 cm) in the 40 days before collection. The data in Table 2 do indicate an age effect, that is the older parts of the plant (or slower growing parts) nearer the ground show higher concentrations of ^{210}Pb. Moreover, correlated with this is an increase in the ^{210}Po/^{210}Pb ratio towards 1. Thus if "Grass, centre" is of recent origin, "Grass, lower" would appear to be about 3 months old.

The levels in reindeer may also be higher than in cattle because of the low ash content of lichens, less than 1 per cent as compared with 5 per cent for grass. Thus, if we assume the mineral requirements of reindeer and cattle to be similar, in order to obtain sufficient mineral the reindeer must consume much more material and consequently more of the radioactive nuclides.

The fact that the ^{210}Po/^{210}Pb activity ratios in the lichen and rumen are greater than 1 is of interest in that in a fall-out mechanism (neglecting other mechanisms) this ratio, as in the New Hampshire plants and Chicago grass, should be 1 or less, especially as in the atmosphere, at least in the temperate zone, it is approximately 0·1 (ref. 16). The ratio of two or more observed in the lichens implies either a high differential affinity of these plants for ^{210}Po from precipitation or rapid leaching of the ^{210}Pb from the plants after precipitation. The latter process also implies a non-constant mechanism, that is both nuclides build up and then the ^{210}Pb is leached preferentially. Continual leaching does not seem likely, since in this case the ^{210}Po could not build up to specific activities greater than those of its parent.

The specific activities of the ^{226}Ra were much lower than those of the ^{210}Pb and thus the ^{226}Ra does not appear to be a direct source of the ^{210}Pb. The correct specific activity of ^{226}Ra in lichens is closer to that of the Finnish lichens than to those of the others because this sample was carefully chosen to be dust free, having been collected from an area about 10 miles from the nearest road[17]. Consequently, its ash content was less than 1 per cent of the dry weight as compared with the values of between 5 per cent and 10 per cent for the others. The higher ^{226}Ra activities in the other lichens can, in the main, be attributed to contamination with dust.

Animals. Bone from animals, though not a direct source of ^{210}Pb for human beings, is of interest as, by integrating the intake, it may indicate the average ^{210}Pb content of the meat. The actual activity measured in muscle, on the other hand, represents the intake only immediately before slaughter (a week or two) and thus is not representative of the long-term average of meat. Investigations on bone may also lead to more subtle and better correlations in nutritional and metabolic studies of these animals because of the much higher specific activities of the nuclides of interest. For example, in reindeer bone the specific activity is twenty times that in bovine bone[14], whereas in muscle the respective ratio is only about twice as large[10].

The 11 pc. ^{210}Pb/g ash observed in the Alaskan caribou bone is about twice that in the Finnish bone. This may possibly be due to metabolic differences, but, because they are a very closely related species, the more probable cause seems to be the reduced dietary intake of this isotope by the semi-domesticated reindeer as a consequence of supplementary fodder feeds low in ^{210}Pb. Moreover, the Finnish lichens, because of their lower concentrations of ^{210}Pb, as indicated in the single sample measured, would supply less of this nuclide than would the Alaskan ones.

An analogous explanation also accounts for the differences in the ^{210}Pb concentrations between antler and femur of the Alaskan animals, that is, the antler is formed over a short period of time (3 months) in the spring[18] when, owing to the presence of other vegetation, lichens constitute a smaller fraction of the diet than that averaged over the entire year. A comparison of ^{210}Pb concentrations in femur with those in antler indicates that these concentrations do not vary much from animal to animal from a given region and that the concentration of ^{210}Pb in femur is about 1·8 times that in antler. Thus it is possible that a few animals, and even their antlers, alone, may well form a representative sample of this population.

The ^{210}Po activities in bone are somewhat higher than those of ^{210}Pb, possibly reflecting the equivalent situation in the lichens and rumen. In antlers, on the other hand, the ^{210}Po activities are lower than those of the ^{210}Pb which indicates a preferential deposition of the latter. Moreover, these deposits do not seem to be of sufficient age to allow attainment of radioactive equilibrium.

Although the ^{226}Ra activity in bone is much lower than the equivalent ^{210}Pb and is thus not a major source of this nuclide, it is comparable with DiFerrante's highest values in cattle[19]. The source of this high ^{226}Ra seems to be the lichens, as, although they contain little ^{226}Ra (per g), the ash content (calcium) is also small and consequently the ratio, ^{226}Ra/calcium, is about equal to that observed in bone.

The concentrations of ^{210}Pb in the muscle of reindeer and caribou are somewhat higher than those found in cattle, but only by factors of 2–4. However, the Finnish, rather than the Alaskan, animals in this case show the higher activities. This difference may be due to species or feeding habits, but it seems more likely to be seasonal variation. Hanson and Palmer[20] and Lidén and Svensson[21] observed very large seasonal variations in the ^{137}Cs content of animals and humans, which the authors attributed to the changes in feeding habits of the animal; they consumed lichens and dormant foliage with their high rates of accumulation versus growth only when necessary—that

is in the winter. Thus the Finnish animals, slaughtered in the early spring, contained the winter's accumulation of ^{210}Pb, whereas the Alaskan ones, killed in the late autumn, were somewhat depleted of this nuclide.

The ^{210}Po concentrations were comparable in all the animals and an order of magnitude greater than those in steer meat. These high concentrations may arise from the much greater intake of ^{210}Po by reindeer than by cattle and to the relatively higher ^{210}Po/^{210}Pb ratio in the food, it being about 0·2 in grass and 2 in lichens. Osborne has shown that at natural levels in humans the ^{210}Po/^{210}Pb ratio in soft tissue may be 3 or more[22]. Thus, in the case of reindeer where the ^{210}Po intake and the ^{210}Pb concentrations in bone are relatively high, ^{210}Po accumulation in the soft tissues may also be expected to be high.

In contrast to the reindeer and caribou, the concentrations of ^{210}Pb found in Icelandic sheep show that not all herbivores from this region contain relatively large amounts of these nuclides. In these animals, the ^{210}Pb and ^{226}Ra concentrations are comparable with those in bovine bone[14], suggesting that the ^{210}Pb content in its diet is comparable with that of cattle from the United States. By analogy with Puerto Rico, an oceanic island which probably has lower ^{210}Pb fall-out rates than do continental regions, and consequently lower ^{210}Pb concentrations (in humans the concentrations in bone are about 65 per cent of those in residents of continental regions)[23], the ^{210}Pb content of the diet of sheep in Iceland would be lower than that of reindeer and caribou even on a similar diet.

While muscle from caribou and reindeer has concentrations of ^{210}Pb low relative to those in bone, it still constitutes the major source of this nuclide in Lapps and Alaskans. Miettinen *et al.*[2] report that, in Finnish Lapland, male reindeer breeders consume about 12·4 kg/month or 400 g/day of reindeer meat which, if we use the ^{210}Pb content for the reindeer muscle (0·2 pc./g), implies that these people ingest about 8 pc./day. The rate is more than four times the mid-western United States rate of about 1·8 pc./day[10].

Other Lapps listed by Miettinen *et al.* consume from 1·2 to 12·0 kg/month which represents about 0·8–5 pc./day from meat alone. If the other food consumed is comparable with that from the United States, even these other Lapps ingest about twice that of the United States residents.

Similar dietary information on Alaskans[4] shows that in certain regions the average consumption of reindeer and/or caribou meat ranges up to 900 g/day (Anaktuvuk Pass Eskimos), so that even though the ^{210}Pb levels measured in the Alaskan caribou are lower than in the Finnish reindeer, the total intake by Alaskans is comparable with that of the Lapps.

Eskimo bone has not been measured here because of the difficulties in obtaining it. However, some comparison may be made from data on soft tissues in Table 2 from residents of Barrow, Alaska, who consume about 170 g/day of caribou or reindeer meat[4]. The values for placenta appear to range in wet tissue from 0·001 to 0·005 pc. ^{210}Pb/g and from 0·009 to 0·030 pc. ^{210}Po/g. These concentrations for both nuclides are somewhat higher than those for soft tissue found by Osborne[22] and by me[10].

Although the ^{210}Pb concentrations in placental tissue in Arctic residents are somewhat higher than in the soft tissues of non-Arctic residents, the ^{210}Po ingestion in the former group may be extremely high, 40–160 pc./day. These levels are 20–100 times those of others if we assume a concentration of 0·2 pc./g wet meat and a consumption of about 200–800 g/day[2,4]. Thus, the steady-state amount of ^{210}Po in the body acquired from a constant daily intake may be estimated from equation 48 of the report[9] issued by the International Commission on Radiological Protection, derived from the exponential model for the uptake and excretion of nuclides:

$$\frac{mC}{I} = \frac{T_e f}{0{\cdot}693} \qquad (1)$$

where m is the mass of the body, C is the concentration of the nuclide of interest, I is the daily intake, T_e is the effective half-life of the nuclide in the body, and f is the fraction of the nuclide going from the food to the body.

If for ^{210}Po $T_e = 25$ days and $f = 0{\cdot}06$, then the portion of the whole-body content from this source is 2·2 times the daily intake. In the case of interest it is 90–350 pc. The ^{210}Po, which deposits mainly in the soft tissues, is then quite significant, being 125–350 per cent of that in non-Arctic populations in whom the ^{210}Po content of the soft tissues is estimated to be about 230 pc. (ref. 24). In bone, the ^{210}Po levels from this source would be increased only a few per cent.

The large increase in levels of ^{210}Po is indicated in the data on human placentae which show that, if the metabolic properties of this nuclide in this tissue are assumed to be similar to those in the lung, skeletal muscle or spleen, Arctic dwellers accumulate six to ten times that found in the soft tissues of Britons[22]. The concentrations in the placentae are as much as three times those found in the liver and kidney of people living outside the Arctic. In addition to this comparison, it should be noted that because the placentae studied were obtained in the summer, they probably represent only the lower limit of concentrations that could be found. These tissues were formed during the winter when the main food was caribou killed in the autumn, which after summer forage (little intake of lichens) are known to contain minimum amounts of ^{137}Cs (refs. 20 and 21), and thus probably also of ^{210}Pb and ^{210}Po.

Dosimetry. In the mid-western United States, ^{210}Po from the deposited ^{210}Pb has been shown to contribute 20 per cent of the total skeletal dose in the human (50 per cent of that from internally deposited nuclides)[10]. The data presented here show that in the Arctic these nuclides exist in substantially greater concentrations in reindeer and caribou than in mid-western cattle and in Icelandic sheep. The consequent intake by humans consuming the meat from the Arctic animals is also large, but by a smaller fraction than previously estimated[17]. (C. R. Hill, in a personal communication, has pointed out that the previously reported values of ^{210}Pb in reindeer muscle were mainly values of ^{210}Po.) The data on the Eskimo placentae give some support to this conclusion, but to a lesser extent than Hill's data on the rib bone of Canadian Eskimos. In two cases, high activities of ^{210}Po were observed and probably also of ^{210}Pb, as in bone the ^{210}Po/^{210}Pb ratio is near unity, at least in people living outside the Arctic region[10,22]. The result of 2·3 pc. ^{210}Po/g ash found by Hill[25] is more than fifteen times greater than the average for people living in the mid-western United States. (*Note added in proof.* Since submission of this paper, Hill has reported this in more detail. The values measured were actually ^{210}Pb (*Nature*, 208, 423; 1965).)

These findings imply that in users of reindeer and caribou meat the total radiation dose rates from the natural sources are somewhat higher than in non-users. The total skeletal rates to people living in the mid-western United States are about 100 mrad/yr[26]. If the relative biological effectiveness for α-particles is assumed to be 4, the effective dose is about 130 mrem/yr, of which about 20 per cent is contributed by the ^{210}Pb–^{210}Po pair. Thus, populations ingesting four times the average level of ^{210}Pb would experience dose rates about 30 per cent greater than those living in the mid-western United States. (It should be noted that in this latter group only about half is acquired by ingestion, the other half coming from inhalation, the absolute amount of which would be about the same in Arctic residents[10]. Thus, quadrupling the ingestion rate would increase the total amount only by a factor of 2·5.) In the case of Hill's Eskimo, the bone would experience a total dose of more than 400 mrem/yr, three times that of people living in the mid-western United States. The ^{210}Pb–^{210}Po dose alone may then be comparable with the high fall-out doses from bombs as measured in the Arctic.

NEW PERGAMON PUBLICATIONS

THE SOLAR WIND

R. J. Mackin and M. Neugebauer
California Institute of Technology

Proceedings of the Jet Propulsion Laboratory Conference on Solar Wind organized to present the collected and analysed results of the Mariner-2 interplanetary experiments to scientists interested in solar wind. The participants represented 27 different scientific institutions in four countries representing fields of theoretical and experimental interplanetary physics, astrophysics, radio astronomy, solar physics, plasma physics, and aerodynamics.

ELECTRON DIFFRACTION AND THE NATURE OF DEFECTS IN CRYSTALS

Australian Academy of Science

This volume contains extended abstracts of papers which were presented at the International Conference on Electron Diffraction and The Nature of Defects in Crystals held in Melbourne, 1965.

Contents: The relation of intensities to structure; Dynamical theories of electron diffraction; Intensities and geometric factors; Influence of temperature on electron diffraction intensities of Al; Electron diffraction study on the titanium-oxygen alloy system; The phase grating approximation for thin single crystals; Cyclical method in structures by electron diffraction; Scanning technique for electron diffraction; Epitaxy; Inelastic and thermal scattering; Slow-electron diffraction and surface studies; Contrast in electron microscopy; The study of crystal defects by diffraction methods, particularly with electrons; The nature of defects in crystals; Radiation induced defects; Order and disorder of structures containing gross chemical defects; Point defects; Geometry and structures of dislocations; Interaction between defects; Controlled defects at low concentrations.

332 pages **£5/$14.00**

INSTRUMENTS OF COMMUNICATION

An Essay on Scientific Writing

P. Meredith, Professor of Psychology, University of Leeds

This book has been written with the purpose of undermining the habit of treating language as mere words, something unreal compared with the realities of science. The words used by scientists are shown to be causal agents with far-reaching properties. Through the learning of language the brain is equipped with syntactic instruments of which the materials and operations of scientific discovery are translated into the forms of language.

Contents: On the communication of understanding; On the meanings of science; On forms of representation; On the instrumentality of language; On the writing of science; Appendix—On the syntax of concepts; Indexes.

650 pages **July 1966** **£7/$21.50**

ANALYTICAL CHEMISTRY

Progress in Nuclear Energy, Series 9 Volume 6

D. C. Stewart and H. A. Elion

Contents: J. KORKISCH—Ion exchange in mixed and non-aqueous media; Cation exchange; Anion exchange; J. W. O'LAUGHLIN—Some neutral bifunctional organo-phosphorus compounds as solvent extractants; J. FARIS & R. F. BUCHANAN—Anion exchange in nitrate solutions: Aqueous nitric acid; Nitrate media; Spectrochemical trace element analysis; G. A. BURNEY, E. K. DUKES and H. J. GROH—Analytical chemistry of Neptunium: Discovery, occurrence, and synthesis; properties; Methods of separation; Identification and quantitative determination, Other determinations; R. R. LANGE—The analytical chemistry of Polonium; The chemistry of Polonium; Separation of Polonium; Detection of Polonium; Recommended analytical procedures.

INTERNATIONAL JOURNAL OF HEAT AND MASS TRANSFER

Editors: F. A. Brun, A. J. Ede, Carl Gazley, U. Grigull, J. P. Hartnett, A. V. Luikov, Takashi Sato, D. B. Spalding

This journal provides a central vehicle for exchange of basic ideas in heat and mass transfer between research workers and engineers located throughout the world. The emphasis is on original research, both analytical and experimental of permanent interest to researchers and engineers in the field of heat and mass transfer.

Some contents published in a recent issue: V. A. HALLET—Surface phenomena causing breakdown of falling liquid films during heat transfer; J. MADEJSKI—Activation of nucleation cavities on a heating surface with temperature gradient in superheated liquid; J. C. SAMUELS—Heat conduction in solids with random external temperatures and/or random internal heat generation; J. H. LIENHARD and V. E. SCHROCK—Generalized displacement of the nucleate boiling heat-flux curve, with pressure change; C. C. PITTS and G. LEPPERT—The critical heat flux for electrically heated wires in saturated pool boiling.

Introduction to Cybernetics

by **V. M. Glushkov**
Ukrainian Academy of Sciences
Translated from the Russian edition

Written by a leading Russian authority, this book contains discussions of contemporary cybernetics such as the theory of algorithms, digital automata, digital self-organizing systems, and mathematical logic. It relates fundamental data concerning the theory of Boolean functions, the abstract and structural theory of discrete automata, the theory of discrete self-organizing systems, and the universal algorithmic language and foundations of the restricted predicate calculus.

September 1966, about 335 pp., approx. 100s.

VOLUME 3

Advances in Control Systems

edited by **C. T. Leondes**
University of California, Los Angeles

CONTENTS: THOMAS L. GUNCKEL, II, Guidance and Control of Re-Entry and Aerospace Vehicles. P. KENNETH and R. McGILL, Two-Point Boundary Value Problem Techniques. W. W. SCHMAEDEKE, The Existence Theory of Optimal Control Systems. JAMES M. SWIGER, Application of the Theory of Minimum Normed Operators to Optimum Control System Problems. H. W. SORENSON, Kalman Filtering Techniques. STANLEY F. SCHMIDT, Application of State-Space Methods to Navigation Problems. *Author Index—Subject Index.*

Biology of Parasites:

EMPHASIS ON VETERINARY PARASITES

edited by **E. J. L. Soulsby**
University of Pennsylvania

An up-to-date synthesis of the existing knowledge in the fields of infective stages and infective mechanisms, physiology, pathology, and immunity of parasites of medical and veterinary importance.

September 1966, 350 pp., 108s.

Enzymes in Food Processing

by **Gerald Reed**
Universal Foods Corporation, Milwaukee, Wisconsin

A Volume of Food Science and Technology: A Series of Monographs.

The application of enzymes in the food industry is presented in this volume developing both the composition and the use. The author's aim is to bridge the gap between food technology and its related sciences. Part I is the study of enzyme properties in general, and the use of enzymes in food processing. Part II describes the practical application of these enzymes in various sections of the food industry.

August 1966, 484 pp., 148s.

Magnetism

A TREATISE ON MODERN THEORY AND MATERIALS

edited by **George T. Rado**

Berkeley Square House, London, W.1

Although data from Arctic placentae show a dramatic increase in ^{210}Po levels over those in other tissues from non-Arctic residents, the actual increase in dose at natural levels is small (about 10 per cent), based on the assumptions that the normal level is 100 mrem/yr, that 0·01 pc. ^{210}Po/g wet tissue produces a dose of 1 mrad/yr, and that the relative biological effectiveness for α-particles is 4. (With the usually assumed relative biological effectiveness of 10, the dose would be increased to about 130 mrem.) However, these numbers may be significant relative to the much larger values in bone because, for instance, the radiation effects to soft tissue may be greater than to bone, or the relative biological effectiveness at low dose rates may be much different than that used here.

Conclusion

Further investigations of this type, together with the epidemiology, would provide information of value in assessing the effects of low-level radiation on human and animal populations. (The reindeer and caribou are exposed to skeletal doses of 1–10 rems/yr (relative biological effectiveness = 4) which is fifty times that of cattle and 500 times that of humans.) Natural 'fall-out' is also of particular use in tracing food chains and in studying the metabolic properties of the nuclides and elements involved. Moreover, similar studies of this type appear to be feasible elsewhere, as the high levels of natural (and artificial) 'fall-out' are, with our present knowledge, only by chance characteristic of the Arctic, that is, the lichen is a slow-growing plant eaten only by reindeer and caribou which, in turn, form a substantial part of the human diet. Similar conditions might obtain in other regions, such as deserts, where vegetation, for lack of water, may grow only slowly. This phenomenon is indicated in Hill's data on camel bone[8] and in DiFerrante's ox bone[14], in which the specimens with the higher activities came from the more arid regions.

I thank the many people who contributed many ideas and specimens to this research, particularly R. A. Dudley of the International Atomic Energy Agency, J. N. Wolfe and J. J. Davis of the U.S. Atomic Energy Commission, J. K. Miettinen of the University of Helsinki, L. A. Viereck of the State of Alaska Department of Fish and Game, and R. T. Light of the U.S. Public Health Service. Special thanks are due to L. D. Marinelli and J. E. Rose for their help and encouragement. The work was performed under the auspices of the U.S. Atomic Energy Commission.

OBITUARIES

Prof. R. O. Kapp

Reginald Otto Kapp, professor emeritus of electrical engineering in the University of London, died suddenly on February 20 at the age of 80, four days after the death of his wife.

Kapp was born at Brentwood in 1885. After early education in Germany, he graduated in electrical engineering at the University of Birmingham, where his father, Prof. Gisbert Kapp, was head of the department. He then spent four years with Messrs. Brown Boveri in Baden, Switzerland, working on the development of electric traction. In 1913 he returned to Britain to join the staff of Messrs. Kennedy and Donkin, engineering consultants, but his new work was soon interrupted by the outbreak of the First World War in which he served with the Royal Engineers in Salonika and elsewhere.

After the War, Kapp returned to consultancy and, under Sir John Kennedy, began detailed studies of electrical power supplies and demands in Britain. These studies provided load forecasts and financial estimates which formed the technical basis of the Electricity Act, 1926, the legal instrument which established the grid system. The grid encouraged an increase in the size of generators, and Kapp worked on the associated design and switching problems. The integration of power generating systems also aroused an early interest in the economic and technical advantages of standardization.

In 1935 Kapp was appointed to the Pender chair of electrical engineering at University College, London. At the beginning of the Second World War, the College departments were evacuated to other universities, and Kapp, as Dean of the Faculty of Engineering, went with the engineering departments to Swansea. On their return to London, he was mainly concerned with the post-war rehabilitation of his department.

In 1950 Kapp reached the academic retiring age of sixty-five but, still full of vitality, returned to part-time consultancy with his former employers. He was chairman of a committee appointed by British Railways to reduce inductive interference between railway telecommunications and power lines. He also worked on energy storage by compressed air and on tidal systems as sources of power. As he had taken advantage of his early training on the Continent to equip himself as a linguist—his German, Italian and French were impeccable—he was much in demand as a chairman at international conferences. His linguistic abilities combined with his interest in standardization, of terminology as well as of equipment, led him to the chairmanship of committees of the International Standards Organization and the International Electrotechnical Commission as well as of the British Standards Institution. Consultancy work

requiring the critical assessment of proposed systems of generation and distribution of electrical power took him in this later period to Egypt and to Argentina. He enjoyed his travels immensely, making many friends abroad, taking great delight in trying exotic foods and in solving new problems of linguistic communication.

But, full as it was, his career as a professional engineer was only part of his public life. For many years he had pondered two fundamental problems, one philosophical—the relation of 'mind' to 'matter', and one cosmological—the creation and evolution of the universe. His approaches to these problems, adumbrated in *Science versus Materialism* (1940), were developed with characteristic tenacity in later works. The philosophical problem was further discussed in *Mind, Life and Body* (1951) and in his Riddell Memorial Lectures on *Facts and Faith: the Dual Nature of Reality* (1955). He then returned to cosmology. By the ruthless application of Occam's Razor, which Kapp later elevated to 'The Principle of Minimum Assumption', he disposed of the 'big bang' and other contemporary theories of the origin of the universe and, in 1940, concluded that creation is continuous: matter is continuously being created at random throughout existing space and is continuously being destroyed at random throughout existing matter. Inferences from this hypothesis, including the idea that the continuous destruction of matter is the cause of gravitation and the prediction that lunar rock will be found to be micro-porous and mechanically weak, are worked out in *Towards a Unified Cosmology* (1959). This book, his final work, is about to be published in a German edition. Kapp was disappointed by the reception of his cosmological theories and regretted that he lacked the mathematical skill to exploit fully the implications of his physical insights.

He immensely enjoyed tackling new huge problems, technological or administrative, obscured by detail and complicated by conflicting interests or economic constraints. His invariable technique was, first, patiently to seek the relevant guiding principles and then, having established them, to apply the principles rigorously and without fear or favour; Kapp abhorred the *ad hoc*. He also enjoyed writing, especially as a means of solving intellectual problems: successive drafts on a given thesis were for him a means of self-communication, each new draft being not merely a polishing but a significant development of its predecessor—a process which continued until a solution, usually of a problem much more fundamental than the one he began with, was obtained. His interest in writing, and his long experience of the inadequacies of the working papers on which his consultancy work depended, led him to establish a lectureship in the presentation of technical information at University College and to found a Group, of which he was the very active president for seventeen years, and, more recently, a Research and Education Trust, all concerned with aspects of scientific and technical writing. He also led the British Society for the Philosophy of Science to its present autonomy and founded the Occam Society.

He served on the governing bodies of Middlesex Hospital Medical School and of Northampton College of Advanced Technology where, as chairman of the academic council, he recently devoted much thought to the transition of the College to university status. His committee work, always thoroughly prepared, gave the impression to those who shared any one committee with him that that particular committee had commanded his whole attention since the previous meeting. But at one time in the 1950's he was an active member, if not chairman, of fifty assorted committees.

Yet he found time also to enjoy the arts—the ballet, the theatre and music especially—and to publish occasional compositions for the piano.

He died of a heart attack, physically tired by the long illness and death of his wife, but in full possession and control of his formidable faculties to the last, and leaving, as his friends would have expected, all his affairs and papers in perfect order. A son and daughter, both married, survive him.

B. C. BROOKES

Prof. A. Fraenkel

PROF. ADOLF ABRAHAM HALEVI FRAENKEL, emeritus professor of mathematics at the Hebrew University of Jerusalem, died on October 15, 1965, at the age of 74, after a short illness.

Prof. Fraenkel was born in Munich in 1891, of an illustrious Jewish family. He studied mathematics at the Universities of Munich, Marburg, Berlin and Breslau. In 1922, he started teaching at the University of Marburg, later obtaining there the chair of the renowned German algebraist, Hensel. In 1928, he was called to the University of Kiel. Three years later, he received an invitation from Dr. Chaim Weizmann, who was to become the first president of the State of Israel, to join the recently created Hebrew University of Jerusalem. Having been an ardent Zionist since his youth, Fraenkel accepted this invitation and, alternating with Prof. Fekete, became chairman of the Mathematical Institute of the Hebrew University. It was mostly due to him that the Institute quickly achieved a world-wide reputation. Almost all the present professors there are his former students, while other students occupy important positions in other scientific institutions.

During the years 1938–40, Fraenkel served as rector of the Hebrew University. For many years, he headed its Institute of Adult Education, spending on it much time and fruitful effort. He was a member of the National Council of the Jewish community in (then) Palestine and was active in the establishment of the State of Israel in 1948. He became one of the founding members of the Israel Academy of Sciences and Humanities.

Fraenkel started as an algebraist and was one of the first to study the theory of abstract groups, thereby paving the way for the investigation of abstract algebraic structures in general. His main contribution, however, was in the field of abstract set theory, a contribution which is still very much alive and finds its external expression in the fact that one of the major axiom systems of set theory is known as 'ZF', the Zermelo–Fraenkel system. Zermelo was the first to publish, in 1908, a workable axiom system for set theory in order to fortify the foundations of that discipline which had become shattered through the discovery of paradoxes at the turn of the century. Fraenkel, in 1921, just a few months before a similar accomplishment by the late Norwegian mathematician, Th. Skolem, was able to increase decisively the logical rigour in the formulation of one of the axioms, the so-called axiom of subsets (or *Aussonderungsaxiom*), and to add considerable strength to the system by the addition of another axiom, the axiom of replacement. As a result of the life-long interest in the axiom of choice, an interest which was of combined mathematical and philosophical origin, he made significant contributions towards the final proof of independency of this axiom, achieved only three years ago by P. J. Cohen and hailed as one of the major achievements of this century.

Fraenkel's philosophy of mathematics was an unabashed Platonism, and he stuck to this view even when it was no longer fashionable. But his deep convictions in this respect did not hinder him from becoming one of the main interpreters of intuitionism in his text-books, which have long since become classics in their fields.

Fraenkel was deeply religious but of extraordinary tolerance and liberalism towards his environment. He combined his religious and mathematical interests in a thorough investigation of the Jewish calendar.

For many of his students Fraenkel was the decisive factor in shaping their lives, and they will never forget this man who combined ice-cold scientific rigour with the warmest interest in their scientific and other progress,

who applied the highest standards to himself and tried, successfully, to live up to them, but took the foibles of his environment smilingly in his stride.

Among Fraenkel's hobbies were mountaineering and swimming, both of which he pursued until his last days. Having served during the First World War as a meteorologist with the German Army, he continued to remain interested in the field for the rest of his life.

Prof. Fraenkel is survived by his wife and four children.

Y. BAR-HILLEL

NEWS AND VIEWS

Acceleration at the Rutherford

THE £11 million 7·2 GeV proton synchrotron at the Rutherford High Energy Laboratory at Chilton, Berkshire, has at last begun to resemble the white elephant which is the Thai symbol of prosperity and good luck. Scarcely 10 months after *Nimrod* was opened in April, 1964, disintegration of the power supply motors caused a 10-month halt for repairs that were only completed 5 months ago. Now the operation of the laboratory is only interrupted every 3 weeks when ultrasonic tests are made in order to assure the laboratory that the stable door at least is guarded.

In practice, *Nimrod* has been running for 80 per cent of the time allocated to experiments—60 per cent of the total clock time—the other 20 per cent being lost in periodic breakdowns lasting from 30 min to a few hours. At this rate, Dr. Thomas Pickavance, the director of the laboratory, thinks it will be economic to run for another 15–20 years. Considering that the machine is in nearly continuous operation, Dr. Pickavance is pleased with the present level and, in fact, hopes within the year to equal the 90 per cent record at CERN—which, according to him, has had much longer breakdowns. Dr. Pickavance's colleagues, such as Dr. G. H. Strafford, head of the High-Energy Physics Division, believe that brief interruptions do not affect most experiments, and that increased beam extraction and greater beam intensity would be more important improvements. On another scale the laboratory hopes soon to circumvent, by introducing portable units, the bottleneck caused when an experiment is dismantled. Already twice as many experiments have been submitted as there is floor space available; the waiting period is often one to two years, though much of this is profitably used for preparation. Twelve to fifteen university physics departments make regular use of *Nimrod*, though only Oxford, Cambridge, and London are convenient for commuting.

Pickavance believes that as larger machines are built small ones such as *Nimrod* will not be put out of business; there is still a great deal of work to do and a large number of machines will be needed to do it.

Nimrod's future role will depend largely on international plans; Pickavance mentioned that sites for a 300 GeV European accelerator have been considered but nothing definite decided. The United States is planning a 200 GeV accelerator for early in the 1970s; France and the U.S.S.R. have recently agreed to co-operate on the 70 GeV electron accelerator being built in Serpukhovo by the Russians.

Electrostatic Generator at Oxford

A TANDEM electrostatic machine for 20-MeV protons in coupled operation has been installed in the Nuclear Physics Laboratory, University of Oxford. The system consists of a vertical injector—the pressure vessel of which is 42 ft. long and 13 ft. internal diameter—developed by the Electrostatic Generator Group of the Rutherford High Energy Laboratory, coupled to a horizontal 6-MeV (type E.N.) tandem, of which the generator was provided by High Voltage Engineering Europa of Amersfoort, Holland; the commissioning was carried out by the Oxford Electrostatic Generator Group. In single operation, the injector has delivered microampere beams of negative hydrogen ions at 10·2 MeV, negative oxygen ions at 9·5 MeV and He^{++} at 15·6 MeV, corresponding to 9·7 MeV on the terminal.

In operation, when coupled with the tandem, protons of 20 MeV energy have been delivered on target. The transmission efficiency has varied between 12 per cent and 30 per cent: this is illustrated in the case of hydrogen by 0·25 μamp analysed proton beam for 1·5 μamp of hydrogen negative beam injected into the tandem, and for oxygen by 0·9 μamp of oxygen analysed in the 6+ charge state for 1·3 μamp of negative oxygen injected.

Earthquakes and Buildings

THE book *Earthquake Investigations in the Western United States, 1931–64*, published by the U.S. Department of Commerce, Coast and Geodetic Survey (Publication 41–2), is a notable record of activity in the fields of earthquake recording and engineering and seismology.

Some of the material was first published in 1936 (U.S.C.G.S. Special Publication 201), including papers by R. S. McLean and W. W. Moore, R. R. Martel and the late Frank Neumann. New papers include several on instruments and instrumental studies and on damage studies.

The paper by John A. Blume on "The Building Vibrator" describes three vibrators at present in use, together with the methods of testing. In buildings, the vibrator is securely braced between two columns. A 4 in. × 4 in. strut is placed horizontally between the end of the vibrator and the adjoining column and is screwed tightly into place by means of two large bolts attached to the frame of the machine, or by a jack. To steady the apparatus, ballast is usually placed on skids bolted to the base of the machine. On structures in which there are no columns or walls for bracing, it is necessary to resort to other methods of transmitting the disturbing forces. On the Colorado Street Bridge, the vibrator was held in place mainly by piling a large number of sacks of cement on the skids. For ground shaking tests a heavy wooden framework was constructed to enclose a large vibrator. For horizontal forces, the frame may be jacked between curbs of a roadway, and it may be weighted down for vertical shaking. Resulting vibrations in structures or in the ground are measured by portable seismographs. For buildings a magnification of about 200 may be used, but for dams or on the ground the magnifications may be 1,500 to 10,000.

The tests have included buildings, dams, bridges, rock, and hard and soft ground. In each case, records showing forced vibration have been obtained. The test results indicate that such machines can be used to obtain valuable information that otherwise would be difficult to determine regarding the vibration characteristics of structures. This is especially true when simultaneous timing and recording are available from several sections of the structure. The use of the vibrator enables the positive identification of several of the highest natural periods of vibration in each translational direction of multi-storey buildings, and also the plotting of forced vibration

resonance, curves, and mode shapes for these periods. In addition, torsional modes of vibration have been established together with the centres of rotation. It is also possible to obtain viscous damping factors from the shapes of the resonance curves.

Seismologists hope that the work of recording strong earthquake motion with the related activities of questionnaire and vibration programmes will continue, so that, like statistics on precipitation, wind, temperature and tides, reliable data on ground motions will be available. In the meantime, it is hoped to have accumulated sufficient material in two years to warrant the publication of another volume of papers.

Phosphorus in Soil

SINCE it became apparent many years ago that a determination of the total nutrients in the soil gave little indication of what would become available to the plant during a growing season, soil chemists have devised numerous relatively simple laboratory techniques to assess availability. Based on convenience and local experience, these methods have played a useful part in assisting the farmer with his fertilizer programme, but inevitable difficulties arose in comparing the results of work in different areas. Soil phosphorus has been a particularly complex problem because crop responses to applied phosphorus have varied widely, not only between soils but also between seasons, and correlations of laboratory and field data have been burdened by anomalies. It was fitting, therefore, that a serious attempt should be made to examine techniques and experimental results from a large number of soils. At a conference in October 1962, organized by the National Agricultural Advisory Service, fifteen papers covering various aspects of the subject were presented and discussed, and five syndicates considered and reported on several specific questions confronting the adviser: (*a*) the concept of intensity and capacity factors; (*b*) the possibility of selecting one routine method for determining available phosphorus; (*c*) the mode of expressing soil phosphorus; (*d*) the classification of soil phosphorus figures; and (*e*) the factors concerned in the interpretation of the results. A full record of the proceedings has now been published in *Soil Phosphorus* (Ministry of Agriculture, Fisheries and Food. Technical Bulletin No. 13. Pp. v+159. London: H.M.S.O., 1965. 37*s*. 6*d*. net). It is a most valuable guide to the present position with respect to the measurement of fertility levels, the difficulty of assessing the influence of soil organic matter, the grouping of crops in manuring recommendations and the kind of investigations still required to improve the advice given to farmers.

Water in Living Systems

Forms of Water in Biologic Systems comprises a series of papers delivered at a conference of the New York Academy of Sciences in October 1964 (*Ann. N.Y. Acad. Sci.*, 125. Article 2. By H. J. Berendsen and 39 other authors. Pp. 249–772. New York: New York Academy of Sciences, 1965. 10 dollars). Only a month before, a similar British symposium, organized by the Society for Experimental Biology, was held at Swansea, under the general title "The State and Movement of Water in Living Organisms". Both these symposia have now appeared in print, and they testify to the considerable interest which exists at the present moment in the properties of the fluid which is undoubtedly the most important single chemical compound in living things. Inevitably the two symposia will be compared. What emerges from the comparison is that there is little overlap, for whereas the Swansea symposium was oriented towards what might be called the larger-scale aspects of plant and animal water relations (though it deals also with the theoretical and physical background), the New York symposium is concerned rather more with physico-chemical and macromolecular aspects of the subject. Particularly interesting is a contribution from Prof. Fernandez Moran appearing in the discussion at the end, in which he outlines some exciting developments in the direction of high-resolution electron microscopy, at liquid helium temperatures, of structures involving water on the molecular level. This seems to indicate a line of advance from which much may be expected.

Document Preservation

THE preservation of paper is a recognized necessity—sometimes, it may be thought, an unfortunate one. Micro-filming, the obvious solution to the problem of storage, has some practical drawbacks. Much thought has therefore been given to the subject, but much of it is pointless unless the resistance of a paper to ageing can be forecast numerically.

In 1928 the National Bureau of Standards, Washington, D.C., evolved such a test. It was based on the determination of the decrease in folding resistance after heating for 72 h at $105° \pm 2°$ C. As a result of evaluations of stored papers at intervals during the following years[1], it is considered that the conditions of this test are equivalent to natural ageing for 25 years under normal room storage conditions. On the relatively short view of a century or so, a recent article entitled "Archives Document Preservation" by Raff, Herrick and Adams of the Washington State University, Pullman, Washington[2], is of particular interest. These workers started with the accepted fact that acidity found in paper on storage is the principal cause of deterioration. Treatment with calcium and magnesium bicarbonates is a recognized antidote. The authors carry this principle a stage further by using the alkali salts of organic polyacids; on impregnation with this mixture, a paper will be both neutralized by the buffering effect and also reinforced. Preliminary experiments justified these expectations, but showed the necessity for the addition of a plasticizer in order to improve the folding resistance.

Such papers, when subjected to the standard accelerating ageing test, showed little or no decrease in *p*H value or folding resistance; the wet strength was actually increased by the test. The quantitative significance of these results must be assessed with caution, however, since the accepted ageing test referred to above is based on paper fibres alone and may not necessarily apply to paper treated by the authors' method.

Medical Sciences at Toronto

THE University of Toronto has completed plans for its new Medical Sciences building, the largest and most complex structure planned for any Canadian university. By this means Toronto hopes to become one of the largest medical schools in North America, increasing its class to 250 a year by the time the main facilities are completed in 1969.

The complex of buildings will comprise a teaching block of five floors and a research tower of eight with an adjacent three-storey auditorium; the cost of the building is estimated at 29·5 million dollars and equipment will cost an additional 6·5 million dollars. The University plans to break ground this June, to complete the teaching and research blocks by September 1969, and to finish the auditorium building the following year.

The stimulus for the project was a committee report in May 1964 which said that "inadequacies of space have frustrated the development of research and the increasing demands of administrative duties and teaching have markedly reduced the effectiveness of the existing staff and hindered the acquisition of new staff of high calibre".

This new building should enable Toronto to keep pace in the future with the rapidly increasing demands of medical teaching and research.

Lenin Prizes

THE 1966 Lenin Prizes for Science and Technology have now been announced by the Soviet Government. In science, 21 research workers were awarded prizes for work on eight projects. These included the theory of superconductive alloys; theoretical and experimental research into excitons in crystals; research on the origin of peculiarities in surfaces of negative curvature; work on a mathematical theory of the synthesis of control systems; a cycle of works on irregular problems; investigations into elemental-organic compounds; a chromosome theory of heredity and a theory of mutations; and the book, *X-Ray Diagnosis of Diseases of the Bones and Joints*.

The technologists carried the day by sheer weight of numbers. Altogether 103 research people working on ten projects were awarded prizes in technology. These were for developing a new process for manufacturing a large module gear wheel; for developing and introducing automatic die-casting production of machine components; for developing the means for welding train rails in field conditions; for designing and introducing the mass production of a 100,000 kW steam heating turbine; for research into complex structures with *p-n* junctions and developing and introducing the mass production of power silicon rectifiers; for discovering oil and gas deposits in South Mangyshlak and prospecting two other deposits; for scientific verification and practical application of block systems for working oil deposits in the Kuibyshev region; for providing the scientific basis and the practical mechanisms for boring in underground conditions; for developing a practical ladle treatment by liquid synthetic slags for the manufacture of high-quality steels; and for introducing new industrial methods in building the Norilsk town and Combine in the permafrost soil and harsh climatic conditions of the Arctic Circle.

U.S. Science Advisory Committee

THE following new members have been appointed for four-year terms to the United States President's Science Advisory Committee: DR. I. BENNETT, director, Department of Pathology, Johns Hopkins University; PROF. S. DRELL, professor of physics, Stanford University; W. HEWLETT, president, Hewlett-Packard Company; PROF. C. SLICHTER, professor of physics, University of Illinois; DR. C. TOWNES, provost, Massachusetts Institute of Technology.

University News:

Massachusetts Institute of Technology

DR. HERBERT S. BRIDGE has been appointed professor of physics at the Massachusetts Institute of Technology. Dr. Bridge has worked with the Cosmic Ray Group of the M.I.T. Laboratory for Nuclear Science since 1946 and has been a principal investigator in NASA's solar wind experiments. Dr. Jerome Y. Lettvin has been appointed professor of communications physiology with faculty association in both the Department of Biology of the School of Science and the Department of Electrical Engineering in the School of Engineering.

Strathclyde

DR. PETER J. HEALD, head of the Department of Animal Biochemistry at the Twyford Laboratories, Ltd., Park Royal, London, has been appointed to the chair of biochemistry in the University of Strathclyde with effect from September.

Sussex

DR. R. J. TAYLER, at present Fellow of Corpus Christi College, Cambridge, has been appointed professor of astronomy.

Appointments

COUNCIL of the Scottish Marine Biological Association has appointed Mr. R. I. Currie, of the National Institute of Oceanography, to be director of the Millport/Oban Laboratory in succession to Dr. C. H. Mortimer. At the same time Mr. R. S. Glover will become director of the Oceanographic Laboratory, Edinburgh. Mr. Currie and Mr. Glover will act as joint secretaries to the Association.

ADMIRAL of the Fleet the Earl Mountbatten of Burma has been elected a Fellow of the Royal Society, under the statute of the Society which provides for the election of persons who have either rendered conspicuous service to the cause of science or are such that their election would be of signal benefit to the Society.

PROF. E. R. LAITHWAITE, professor of heavy electrical engineering at the Imperial College of Science and Technology, University of London, has been awarded the S. G. Brown Award and Medal of the Royal Society for 1966, for his work on the linear induction motor.

Announcements

A NEW *Journal of Computational Physics* is to be published in July by Academic Press.

A NEW journal, *Chemistry and Physics of Lipids*, is to be published quarterly by the North-Holland Publishing Company. The first issue is scheduled for July/September 1966.

A SYMPOSIUM on "Polymer Degradation" will be held at the Welsh College of Advanced Technology on July 1. Further information can be obtained from the Organizer of Short Courses, Welsh College of Advanced Technology, Cathays Park, Cardiff.

THE 1966 summer meeting of the British Society for the History of Science will be held at St. Anne's College, Oxford, during July 1–2. Further information can be obtained from M. P. Earles, Chelsea College of Science, Manresa Road, London, S.W.3.

THE seventy-second annual conference of the Museums Association will be held in Sheffield during July 4–8. Further information can be obtained from the Secretary, the Museums Association, 87 Charlotte Street, London, W.1.

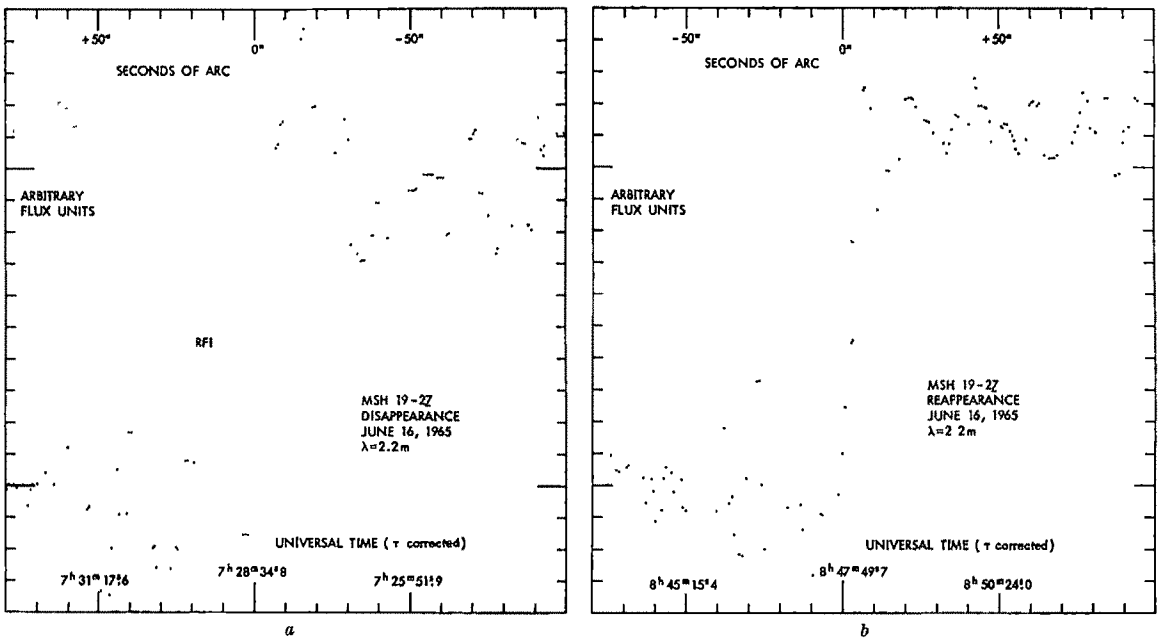
AN international conference on "Lens Design with Large Computers" will be held in Rochester, New York, during July 5–8. Further information can be obtained from the Institute of Optics, University of Rochester, Rochester, New York.

THE Water Pollution Research Laboratory, at Elder Way, Stevenage, has published a list of substances for which information on their toxicity and biodegradability is available. This list and any enquiries about the properties of a specific substance may be obtained from the director of the Laboratory.

A RESIDENTIAL advanced summer school on "Molecular and Cellular Aspects of Immunobiology", sponsored by McGill University and the National Research Council of Canada, will be held near Montreal during July 4–15. Further information can be obtained from Prof. A. Sehon, Department of Chemistry, McGill University, Montreal, Quebec.

A CONFERENCE on "The Economics of Automated Materials Testing", arranged by the Institution of Engineering Inspection in collaboration with the Materials and Testing Group of the Institute of Physics and the Physical Society, will be held at the Imperial College of Science and Technology, London, during July 4–6. Further information can be obtained from the Secretary, Institution of Engineering Inspection, 616 Grand Buildings, Trafalgar Square, London, W.C.2.

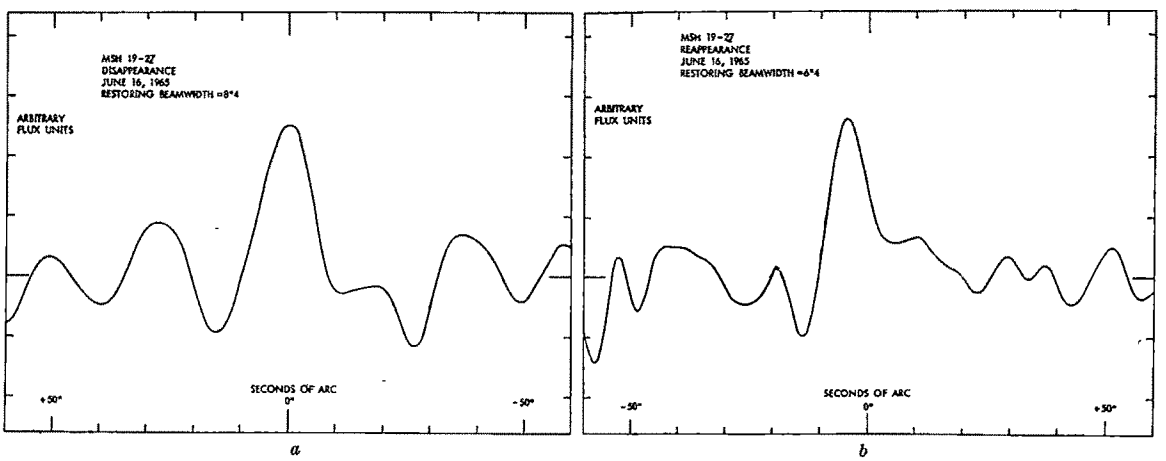
LUNAR OCCULTATION AND PROVISIONAL IDENTIFICATION OF *MSH* 19-27



By LARRY W. BROWN

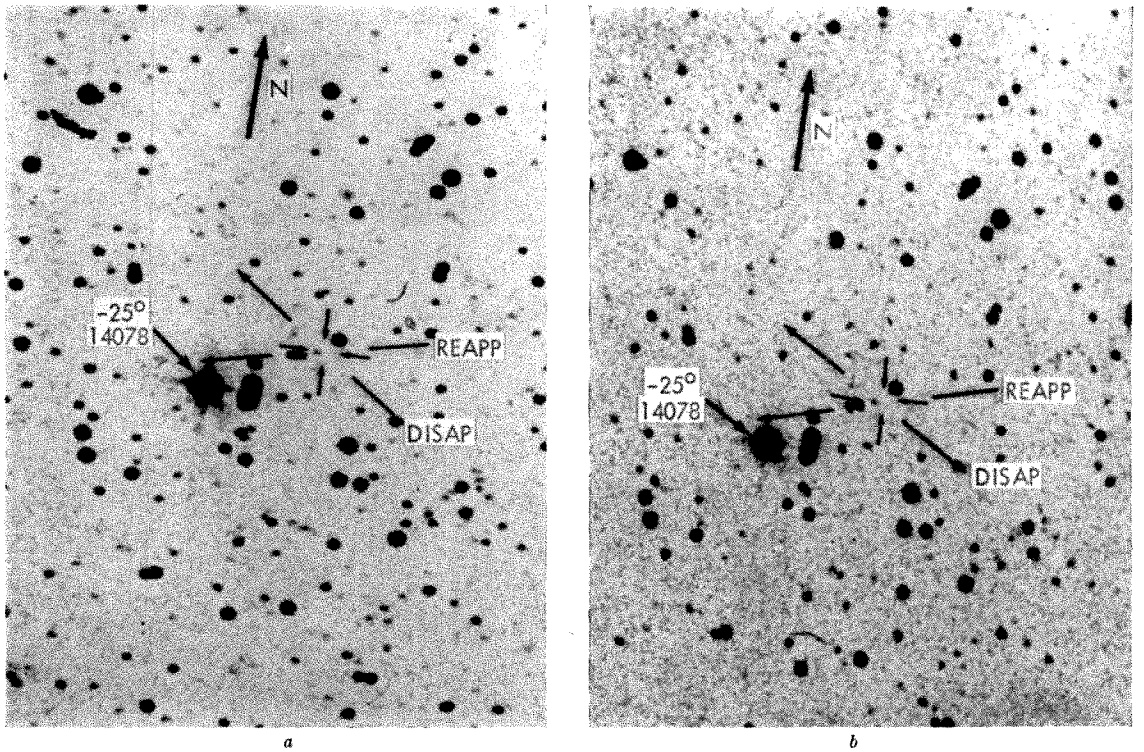
Radio Astronomy Section, Laboratory for Space Sciences, National Aeronautics and Space Administration, Goddard Space Flight Center

A LUNAR occultation of the radio source *MSH* 19–27 was observed on June 16, 1965. The observation was made at the National Aeronautics and Space Administration's Data Acquisition Facility located in the western North Carolina mountains (latitude 35° 12′ 0·05″ N., longitude 05h 31m 29·294s W.). In addition to position and diameter measurements, the occultation has provided a possible optical counterpart to the radio source.



The observation was made with a parabolic antenna 85 ft. in diameter, which tracked the centre of the Moon for the duration of the occultation. The receiver was a switched-type system using gain modulation. The receiving frequency was 137 Mc/s with an intermediate frequency of 30 Mc/s, bandwidth of 2·5 Mc/s and RC integration time of 3 sec. Digitized records of the disappearance and reappearance of the source are presented in Figs. 1*a* and *b*, respectively.

The records were analysed in an IBM 7094 computer with a programme adapted from the work of Von Hoerner[1], which was based on the restoration programme discussed by Scheuer[2]. This programme convolves the digitized data with various restoring functions to produce the brightness distribution as it would be observed with a Gaussian fan beam scanned along the position angle of the occultation. Examples of the restored data are presented in Fig. 2*a* and *b*.



a *b*

Fig. 1. *a*, Digitized data disappearance; *b*, Digitized data reappearance

a *b*

Fig. 2. *a*, Restored data: disappearance restored with a beamwidth of 8·4″; *b*, Restored data: reappearance restored with a beamwidth of 6·4″

a *b*

Fig. 3. 20× enlargement of National Geographic—Palomar Survey Plates. *a*, Red plate; *b*, blue plate

The data have been restored with seven different beam-widths and a gaussian curve fitted to the resulting brightness distribution. Analysis of the fit provides the best values for the position of the intensity peak and the diameter of the source along the scan. The diameters and corresponding position angles are given in Table 1.

Table 1

Phase	Position angle	Diameter	Time of occurrence U.T.	Restoring beamwidth used
Disappearance	58°	8·0″ ± 1·7″	07h 28m 35·0s ± 1·6s	4·6″ 8·0″
Reappearance	104°	5·9″ ± 1·5″	08h 47m 38·0s ± 1·5s	3·4″ 5·9″

The position of the source has been computed from universal times (corrected for RC integration time[3]) corresponding to the peak intensities of the restored brightness distributions. There are two possible positions for the source corresponding to these times:

Position 1: R.A. (1965·5) = 19h 26m 58·46s ± 0·03s
Dec. (1965·5) = −25° 55′ 32·4″ ± 0·5″

Position 2: R.A. (1965·5) = 19h 26m 51·18s ± 0·03s
Dec. (1965·5) = −25° 44′ 1·4″ ± 0·5″

In calculating these positions, it has been assumed that the difference in universal and ephemeris time is 35·0 sec.

The ambiguity in position can be resolved by considering the position given in the *MSH* catalogue[4].

Table 2

	Position 1	*MSH*	Position 2
R.A. (1950·0)	19h 26m 1·62s ± 0·03s	19h 25·6m ± 0·3m	19h 25m 45·42s ± 0·03s
Dec. (1950·0)	−25° 57′ 26·6″ ± 0·5″	−25° 44′ ± 5′	−25° 45′ 55·4″ ± 0·5″

Because position 2 lies within the quoted error limits of the catalogue while position 1 lies considerably outside the declination limits, the source is assumed to be at position 2.

The radio position of the source was located on the National Geographic Society—Palomar Observatory Sky Survey Plates from comparison with a number of 8th and 9th magnitude stars in the area. The optical positions were obtained from the *Cordoba Durchmusterung Catalogue* which has positions given to the nearest 0·1′ of arc. Within the error limits of the plate measurement, the radio position was found to coincide with the position of an extremely faint object ($\Delta\delta \approx 0''$ $\Delta\alpha \approx 1''$). Owing to the fact that in most cases the optical and radio positions do not coincide exactly, an area twice the radio diameter and several times the optical diameter was examined for other possible objects. The probability of the identification was increased when no other objects were found in this area.

Because of the extreme faintness, any interpretation of the nature of the object was seriously affected by the photographic limits of the survey plates. Figs. 3*a* and *b* are 20× enlargements of the source area on the red and blue plates, respectively. In red light, the source appeared to consist of a faint object with two centres of light concentration; while in blue light, there was only one centre (apparently brighter than the red) surrounded by a faint halo. A number of different types of objects were examined on the survey plates in an attempt to find similarities. While no conclusions could be reached, the blue image was found to be similar in some ways to a faint galaxy with a luminous nucleus. However, the nature of the object was not identified and must await more optical evidence.

I wish to thank Dr. S. Von Hoerner of the National Radio Astronomy Observatory for supplying his computer programme and H.M. Nautical Almanac Office for predicting the occultation.

ASYMMETRICAL STOP ZONES IN JUPITER'S EXOSPHERE

By SAMUEL GULKIS* and DR. THOMAS D. CARR
Department of Physics and Astronomy, University of Florida, Gainesville, Florida

A VARIETY of mechanisms has been suggested to account for the bursts of radio noise which are received sporadically from Jupiter at decametre wavelengths. For example, there are the Čerenkov emission model of Warwick[1], the Doppler-shifted cyclotron emission model proposed by Ellis and McCulloch[2], and the "escaped-whistler" model, based on the ideas of Carr[3], Field[4], and Chang[5]. In these three models and in others, emission occurs in the extraordinary mode near or well below the electron gyrofrequency, and the radiation reaching the Earth is initially guided by Jupiter's magnetic field (although propagation is not strictly along the field lines in some of the models). The asymmetry which is observed in the pattern of emission probability as a function of central meridian longitude at a given frequency is assumed to be due to asymmetrical beaming of the radiation. The beaming asymmetry, in turn, is assumed to be caused by field distortions resulting from a tilt of the magnetic dipole axis with respect to the rotational axis, from a displacement of the dipole centre relative to the centre of the planet, and from local departures from a true dipole field configuration. It is the purpose of this article to point out that in addition to altering the beaming pattern, another effect of field distortions is to produce a variation with longitude in the thickness of the stop zone for frequencies in the vicinity of the gyrofrequency. Čerenkov radiation, Doppler-shifted cyclotron radiation, and whistlers would all be expected to escape most often from regions in which the stop zone is thinnest (although it is not entirely clear in any of the models how the stop zone is traversed). This effect may be partially responsible for the structure of the observed emission probability pattern.

For quasi-longitudinal propagation in a plasma in which the collision frequency is relatively low, the Appleton–Hartree equation reduces to:

$$n^2 = 1 - \frac{f_p^2}{f(f \pm f_H)} \qquad (1)$$

where f is the wave frequency, f_p is the plasma frequency, and f_H is the electronic gyrofrequency associated with the magnetic field component parallel to the direction of propagation. The positive and negative signs refer to the ordinary and extraordinary modes respectively. The magnitude of the propagation vector, k, is related to the refractive index, n, by the relation:

$$k = \frac{2\pi f}{c}\sqrt{n^2}$$

For positive values of n^2, k is real, and normal propagation occurs. For negative values of n^2, k is imaginary, and in the steady state only evanescent waves exist. A stop zone is a region in which $n^2 < 0$. At the boundaries separating stop zones from regions in which propagation is possible, either $n^2 = 0$ or $n^2 = \infty$. Booker[6] has discussed these forbidden regions, and has plotted stop zone boundaries for both modes in the terrestrial magnetosphere at specified frequencies. His assumption of a field due to a centred dipole aligned with the rotational axis and of a radically symmetrical electron density distribution leads to stop zones which are independent of longitude and are symmetrical about the equator. However, in the case of Jupiter, the field is not so symmetrical. This, we will show, leads to an asymmetrical forbidden region. For the extraordinary mode, which is the only case we are considering, n^2 is positive wherever $f_H > f$ or wherever $f(f - f_H) > f_p^2$.

Let us first consider a hypothetical planet having a centred axially aligned magnetic dipole and a radially decreasing electron density. There will be only one stop zone for longitudinal propagation in the extraordinary mode at a given frequency, f. The equation of the inner boundary, determined by the condition that the gyrofrequency equals the wave frequency, is given by:

$$R_1^3 = \frac{K}{f}\sqrt{1 + 3\sin^2\theta} \qquad (2)$$

where R_1 is the radius vector measured from the dipole centre, θ is the magnetic latitude, and K is a constant dependent on the strength of the dipole moment. If f is in Mc/s, then $K = 2{\cdot}80\, H_0 R_0^3$, where H_0 is the magnetic field strength in gauss at a point on the magnetic equator at a distance R_0 from the dipole centre. On the outer boundary of the stop zone, $f(f - f_{H_2}) = f_{p_2}^2$, where f_{H_2} and f_{p_2} are the gyrofrequency and the plasma frequency, respectively, at this boundary. The radius vector, R_2, to a point on the outer boundary at magnetic latitude θ may be found from:

$$R_2^3 = \frac{R_1^3}{1 - f_{p_2}^2/f^2} \qquad (3)$$

where R_1 is given by equation (2) and f_{p_2} is itself a function of R_2. Equation (3) can be simplified if it is assumed that $f_{p_2}^2 \ll f_{H_2}$, implying that $10^{-5}\, N_2^2 \ll H_2^2$. This is not unreasonable for a model of Jupiter's magnetosphere, since for a value of H_2 on the order of 10 G, it is required only that N_2 be smaller than, say, 10^6 electrons cm^{-3}. Then the expression for R_2 can be approximated by:

$$R_2 = \left[1 + \frac{f_{p_2}^2}{3f^2}\right] R_1 \qquad (4)$$

The stop zone thickness is given by:

$$(R_2 - R_1) = \frac{f_{p_2}^2}{3f^2}\, R_1 \qquad (5)$$

The term $f_{p_2}^2$ can be replaced by $80{\cdot}6 \times 10^{-6}\, N_2$, where N_2 is the electron density in cm^{-3}. Equations (2) and (4) indicate that the location of the inner boundary of the stop zone depends only on the magnetic field, while that of the outer boundary depends on both the magnetic field and the electron density.

The variation of plasma frequency (or electron number density) with radial distance must be known before an explicit expression for either R_2 or $R_2 - R_1$ can be found in terms of independent variables. Thus, if we assume that $N = N_0 \frac{R_0^m}{R^m}$, the expression for the stop zone thickness becomes:

$$R_2 - R_1 = 2{\cdot}7 \times 10^{-5} N_0 R_0 (2{\cdot}8 H_0)^{(1-m)/3} (1 + 3\sin^2\theta)^{(1-m)/6} f^{(m-7)/3} \qquad (6)$$

However, even without precise knowledge of the electron distribution, it is possible to draw certain conclusions regarding the variation of stop zone thickness with longitude. It is apparent from equation (5) that a necessary condition for the stop zone thickness to remain constant is that $f_{p_2}^2\, R_1$ (or $N_2 R_1$) be constant. Thus, for an axially symmetrical dipole field and a radially symmetrical electron distribution, the stop zone thickness varies with latitude but not longitude, as suggested by Fig. 1*a*. On the other hand, if the field is not symmetrical, either because of a displacement or a tipping of the dipole or

* Present address: Arecibo Ionospheric Observatory, Box 995, Arecibo, Puerto Rico.

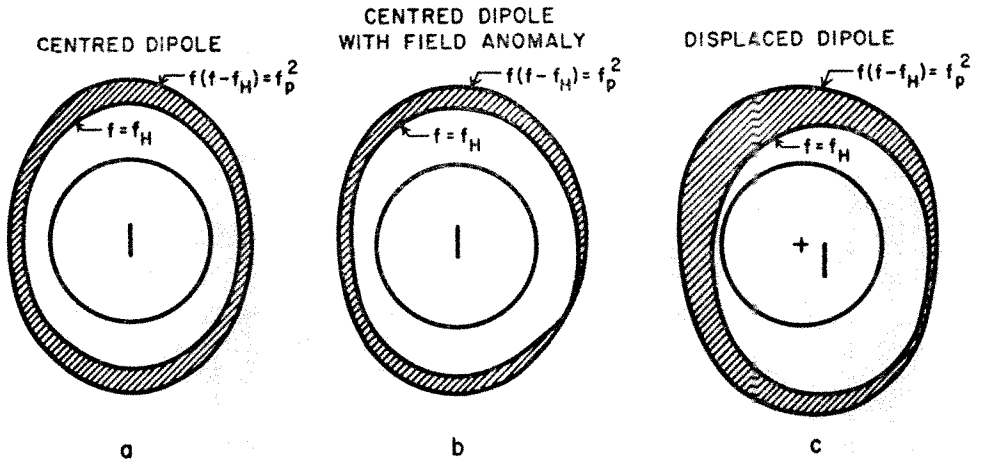

Fig. 1. Variation of thickness of the stop zone (represented by the shaded region) with latitude for various magnetic field models. The thickness has been greatly exaggerated to illustrate its variation

because of field anomalies, R_1 now depends on longitude as well as latitude, and the stop-zone is no longer symmetrical. It is thinnest at longitudes for which the field is strongest. A variation of electron density with longitude would also destroy the symmetry of the stop zone, which would in this case be thickest at longitudes of highest electron density. The effect of a localized field anomaly is suggested by Fig. 1*b*, and of a displacement of the magnetic dipole by Fig. 1*c*.

It appears very likely that if any of the aforementioned mechanisms is indeed responsible for the Jupiter radiation, stop zone asymmetries must be one of the factors producing the characteristic variations of occurrence probability with central meridian longitude. Beaming of the escaping radiation into thin sheets is probably another contributing factor. Thus, if the probability of escape of radiation from a given region of Jupiter toward the Earth is high, then the stop zone near this region must be relatively thin and the field orientation must be suitable to produce a beam in the right direction.

It is possible that the striking correlation of Jupiter activity with the position angle of the satellite Io, which was discovered by Bigg[7], is due at least in part to the influence of the satellite on Jovian stop zones. The effect might result either from perturbations by Io of the magnetic field or of the electron density in any of a number of ways.

If Io is directly involved in the emission of radiation, it would seem most likely that the radiation must originate either near the satellite or near a region where field lines passing close to the satellite intersect the surface of Jupiter. In either of these cases, initial propagation toward the Earth would be more or less transverse to the field. Longitudinal propagation has been assumed in the preceding equations for the sake of simplicity. However, the effects of changes in field strength and electron density on stop zone thickness are not qualitatively different when propagation is not longitudinal, and the foregoing general conclusions would still apply.

This investigation was supported in part by the National Aeronautics and Space Administration, the National Science Foundation, the Office of Naval Research, and the Army Research Office Durham).

BRIGHTNESS DISTRIBUTION OF ANTARES FROM LUNAR OCCULTATIONS

By J. H. TAYLOR, jun.
Harvard College Observatory, Cambridge, Massachusetts

THE first direct measurements of the angular diameters of stars were made by Michelson and Pease[1], using an interferometer which yielded an effective angular resolution of about 0·02 arc sec. More recently, Hanbury Brown *et al.*[2] have used an intensity interferometer to measure the diameter of Vega to a resolution of 0·004 arc sec. The present article discusses a third method of measuring stellar diameters and brightness distributions, namely the method of lunar occultations.

During the years 1950–53 there occurred a series of lunar occultations of the star Antares, at least five of which were observed with fast photo-electric equipment[3–6]. On the assumption that the star appears as a uniformly illuminated disk, the resulting light curves were shown to indicate a diameter of about 0·040 arc sec for Antares, the same value as that deduced by Pease[7] from interferometer measurements. A more complete analysis of these occultations has now been performed. The process required a convolution of the photo-electric data with a suitable restoring function and gave an effective angular resolution of 0·0084 arc sec. The results suggest that Antares (a star of magnitude 0·9 and spectral type *M*1 Ib) consists of a bright central component about 0·019 arc sec in radius, surrounded by an outer shell extending to about 0·028 arc sec

It is further shown that the diameters of a surprisingly large number of stars can be measured by the same method. The limiting resolution for stars of seventh magnitude observed with a 50-in telescope is of the order of 0·001 arc sec, which would permit the resolution of twenty or so stars at a given location in a year.

Scheuer[8] has derived an elegant solution to the mathematical problem of recovering one-dimensional brightness distributions from occultation observations. The method

was developed for the purpose of studying radio sources occulted by the Moon and it has been used by Hazard[9], von Hoerner[10,11], and others. The restoring process yields the brightness distribution of the occulted object as it would appear if scanned with a fan beam of Gaussian shape, oriented parallel to the limb of the Moon. So long as the lunar limb can be regarded as a smooth diffracting screen, the minimum effective beamwidth of the restoration is determined by the signal-to-noise ratio, the band-width, the time resolution of the observations, and the diameter of the telescope. The method is applied here for the first time at visual wave-lengths.

The problem of recovering full two-dimensional brightness distributions from fan beam observations has been discussed by Bracewell[12]. If the object under investigation is known to possess circular symmetry, then a single fan beam observation suffices to determine the radial distribution of brightness. In the present case, while observations were obtained with the fan beam oriented in different position angles, the differences in the resulting data were not significant, and circular symmetry has been assumed. This assumption is supported by previous observations of Antares made with a rotating Michelson interferometer[13].

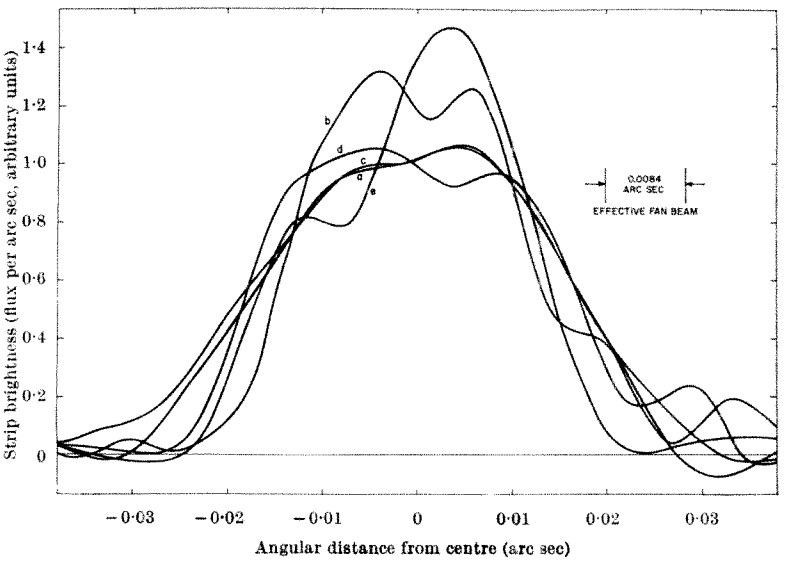

Fig. 2. Strip-integrated brightness distribution of Antares derived from five different lunar occultation observations

Table 1 lists the circumstances of the five occultations of Antares which provided the observations used in this article. Two other observations available in the literature[3,6] were rejected because of reported non-linearities in the electronic recording equipment. A sample of the observed data is reproduced in Fig. 1. The restorations to strip-integrated brightness distributions were performed digitally with a modification of von Hoerner's computer programme. An effective wave-length of 5100 Å was assumed for all of the observations. The results for a restoring beamwidth of 0·0084 arc sec are plotted in superposition in Fig. 2, normalized so that the areas under the curves are equal.

Antares, like many red giant stars, varies slightly in luminosity, but its variations over the period of the observations are believed to have been small and have been neglected. If one also rules out the possibilities of an appreciably elongated star, or an unresolved double star, then the differences among the five curves in Fig. 2 must be attributed to errors. The principal source of systematic error is the uncertainty in v_r, the velocity of approach of the lunar limb. This uncertainty results from our lack of knowledge of the precise angle between the mean lunar limb, assumed in the analysis to be smooth and circular, and the actual limb at the point of occultation. The uncertainty causes a proportional ambiguity in the horizontal scales of the strip-integrated brightness distributions. These effects are minimized in the case of head-on occultation, and conversely are greatest in the case of a grazing event. It is easy to show that the root mean square error of v_r, namely Δv_r, can be expressed approximately by the relation:

$$\Delta v_r/v_r = [(1-\cos\alpha)^2 + \tan\varphi \sin\alpha)^2]^{1/2}$$

where φ is the angle between the normal to the mean lunar limb and the direction of the Moon's motion, and α is the root mean square slope of the lunar surface over the relevant distance scale of a few tens of metres. If one assumes that α is approximately 8°, as indicated by radar investigations of the Moon[14], then the uncertainties in v_r for the occultations in question range from 3 per cent for event d to 35 per cent for event b. These uncertainties are sufficient to explain the discrepancies in the widths of the curves of Fig. 2.

Corrections to the values of v_r were made on the assumption that the brightness of the central region of the star is constant in time. The adopted values of v_r were each multiplied by the factor necessary to equalize the average central ordinates of the strip brightness distributions. The corrections are of the order of 10 per cent or smaller, and have the effect of reducing by 15 per cent the root mean square scatter of the points that determine the mean strip distribution. The corrected strip scans then agree to within their own random uncertainties.

For the purpose of deriving the radial brightness distribution of Antares, the strip scans were folded and averaged and then corrected for instrumental smoothing by the method of successive substitution[15]. The inverse Abel transform[12] of the mean strip scan was computed numerically, the result being the radial brightness distribution $I(r)$ plotted in Fig. 3. The error bars were derived from the root mean square deviations of the five corrected strip scans from their mean.

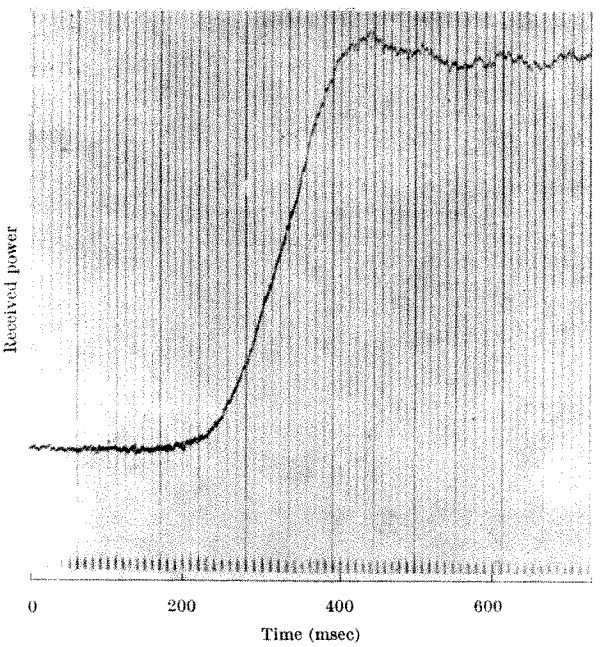

Fig. 1. Photoelectric light curve for occultation of Antares 1952 April 13 (after Evans *et al.*, ref. 5)

For comparison with limb darkening laws predicted for model stellar atmospheres. the radial brightness distribution has been replotted in Fig. 4 as a function of $\mu=[1-(r/R_0)^2]^{1/2}$, where r is the angular distance from the centre of the star, R_0 is the overall radius of the star, taken as 0·028 arc sec, and μ is the cosine of the angle between the line of sight and the normal to the surface of the star at r. The observed distribution is not well described by a law of the form $I(\mu) \approx a + b\mu$, as might be expected if the outer layers of the star were in radiative equilibrium, or by a law of the form $I(\mu) \approx \mu^c$, as might be expected if convective equilibrium prevails.

Figs. 3 and 4 suggest that Antares is composed of a central component of approximately uniform brightness, 0·019 ± 0·003 arc sec in radius, which accounts for 80 ± 10 per cent of the flux at 5100 Å, and an additional component—perhaps a semitransparent shell or enormous prominences in the outer atmosphere of the star—which extends to at least 0·028 ± 0·004 arc sec from the centre and accounts for the remainder of the flux.

On the assumption that the radiation from Antares comes from an overall disk of radius 0·028 arc sec, the

Table 1. CIRCUMSTANCES OF THE OCCULTATIONS OF ANTARES

Event	Date	Position angle	Angle between normal to limb and Moon's motion, φ	Velocity of approach, v_r (arc sec per second)	Reference
a	1950 May 4	267°	14°	0·414	Fig. 3, ref. 4
b	1951 July 15	43°	68°	0·181	Fig. 3, ref. 4
c	1952 April 13	349°	58°	0·241	Plate 12, ref. 5
d	1952 April 13	301°	12°	0·459	Fig. 3, ref. 4
e	1953 March 8	235°	52°	0·233	Fig. 3, ref. 4

effective temperature of the star is estimated to be 3,200° K. For this calculation we have used 1,919 arc sec and 5,800° K for the angular diameter and effective temperature of the Sun, +0·94 and −26·78 for the apparent magnitudes of Antares and the Sun, and 2·5 for the difference between the bolometric corrections for Antares and the Sun (all numerical values from Allen[16]). The temperature estimate for Antares should, however, be regarded with caution, since the uncertainty in the bolometric correction for Antares is large.

The limits of resolution by the lunar occultation method have not been reached in the foregoing Antares example. Two observations[5] of occultations of Antares *B* (a companion star of magnitude 6·6 and spectral type *B*4 *V*) were restored with an effective beamwidth of 0·003 arc sec. The star was not resolved; nor would one expect it to be, since the calculated diameter, based on the known colour and apparent magnitude, is only 0·0001 arc sec[17]. The limiting resolution was in this case determined by the optical bandwidth, which was of the order of 30 per cent. Upper limits to diameters found in this way are quite valid, since the unknown roughness of the lunar limb cannot diminish the apparent angular diameter of an object.

The limits of resolution set by noise and bandwidth have been formulated by von Hoerner[18]. They are respectively:

$$\beta_r \geqslant 52/q_0^2$$

and

$$\beta_r \geqslant 0{\cdot}616\sqrt{B\lambda}$$

where β_r is the fan beam resolution in arc seconds, q_0 is the root mean square signal-to-noise ratio for integration over 1 arc sec of the Moon's motion, λ is the wave-length in metres, and B is the fractional bandwidth as a percentage. The resolution limit set by telescope size is a consequence of the fact that the diffraction pattern of the occulted star is not scanned by an infinitely narrow slit, but by the finite aperture of the telescope. If a is the aperture (in inches) of the telescope perpendicular to the limb of the Moon, then this limit is given by the relation:

$$\beta_r \geqslant 9a \times 10^{-6}$$

In some cases, where occultations of small, bright stars are observed with large telescopes, it will be advantageous to use a rectangular diaphragm over the telescope aperture.

Atmospheric scintillations typically have a period of the order of 0·1 sec. Since the motion of the Moon relative to the stars is of the order of 0·35 arc sec per sec, scintillation noise will adversely affect stellar diameter measurements only for stars larger than about 0·01 arc sec, for which the occultations last for longer than about 0·03 sec.

Fig. 5 shows graphically the resolution limits for occultation observations carried out with telescopes of 50-in., 100-in., and 200-in. circular aperture, if the observational noise-level is equal to that experienced by Evans *et al.*[5]. The horizontal branches of the curves represent the limits set by telescope size, while the steepest portions are determined by the noise-level with the assumption that the maximum practical bandwidth is 30 per cent.

The diagonal lines in Fig. 5 give the calculated diameter of a star as a function of its spectral type and apparent visual magnitude[17]. It is clear that a number of stars should be resolvable by the method of lunar occultations. An indication of the number of stars available is shown

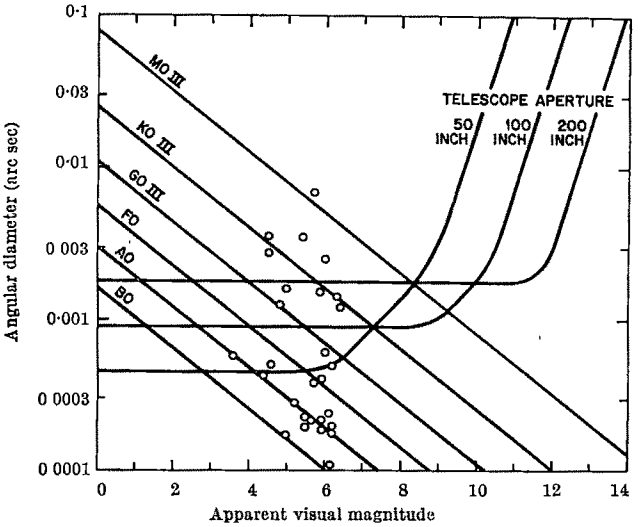

Fig. 5 The limits to resolution of stellar diameters by the method of lunar occultations are shown for three telescope sizes. The diagonal lines give calculated diameters of stars as a function of spectral type and apparent visual magnitude. The circles represent stars brighter than magnitude 6·5, which will be occulted during the latter half of 1966 for observers in the south-west United States

by the circles in Fig. 5, which represent the stars brighter than magnitude 6·5 subject to occultations visible in the south-west United States during the second half of 1966 (ref. 18). Only occultations occurring at the dark limb of the Moon are included.

Fig. 5 indicates that the diameter of the brightest quasi-stellar radio source, 3*C* 273 (visual magnitude 12·6), could be measured to a limit of about 0·01 arc sec, if a lunar occultation were observed under favourable conditions with a 200-in. telescope. Such a measurement would be of great astrophysical interest.

CRANIAL CAPACITY OF THE OLDUVAI BED I HOMININE

PROF. TOBIAS[1] has replied to my communication[2] regarding the cranial capacity of the 'pre-Zinj' hominid, Bed I, Olduvai Gorge. Tobias has presented statistical data regarding variation of this metrical character in higher primates, and claims that the 'pre-Zinj' volume exceeds significantly by 3·79 *S.D.*s the mean volume (502 c.c.) for a sample of seven australopithecines. He has further claimed that since the variation of metrical characters varies in different primate taxa, one cannot *a priori* assume that australopithecine variation was of the same order. While I am certainly in basic agreement with Prof. Tobias's comments, I think it is important to make a few points regarding his arguments, and the relation of his data to the question of taxonomic placement of the Olduvai hominid.

My original communication[2] was not offered with any aim of making taxonomic inclusions or exclusions. The evidence I presented was solely meant to support Prof. Tobias's[3] figure of 680 c.c. for the 'pre-Zinj' endocast. I merely added the last paragraph to forewarn students against accepting the confirmation of his values as supporting any taxonomic conclusion. While I agree with Tobias's argument regarding the fallacy of *a priori* assumptions of comparable variation in all taxa of higher primates, I think it only fair to point out that Tobias has used the *a priori* assumption that if the difference between means is significant, one has evidence suggesting taxonomic separation. It is hard to escape the conclusion that Tobias has made the *a priori* assumption that the forms are taxonomically distinct at both generic and species levels, and is using the statistical data to back his position. I have no quibble with his heuristic procedure, provided that the statistical data are comparable. In this case they are not, and I fail to see the relevance of his arguments regarding primate variability in cranial capacity.

Tobias[3] has shown that the capacity of the 'pre-Zinj' (680 c.c.) exceeds by 3·79 *S.D.*s the australopithecine mean of 502 c.c. He then discusses extant higher primate variability, noting that gorilla show a coefficient of variation (*C.V.*) of 13·6 per cent (the *C.V.*s for modern *Homo* being 12·8 per cent; 6·8 per cent in chimpanzee, and 9·35 per cent in australopithecines, $n=7$). Two points must be made regarding this procedure: (*a*) If the mean for a large sample of gorillas ($n=113$) (mean = 510 c.c.)[4] is compared with Schultz's[5] value of 752 c.c., the difference between means exceeds 3·48 *S.D.*s. (*b*) Comparison of different taxa based on completely different sample sizes is a dubious matter. It makes little sense to compare *C.V.*s and *S.D.*s for large samples ($n > 100$) with those based on very small samples, for example, chimpanzee and gorilla with australopithecines, particularly when the latter are reconstructions based on fragments, and the reconstructions in turn based on other members of the same sample. In short, there is the fallacy of sample size, as well as the fact that in the australopithecine sample the members are not wholly independent.

To illustrate this matter, I have calculated the *S.D.*s and *C.V.*s for a number of fossil hominids. These are shown in Table 1.

It is interesting that the *C.V.* for australopithecines given by Tobias as 9·35 per cent is larger than the values for Solo (7·8 per cent), and neandertals (8·6 per cent). The Chinese material ('Pekin man') is somewhat larger (10·7 per cent). The very high values for the East Asiatic pithecanthropines reflects the outcome of low sample size ($n=3$). The equation for *S.D.*, using ($n=3$), reduces the denominator in the radical to two ($n-1$), thus increasing *S.D.* and *C.V.* If Woo's[6] recent discovery is excluded, the *S.D.* becomes 141 c.c., and the *C.V.* approximately 16·1 per cent. Surely these values are meaningless in terms of illustrating variability in this taxon? There is

no sound basis for comparing *C.V.*s of Solo (7·8 per cent) and *Pithecanthropus* (13·6 per cent) with the chimpanzee or gorilla and conclude anything regarding taxon variability. If values for 113 gorillas or chimpanzees were written on pieces of paper, placed in a hat, and seven drawn, the statistics would be comparable with the australopithecines only with respect to sample size. Even this procedure would not wholly equalize the situation, since one would have to assume *a priori* that variability was comparable in the two taxa, and that is what one is trying to ascertain. Furthermore, after drawing seven values, one has recourse to the remaining population to see how the selection went. This cannot be done with the fossils. In addition to Tobias's listing of factors contributing to taxon variability, one might include the possibility that in a species with larger absolute brain size and body-weights, more variability might be expected. In fact, both Keith[7] and Hagedoorn[8] have shown that this is the case. The ranges approximate absolute values.

Thus any arguments regarding different taxon variability in metrical characters should be based on comparable samples. It may well be the case that taxon variability in higher primates is itself variable, as Tobias argues. His figures do not establish this as absolute fact, since the samples are not comparable. The question is still open. Consequently, for Tobias to use these figures he must implicitly be taking the *a priori* assumption that variability is comparable in different taxa of higher primates.

It should also be pointed out that the sample size of australopithecine endocasts, $n=7$, includes the 'Zinjanthropus' or *robustus* member. Apart from this inclusion, the $n=7$ statement *does not* also imply that the reliability of each value of capacity is the same for all seven. This is another difference between the hominid sample and those of the apes based on Ashton and Spence's[4] data. In the latter case, the reliability should be the same for all members of the sample.

If any *a priori* argument can be advanced, it should be in the direction of granting variability for the australopithecine taxon. After all, this is the first experiment in hominid evolution, This 'experiment' did involve a new behavioural adaptation, cultural behaviour, surely based to some extent on the organization of the brain. Logically, one might expect greater variability in this unstable beginning phase, which soon led to the more advanced pithecanthropine stage, present in Bed II. Thus far, the evidence as given by Tobias does not decide one way or the other in this case.

In any event, the fate of taxonomic designation for the 'pre-Zinj' specimen cannot be decided by reference to *S.D.*s or *C.V.*s, unless the sample size is expanded. Should that occur, there would be much more total morphological evidence than is at present available, and decisions of taxon placement could be based, then, not on cranial capacity but on the total morphological configuration.

Table 1

Fossil group	Cranial capacity	Mean c.c.	*S.D.*	*C.V.* per cent	Ref.
Pithecanthropus		843	114·6	13·6

$$S.D. = \sqrt{\frac{\Sigma(x-\bar{x})}{n-1}} \qquad C.V. = \frac{100\,(S.D.)}{\bar{x}}$$

In sum, I agree with Prof. Tobias's remarks regarding possible taxon variability in metrical characters, but do not find his arguments and application to the australopithecines as necessarily convincing. The 'pre-Zinj' case is comparable with the gorilla in terms of *S.D.*s, and similar arguments could be advanced to end members of the 1,000-c.c. variation in modern *Homo*. While Tobias may be correct regarding australopithecine variability, and the 'pre-Zinj' significant difference in terms of means, this position still remains to be validated empirically. If the extant higher primates are excluded on the basis of sample size, Table 4 indicated that australopithecine variability is comparable, if not more, than that for other hominid groups.

WHEN Holloway[1] ingeniously corroborated my estimate of 680 c.c. as the cranial capacity of *Homo habilis*, I commented briefly on the state of knowledge arising from this confirmation[2]. My remarks were not a reply, since his paper did not call for a reply. In one sentence, I pointed out that the corroborated value of 680 c.c. exceeded the newly re-computed australopithecine sample mean of 502 c.c. by 3·79 *S.D.*s. This simple statement of fact made no reference to the taxonomic implications of this significant difference. The comment was in my view justified because: (*a*) the value of 680 c.c. had previously been doubted by some, but was now shown quite independently to be valid; (*b*) the sample mean and variance for the australopithecines had been re-computed, based on my new estimate of 562 c.c. for the 'adult value' of the Taung cranial capacity, instead of the 600 c.c. previously accepted.

It is therefore difficult to see how Holloway could read into my comments "the *a priori* assumption that if the difference between means is significant, one has evidence suggesting taxonomic separation". In any event, the difference between means was not referred to by me, but the difference between a single value (680) and the australopithecine sample mean.

It is equally difficult to follow Holloway's reasoning when he goes on to say: "It is hard to escape the conclusion that Tobias has made the *a priori* assumption that the forms are taxonomically distinct at both generic and species levels, and is using the statistical data to back his position". This would suggest that my brief comments following Holloway's previous paper constitute the whole case for the distinctness of *Homo habilis*! Yet, this case is based not on a single criterion (cranial capacity), but on several criteria[3–11], and it has been carefully built up over a long series of some eight or more papers. An investigation of these papers shows that the analysis came first, and the taxonomic conclusions thereafter. For example, in a paper prepared as long ago as April 1964 for the thirty-third annual meeting of the American Association of Physical Anthropologists, and published in October 1965 (ref. 9), I stated: "Right up until December 1963, I had believed that I could explain the features of

the juvenile mandible of 'pre-Zinjanthropus' simply as those of an extreme variant of *Australopithecus*. But at that time, I turned my attention from the dentition of this mandible to the cranial capacity and other features of the cranial bones, as well as to remains from other levels above and below the 'pre-Zinjanthropus' level. It was then I realized that the hominizing departures were not confined to the one feature, the teeth, of one individual, 'pre-Zinjanthropus', but were consistent throughout other analysable parts of the morphological pattern and were maintained from the lowest hominid site in Bed I (*MKI*), through the 'pre-Zinjanthropus' level (*FLK NNI*), where they characterized at least two different individuals, and even apparently co-existed on the same level with *A. boisei* himself. It was this dual consistency that made me realize we were not dealing with an isolated extreme variant of the australopithecines, but with a sustained morphological trend existing alongside a persistent australopithecine line". Seen in the light of these earlier publications, Holloway's claim that I was using the statistical data to back a previously adopted position is a complete *non sequitur*.

The relevance of my comments regarding primate variability is as follows: Several workers, including Holloway, have suggested, or implied, that australopithecine variability would have been comparable with that of modern primates. Thus, he pointed out in his earlier paper that "The parameter of cranial capacity is quite variable in the higher primates", and that "The end-points of the greater 1,000 c.c. variation between members of modern *Homo* are not placed in separate species, nor are gorillas, the volumes of which vary between 752 c.c. and 320 c.c.". He went on to claim: "Thus, it would not be unlikely that on the basis of cranial capacity, at least, the 'pre-*Zinj*' materials are within the Australopithecine taxon of early hominids".

Such statements, by both Holloway and others, are valid only in very general terms, since they disregard the fact that the degree of variability of cranial capacity in modern higher primates is itself highly variable. Some living species have high variability and some low, as determined by measurements of large samples. If we are to infer australopithecine variability from that in modern species, it is therefore pertinent to enquire: which modern species are we to select?

When Holloway speaks of "the fallacy of sample size" and the dubious value of comparing the variability of large samples of chimpanzee and gorilla with that of a small sample of australopithecines, he is simply tilting at windmills. In fact, I stated that the estimated australopithecine coefficient of variation is "very likely . . . an imperfect estimate". This was emphasized by the statement, apparently overlooked by Holloway, that "We simply do not know if *Australopithecus* was a highly variable taxon in general, or whether cranial capacity in this group was of low or high variability"[2].

Holloway's statistical exercise on cranial capacity is of little relevance to my warning about varying variability, for time and again he conveys the misleading impression that I have based taxonomic conclusions on comparisons between the variability of the fossil group and that of living primates, when this is precisely what I have warned against doing. Thus, he states that "the samples are not comparable", which is true only if one includes the fossil samples. However, for living hominids, the samples are adequate and comparable. Thus, my statements were based on 144 chimpanzee, 260 orang-utan, 400 male gorilla and 653 gorilla of both sexes. These large samples yield widely differing coefficients of variation. Hence, it seems reasonable to infer that the cranial capacities of living higher Primates differ appreciably in variability. Therefore, the variability of cranial capacity in them provides no basis from which to infer the variability in extinct higher Primates like *Australopithecus*; *a fortiori*, it provides no adequate basis from which to infer—without other evidence—that the brain-size of *H. habilis* is within the range of variation for *Australopithecus*. It is actually closer to the smallest cranial capacity of *Homo erectus* than to the largest cranial capacity of *Australopithecus*: a case could therefore be made out for a null hypothesis that *H. habilis* and *H. erectus* are not drawn from separate populations! Whether or not the capacity of *H. habilis* proves to be within the australopithecine range can be answered only by more discoveries, not by *a priori* considerations, such as the variability in gorillas and modern man, or, still less, the assumption that the australopithecines represent "the first experiment in hominid evolution" and should therefore have had a more variable brain-size.

INTER-RELATIONS OF ACTIVATION, DEACTIVATION AND DESTRUCTION STEPS IN CHEMICAL KINETICS

By DR. MARGARET ROBSON WRIGHT* and DR. P. G. WRIGHT†
Department of Chemistry, Queen's College, Dundee

TEXT-BOOKS universally discuss the dependence of the order of a unimolecular reaction, in the homogeneous gaseous phase, on the partial pressures of reactant and inert species. It is instructive to consider whether analogous transitions in order can occur for bimolecular and termolecular reactions, and (if possible) to formulate criteria for such transitions.

In what follows, the term 'molecularity' is taken to mean the number of molecules, n, simultaneously coming together (participating in an n-body collision) to form the activated complex. It is not taken to mean the total number of individual reactant molecules which together constitute the activated complex.

In this sense of the term, it cannot be asserted without further argument that a bimolecular reaction is necessarily of the second order, nor is a termolecular reaction necessarily of the third order.

It is fundamental to modern theories of chemical reactions that, before reaction can occur‡, reactant species must acquire a certain critical energy, activation, and

* Edward A. Deeds Junior Fellow of Queen's College, Dundee.
† Lately Edward A. Deeds Fellow of Queen's College, Dundee.

‡ There are two exceptions to this: (i) where there is tunnelling; (ii) for example, atom-atom recombinations where the energy is already sufficient for reaction and activation is superfluous.

that, once this energy has been attained, the rate of reaction can be expressed as the rate of passage of activated complexes through the critical configuration conventionally represented as the top of an energy barrier. A rate-determining step, however, may be either the rate of attainment of the critical energy, or the rate of destruction of the activated complexes by reaction; or both steps may be significant. The precise details depend on whether the reaction is unimolecular, bimolecular or termolecular, and also on the experimental conditions.

Activation, when it occurs, and deactivation are both binary collision processes, while destruction by reaction has a molecularity dependent on the process involved. The order of the reaction and its dependence on the total pressure are thus very much concerned with the interplay of activation, deactivation and destruction by reaction.

Inter-relations for the various mechanisms. The salient features of the mechanisms to be discussed are summarized in Tables 1 and 2. The schemes considered are the simplest ones capable of exhibiting the features of interest. Thus, for example, the unimolecular mechanism is presented in drastically simplified form. More complete schemes (such as the long-known treatment of Kassel[1] for unimolecular reactions, and such recent discussions of termolecular reactions as those of Porter, Szabo and Townsend[2] and Benson[3]) resemble those exhibited here in the main qualitative features. A^* denotes an activated molecule which has acquired the critical energy from a favourable collision or successive favourable collisions, and which can then pass, without further acquisition of energy (though, in relevant cases, after encounter with another molecule—or other molecules), through the critical configuration known as the activated complex, and then form products. The kinetic expressions follow from a consideration of the stationary-state concentration of activated molecules or from the procedure, more directly related to the present subject-matter, outlined in the *Appendix*. The partitioning of the activated molecules A^* between their two possible fates is represented by the ratio:

$$\chi \equiv \frac{\text{chance of deactivation (from } A^*)}{\text{chance of conversion to the activated complex (from } A^*)}$$

The dependence of χ on pressure may be inferred from the molecularity of the steps resulting in destruction of the activated molecules A^*.

Mechanistically, group IV is fundamentally different from groups I, II, III*A*, III*B* in that all four schemes outlined in group IV involve the initial bimolecular formation of an associated species. Nevertheless, IV*A* is kinetically equivalent to III*A*, and only by independent evidence could the two be distinguished. Within group IV, however, there are dissimilarities: in contrast to *A*, no activation is required for *B*, *C* (ref. 4) and *D* (ref. 4). In a more specific fashion, *C* and *D* differ from each other in respect of the type of bimolecular associated species. In *C* there is prior formation of an associated AA^*, the excess energy of which, with respect to A_2, must be removed by M before formation of the stable A_2 molecule; where in *D*, an associated species is formed from one reactant molecule and the third body M. It is also probable that the reaction:

$$A + A + M \rightarrow A_2 + M$$

can occur by simultaneous operation of both mechanisms *C* and *D*. The conclusions for such a scheme are very similar to those drawn for *C* and *D*.

Criteria for a transition in the kinetic order. Two classes of mechanisms are to be distinguished: (i) groups I, II and III*A*; (ii) group IV. For the former, if the destruction and deactivation steps are not of the same molecularity then the rate constant is, in principle, pressure dependent. If these steps are of the same molecularity, then kinetics of order equal to the molecularity will be observed for all pressures. This occurs only for the bimolecular mechanism II.

Table 1

	I Unimolecular	II Bimolecular	III*A* Termolecular activated	III*B* Termolecular unactivated, for example, $2NO + O_2 \rightarrow 2NO_2$ ($\rightleftharpoons N_2O_4$)
Elementary steps by which reaction proceeds	$A + A \xrightarrow[\text{bimolecular activation}]{k_1} A^* + A$ $A^* + A \xrightarrow[\text{bimolecular deactivation}]{k_{-1}} A + A$ $A^* \xrightarrow[\text{spontaneous dissociation}]{k_2}$ products	$A + A \xrightarrow[\text{bimolecular activation}]{k_1} A^* + A$ $A^* + A \xrightarrow[\text{bimolecular deactivation}]{k_{-1}} A + A$ $A^* + A \xrightarrow[\text{bimolecular reaction}]{k_2}$ products	$A + A \xrightarrow[\text{bimolecular activation}]{k_1} A^* + A$ $A^* + A \xrightarrow[\text{bimolecular deactivation}]{k_{-1}} A + A$ $A^* + A + A \xrightarrow[\text{termolecular reaction}]{k_2}$ products	$A + A + A \xrightarrow[\text{termolecular reaction}]{k}$ products
Rate of reaction	$\frac{k_1 k_2 [A]^2}{k_2 + k_{-1}[A]}$	$\frac{k_1 k_2 [A]^2}{k_{-1} + k_2}$	$\frac{k_1 k_2 [A]^2}{k_{-1} + k_2 [A]}$	$k[A]^3$
Order	Neither first nor second. Rate constant is pressure-dependent	Strictly second order	Neither third nor second Rate constant is pressure-dependent	Strictly third order
χ	Necessarily pressure-dependent	Function of rate constants alone	Necessarily pressure-dependent	——
Deactivation Destruction	Bimolecular Spontaneous	Bimolecular Bimolecular	Bimolecular Termolecular	—— Termolecular
Transition in order occurs 'at'	$[A] \sim k_2/k_{-1}$	[Not found]	$[A] \sim k_{-1}/k_2$	——
Rate-determining step in high-pressure region.	First order kinetics imply that destruction of activated complexes is rate-determining $k_{-1}[A]/k_2 \gg 1$; $[A]$ large	Under all conditions of pressure second order kinetics imply that reaction is rate-determining.	Second order kinetics imply that activation is rate-determining $k_2[A] \gg k_{-1}$	
Consequent state of supply of activated molecules	Adequate	Adequate	Inadequate	——
Rate-determining step in low-pressure region.	Second order kinetics imply that activation is rate-determining $k_{-1}[A]/k_2 \ll 1$, $[A]$ small	As above	Third order kinetics imply that destruction is rate-determining.	——
Consequent state of supply of activated molecules	Inadequate		Adequate	——

For groups I, II and III*A* there seem to be no universal criteria in terms either of adequacy of the supply of activated molecules, or of conditions in which there is the possibility of a complete Maxwell–Boltzmann distribution of energies in the reaction system or vice versa, except perhaps the following. If, under all conditions of pressure, the rate-determining step is destruction by reaction and an adequate supply of A^* is always present, then the kinetic order is equal to the molecularity. If, on the other hand, there are regions of pressure such that the supply of A^* becomes inadequate and activation becomes rate-determining, then a pressure-dependent rate constant will be observed.

If active intermediates are formed and the mechanisms are as listed in group IV, then, even though destruction by reaction and deactivation have the same molecularity, a transition in order with pressure for the given reaction may be obtained. Similarly, a criterion in terms of adequacy of supply of activated molecules is not strictly applicable to IV*A* and for IV*B*, IV*C* IV*D*, where activation is not required, is irrelevant.

Rate-determining steps and activation equilibria. The rate-determining step may vary with pressure, and from the kinetics inferences may be drawn regarding the possibility of setting up an equilibrium:

$$\text{reactants} \rightleftharpoons \underset{\text{molecules}}{\text{activated}} \rightleftharpoons \underset{\text{complexes}}{\text{activated}}$$

Such an equilibrium is not, of necessity, implied by the establishment of stationary state concentrations of activated molecules.

Since there is no activation step in III*B*, IV*B*, IV*C* and IV*D*, only groups IV*A*, I, II and III*A* need to be considered.

For the simple strictly second-order bimolecular mechanism II, the kinetics imply that, at all pressures, reaction is the rate-determining step. Consequently, there is always an adequate supply of activated molecules and of activated complexes. Kinetic investigations cannot by themselves demonstrate decisively whether this adequate supply corresponds to a complete Maxwell–Boltzmann equilibrium distribution (of translational, rotational and vibrational energies) for the processes written down here. If there were such a distribution, the number of very energetic molecules A^* would be small, and it is normally taken as plausible that the kinetically adequate stationary concentration of A^* is approximately equal to the 'equilibrium' concentration. There is, however, no *a priori* justification for such an assumption[6]. Similar situations are implied for the high-pressure first-order regions of a unimolecular reaction, for the 'low'-pressure third-order region of a termolecular reaction, and the third-order kinetic region of the 'bimolecular' reaction exhibiting variable order. In this last-mentioned case, the pressure of A is low relative to that required for the second-order region, though in absolute terms it often is found to be relatively large.

In contrast, the second-order, low-pressure region of a unimolecular reaction, and the perhaps hypothetical second-order high-pressure region of a termolecular reaction imply that activation is rate-determining. This, in turn, implies an inadequate supply of activated complexes, that is to say, a complete Maxwell–Boltzmann distribution is not attained. For the 'bimolecular' mechanism exhibiting second- and third-order kinetics when the pressure is sufficiently high for second-order kinetics, very little can be asserted regarding the possibility or otherwise of setting up an equilibrium between

Table 2

reactants and activated complexes. It can merely be stated that destruction by reaction is no longer the rate-determining step.

For the three mechanisms I, III*A*, IV*A* which exhibit a pressure-dependent overall rate constant, for a given pressure region the rate-determining step depends critically on the mechanism. This is in direct consequence of the relative efficiencies of the processes of activation, deactivation and destruction. As seen in Tables 1 and 2, there are distinct contrasts between the three cases. For the termolecular reaction III*A*, since reaction requires the simultaneous collision of three molecules while deactivation requires only two molecules, destruction by reaction is, at 'low' pressures, the less efficient process, and thus is rate-determining. In contrast, at low pressures, activation for the unimolecular process I is inefficient relative to decomposition (activation requires the simultaneous presence of two molecules, decomposition is spontaneous), while for the 'bimolecular' process of variable order IV*A*, activation and destruction should be of comparable efficiency. On the other hand, at sufficiently high pressures, for the termolecular reaction III*A*, activation (bimolecular) becomes less efficient than reaction (termolecular) with the rate-determining step now being activation; but for a unimolecular reaction I, activation and deactivation, being bimolecular, are more efficient than spontaneous decomposition which thus is rate-determining.

In contrast to gas phase reactions, analogous transitions in order with concentration are never found for reactions in solution. Reaction is always the least efficient process (for reactions where diffusion is not rate-determining), solvent molecules being able to maintain an adequate concentration of activated molecules.

Appendix. The following kind of argument[6], based on considering the relative chances of alternative fates of the species produced in an initial step, leads in a quite direct way to expressions for rates. As an illustrative example, the treatment for the simplified unimolecular mechanism of Table 1 is presented.

The rate of production of A^* from A, that is, the rate of the activation step, is $k_1[A]^2$. Once A^* is formed it will either: (*a*) be deactivated, with the rate of deactivation proportional to $k_{-1}[A]$; (*b*) decompose, with rate of destruction proportional to k_2.

Thus the fraction deactivated is proportional to $k_{-1}[A]$ and the fraction decomposed is proportional to k_2; therefore the fraction decomposed

$$= \frac{k_2}{k_2 + k_{-1}[A]}$$

and the rate of formation of product = (rate of activation) × (fraction of A^* which are destroyed by reaction but are not deactivated)

$$= k_1[A]^2 \frac{k_2}{k_2 + k_{-1}[A]}$$

ISOTOPICALLY LABELLED MACROMOLECULES IN BIOLOGICAL RESEARCH: DEXTRAN LABELLED WITH RADIOACTIVE IODINE

By Dr. C. R. RICKETTS

Medical Research Council Industrial Injuries and Burns Research Unit, Birmingham Accident Hospital

MACROMOLECULES labelled with radioactive isotopes have several potential uses. Two applications of interest in biological research are firstly for measuring *in vivo* the permeability of membranes to solute molecules of various sizes and secondly to serve as standards in the comparison of samples of a polydisperse substance. The radioactivity provides rapid and accurate measurement, susceptible to automation, and avoids the subtraction of an arbitrary 'blank' value from chemical measurements due to the presence of interfering substances in biological fluids.

Inulin, a polysaccharide with a molecular weight of about 5,000, is widely used for measurement of renal glomerular filtration rate. In a previous article the labelling of inulin with radioactive iodine isotopes by introducing an occasional allyl group into the molecule and adding iodine at the double bond was described[1]. Satisfactory measurements of glomerular filtration rate have been made using labelled inulin[2], with some reservations on the stability of the compound.

Dextran fractions of known molecular weight distribution are available and greatly extend the range of molecular sizes accessible for permeability investigations[3,4]. Dextran has been labelled[1] with radioactive iodine isotopes in the same way as inulin was labelled.

For the higher molecular weights, which are of greater biological interest, fractions which are sufficiently narrow are difficult to prepare. This has been overcome by the injection of polydisperse dextrans and determination of the molecular weight distribution of dextran recovered from the biological fluids by the automatic turbidimetric method developed by Wallenius, Waschewsky, Aronsson and Hegedüs[5]. The advent of the 'Sephadex' range of cross-linked dextrans greatly facilitates the analysis of polydisperse materials in this higher range of molecular weights and makes it possible to investigate a very wide range of permeability from a single injection in one experiment. When also isotopically labelled macromolecules are used the amount of material injected is so small that disturbance of the physiological osmotic equilibrium is avoided.

The present communication reports some extensions of the work with labelled dextran. Introduction of allyl groups was carried out exactly as described for inulin, and allyl dextrans were freeze-dried and stored as powders. Addition of iodine was carried out on a small scale (0·1–1 g) as required. It was found that solutions of iodine (^{131}I or ^{125}I)-labelled dextran could be stored at −20° C for several months without increase in free iodide ions. It was convenient to expose the solution to a small portion of the anion exchange resin 'Amberlite *IRA*-400' in chloride form to remove any iodide ions present immediately before use in an experiment.

Columns of 'Sephadex *G*.200' provide some degree of fractionation of dextran according to molecular size. Use of radioactive dextran facilitates assessment of this separation. The allyl groups and therefore the isotopic iodine atoms are randomly distributed among dextran molecules, consequently the measured radioactivity is proportional to the weight of labelled dextran present. This is true for each fraction from a 'Sephadex' column even though the fractions may contain dextran of different molecular weights. (In contrast iodine-labelled polyvinyl pyrollidone is labelled by an end-group reaction so that the

radioactivity is proportional to the numbers of molecules present in a sample and this number varies inversely with the molecular weight.)

Fig. 1 shows the distribution of radioactivity due to a sample of ^{125}I-labelled dextran of molecular weight (M_w) 150,000, prepared from a dextran fraction (Pharmacia, Ltd.). The sample was mixed with serum and the separation of the protein peaks shows the efficient working of the column. Fig. 2 shows a similar distribution for another sample of radioactive dextran. When fractions from near the ends of the distribution were mixed and re-chromatographed two peaks were obtained showing that genuine separation was occurring, and not simply spreading due to diffusion and flow.

In a further experiment, ^{125}I-allyl dextran was mixed with an excess of the dextran fraction M_w 150,000 from

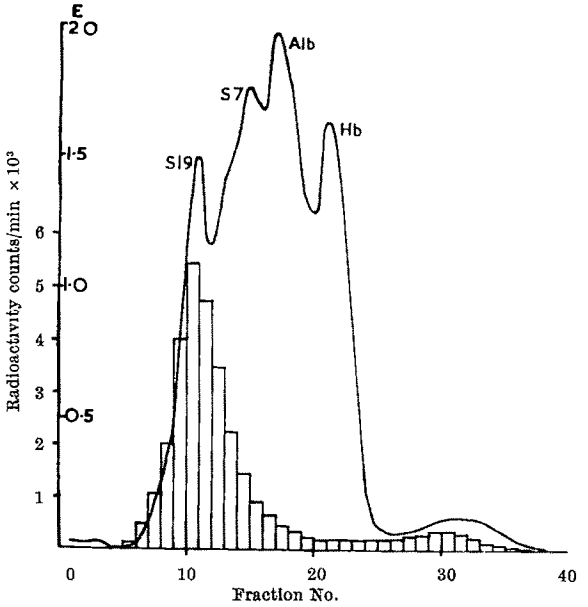

Fig. 1. Showing the distribution of radioactivity due to a dextran fraction of M_w 150,000 labelled with ^{125}I, plotted as a histogram, and the simultaneous resolution of serum proteins, measured as peaks of absorption at 280 mμ. A mixture of 2 ml. serum and 0·05 ml. dextran was separated on a column of 'Sephadex *G* 200' 35·5 cm long and 2·5 cm diameter using 0·9 per cent sodium chloride solution for elution into 5 ml fractions

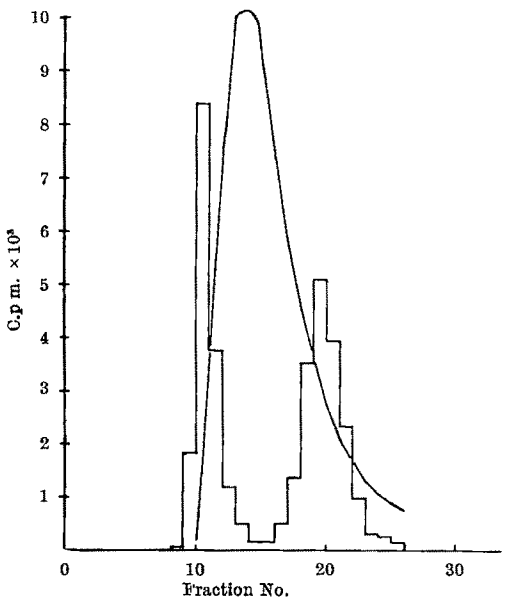

Fig. 2. Showing the distribution of radioactivity due to a reference sample '*R*' of dextran labelled with ^{125}I, plotted as a solid line, and the re-chromatography of a mixture of fractions 11 and 21+22, plotted as a histogram of c.p.m. 'Sephadex' column 45 cm long, other conditions as in Fig. 1

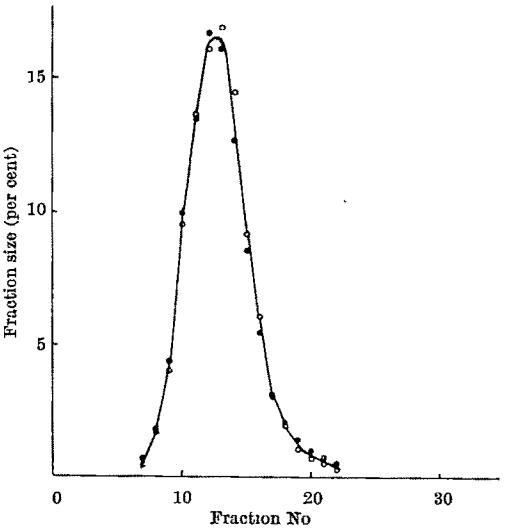

Fig. 3. Dextran labelled with ^{125}I was mixed with an excess of the dextran fraction M_w 150,000 from which it had been prepared and the mixture was run on a column of 'Sephadex *G*.200' as in Fig 1. The diagram shows the distribution of dextran (○), determined by the anthrone estimation and the distribution of radioactivity (●) The distributions are very similar showing that molecular weight distribution has not altered appreciably during the process of labelling

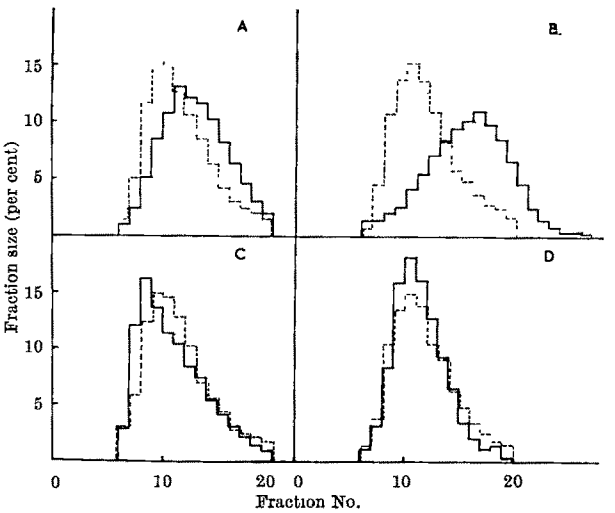

Fig 4 Comparison of four clinically used dextrans with the radioactive reference preparation of dextran '*R*' shown as dotted line. *A*, M_w 75,000, *B*, M_w 40,000; *C*, dextran B P.1963; *D*, dextran conforming to a new specification, B.P. *Addendum 1966*

which it had been prepared. The mixture was separated on a column of 'Sephadex *G*.200' and the radioactivity and dextran content of each fraction were measured (Fig. 3). The ratio of radioactivity to dextran was approximately constant over a range of fractions corresponding with 95 per cent of the whole material. This experiment shows that introduction of allyl ether groups has not been accompanied by hydrolysis sufficient to cause a detectable alteration in molecular size distribution.

The preceding experiment shows the practicability of using radioactive dextran as a reference substance when examining the distribution on 'Sephadex *G*.200' of other samples of dextran which may have quite different distribution of molecular size, as in the examples shown in Fig. 4. The reproducibility of separation of the labelled dextran into fractions was ± 1 per cent of the total radioactivity. The dextran distributions illustrated are those of various dextrans in clinical use. The radioactive reference preparation was also prepared from a clinical dextran conforming to a new specification.

The permeability of a biological membrane may be deduced from the concentrations of serum proteins present on each side of it[6]. For example, the proteins

present in serum and urine in certain diseases have been separated according to molecular size by 'Sephadex' columns and their concentrations have been determined, enabling the permeability of the renal glomerulus to these proteins to be calculated[7].

Columns of 'Sephadex *G*.200' enable a distribution according to molecular size for small samples of dextran, such as may be recovered from serum, to be readily obtained. Radioactive dextran was used in the initial experiments. Fig. 5 shows the distribution on a 'Sephadex *G*.200' column of radioactive dextran from the serum and from the urine of a rabbit. Fig. 6 shows the urine/plasma (*U*/*P*) ratio for the dextran of each fraction. Clearly it is not necessary to use radioactive dextran and Fig. 7 shows similar data for a patient transfused with clinical dextran conforming with the new specification mentioned here. In these experiments radioactive dextran has been mixed *in vitro* with the dextran recovered from biological fluids to act as a reference substance for checking the reproducibility of 'Sephadex' column separations.

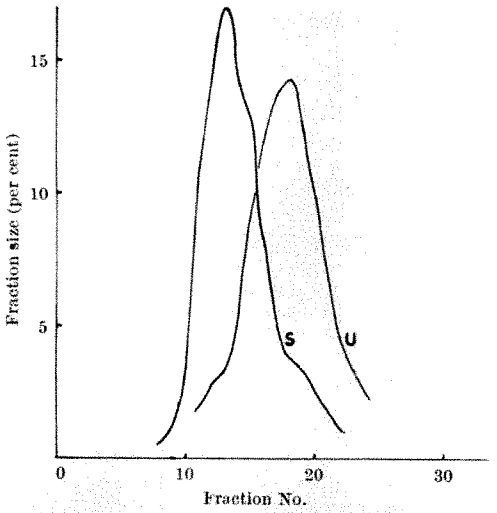

Fig. 5. The distribution of dextran recovered from the serum (*S*) and urine (*U*) of a rabbit given the radioactive reference preparation of labelled dextran '*R*' with 4 ml. 6 per cent dextran of similar molecular weight distribution as 'carrier'. The serum sample was taken in the middle of a 2-h urine collection period

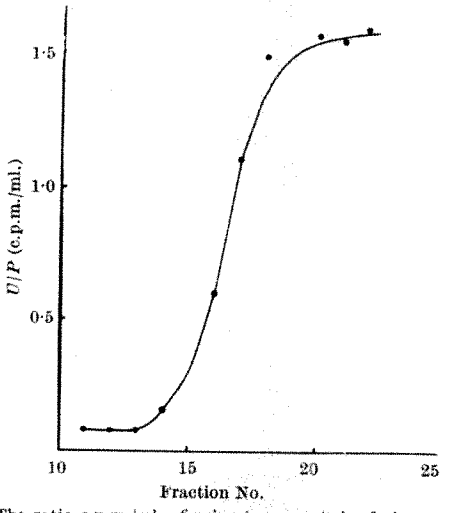

Fig. 6. The ratio c.p.m./ml. of urine to c.p.m./ml. of plasma, termed *U*/*P*, for each fraction, calculated from the data of Fig. 5. The sigmoid shape of the curve is related to the permeability of the renal glomerulus

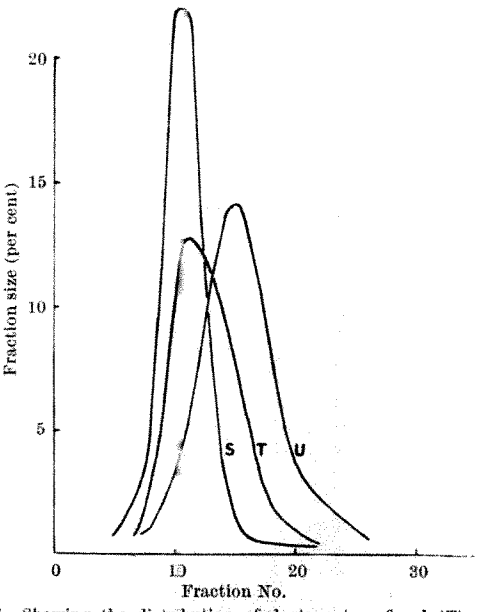

Fig. 7. Showing the distribution of dextran transfused (*T*) and recovered from urine 24 h after transfusion (*U*) and serum 72 h after transfusion (*S*). Dextran was determined by the anthrone method on each fraction from the 'Sephadex *G*.200' column. The patient, who had a burn of 37 per cent of the body surface, was transfused with 4 l. 6 per cent dextran

The further development of this technique and the application to the investigation of renal permeability in normal and diseased man and animals is being actively pursued in collaboration with members of the Department of Experimental Pathology, University of Birmingham[8].

In vitro DESTRUCTION OF SKELETAL MUSCLE BY SENSITIZED CELLS

By Dr. B. A. KAKULAS*

Charles F. Kubik Laboratory for Neuropathology of the James Homer Wright Pathology Laboratories, Massachusetts General Hospital, Boston, Massachusetts

THE aetiology of polymyositis remains obscure even though it is nearing a century since the original descriptions of the disease were reported[1–4], and despite considerable more recent interest[5–8]. The disorder is non-hereditary and shows itself as weakness of the limb girdle muscles and often involves the pharynx and neck. In approximately two-thirds of patients there are cutaneous lesions[7] and in these the disease is better designated as dermatomyositis. A remarkable feature is the high incidence of associated visceral malignancy, which is as much as 20 per cent in some series[8]. Microscopically the lesions consist of segmental muscle fibre necrosis, phagocytosis of necrotic sarcoplasm by macrophages and regenerative changes with which is associated a variable

* Present address: Department of Pathology, University of Western Australia, School of Medicine, Victoria Square, Perth.

leucocytic infiltrate, chiefly lymphocytes, larger mononuclear cells and plasma cells, and fewer neutrophils and eosinophils. Similar alterations occur in skeletal muscle in a wide variety of circumstances[6], but especially in the nutritional myopathies of some animals[9]. From a study of the histopathology it may be reasonably inferred that the pathogenetic mechanism taking place in polymyositis is fundamentally muscle fibre necrosis and the other changes occurring in the lesions are a secondary and non-specific response to selective injury of sarcoplasm.

The cause of polymyositis is suggested to be related to a disorder of immune mechanism because of the sharing, not uncommonly, of clinico-pathologic features with other diseases, such as rheumatoid arthritis or systemic lupus erythematosis, where disordered immunity is also strongly suspected to be of importance, as well as the high incidence of underlying carcinoma in polymyositis, the sensitivity to tumour extracts in some cases[10,11], the elevation of serum globulins and the improvement which follows the administration of corticosteroids[7]. Up to the present, there has been little experimental evidence to support an immunopathogenic hypothesis of aetiology, principally because attempts to devise an experimental model have been hampered by difficulties in interpretation of the lesions[12,13] related to the use of Freund's adjuvant which causes a severe arthritis and adjacent myositis[14], so that adequate experimental control has not been possible. Other workers report 'dystrophy-like' muscle lesions induced by immunological methods[15], but the reported changes do not resemble the histological findings in cases of polymyositis.

In order to explore the possibility that an appropriately sensitized cell may be detrimental to skeletal muscle in a manner related to delayed or cellular hypersensitivity mechanisms[16], an *in vitro* experiment following the methods employed to induce demyelination in cultures of peripheral nerve was utilized[17] and promised to surmount some of the difficulties encountered in *in vivo* models.

To this end, 2-mm cubes of skeletal muscle were excised aseptically from the limb girdles of foetal Sprague–Dawley rats, 19–20 days gestation, and planted on 22-mm coverslips coated with reconstituted rat tail collagen[18]. The explants were fed with a drop of medium consisting of equal parts of human placental serum, 50 per cent nine-day chicken embryo extract, and balanced salt solution with glucose added to give a final concentration of 600 mg per cent. The preparations were placed in a Maximov double coverslip assembly[19] and incubated at 35·5° C. The cultures were re-fed twice weekly and frequent microscopic observations of the living cultures were made. The cultures grew rapidly and many cross-striated young muscle fibres were present in one to three weeks.

Sensitization of young (150 gm) female Sprague–Dawley rats was achieved by the use of homogenates of skeletal muscle, obtained from the pelvic girdles of adult New Zealand white rabbits, in Freund's adjuvant (2 gm of muscle to 3 ml. of adjuvant, containing 3 mg AFB/ml.) prepared in a 'Virtis' homogenator run at alternating fast and slow speeds for about 30 min and with care taken to avoid heating the mixture. Injections of 0·05 to 0·1 ml. of the antigen were made intradermally in both hind footpads of ten rats, each receiving three injections at intervals of one week. Controls consisted of ten normal, untreated rats, ten rats injected once a week for three weeks with adjuvant alone (0·5–0·1 ml. into both hind footpads), and ten rats injected with homogenates of rabbit kidney in adjuvant in the same proportions, dose and site of injection as in the test group. Rats were examined daily for signs of disease.

The rats were killed with chloroform at intervals of three to six weeks after injection, and inguinal lymph nodes from both sides were excised under sterile precautions and followed by necropsy examination. Muscle blocks from upper and lower limb girdles were chosen for microscopy and fixed in Heidenhain's Susa for 24 h, embedded in paraffin and stained by haematoxylin and eosin. Portions of sciatic nerve and of main viscera were also selected.

The excised lymph nodes were placed in a few drops of balanced salt solution and repeatedly incised with a sharp blade. Clouds of cells liberated into the fluid were then washed and centrifuged at 700 r.p.m. for 5 min. The supernatant was decanted, and the cells resuspended in nutrient medium containing penicillin 1,000 u./ml., dissolved in the balanced salt solution, and the concentration of cells adjusted so that one drop of this suspension, fed to a culture, contained approximately 4×10^6 cells. Six cultures containing differentiated skeletal muscle were tested with cells or serum from every animal. Four cultures were tested with one drop of the cell suspension and two comparable cultures were 'fed' with a drop of medium in which the human placental serum was replaced by serum from the test animal obtained by means of cardiac puncture, prior to the excision of the lymph nodes. The living cultures were carefully examined throughout the experiment and observations continued for up to six days following the addition of the lymph-node cells or serum. At the end of the observation period cultures were fixed in 10 per cent formalin and stained by Mallory's phosphotungstic acid haematoxylin method and mounted whole.

Of the forty cultures treated with lymph-node cells from the ten donor rats given three injections of rabbit muscle and adjuvant, thirty-eight showed destructive changes (Fig. 1). Briefly, these consisted of thinning of individual muscle fibres, with vacuolation and granularity of cytoplasm progressing by further attenuation to separation from the collagen substrate and becoming fragmented. Such changes appeared 'suddenly', and required 12–24 h for their development and often first appeared in the most mature area of the outgrowth which was nearest to the original explant, resulting in 'clear spaces' in this area. These destructive changes began from 2 to 6 days after the addition of sensitized lymph-node cells. In phosphotungstic acid haematoxylin stained preparations architectural detail was lost in the fragments and clumps. Nuclei were dark, irregular and often disrupted. Numbers of large macrophages accompanied the breakdown of muscle fibres and many were observed to contain sarcoplasmic debris deeply staining with phosphotungstic acid haematoxylin, and although many lymphocyte-like cells were present at the conclusion of the 6-day period of observation it was apparent that a significant proportion had increased in size when compared to the cells in control cultures.

Lesions were present in the muscles of the hind limbs in all ten rats in the group sensitized to rabbit muscle

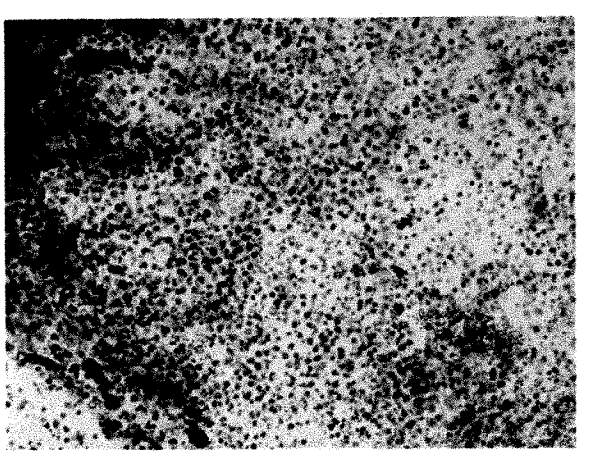

Fig. 1. *In vitro* destruction of muscle fibres following addition of lymph-node cells of rat (*MF8*) sensitized to rabbit muscle. Note dark fragments of fibre remnants, phagocytic cells and fewer lymphocyte-like cells. Culture 12/13-11*L*, phosphotungstic acid haematoxylin. Whole mount (×75)

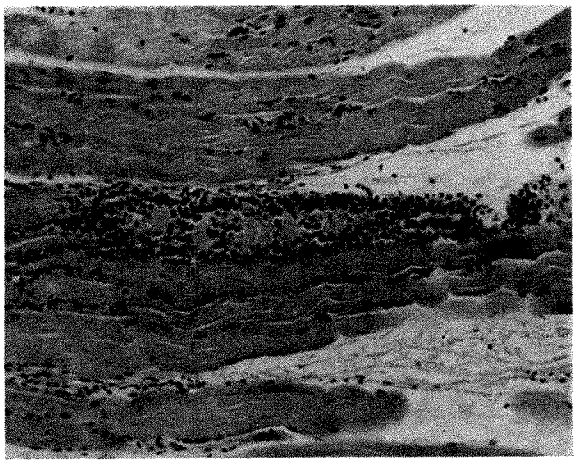

Fig. 2. *In vivo* muscle fibre necrosis and leucocytic infiltration. Pectoral muscle in longitudinal section, rat (*MF*22). (Haematoxylin and eosin. × 140)

and consisted of round cell infiltrates, macrophages, neutrophils and giant cells. There was associated frank necrosis of tissue in some instances. Individual muscle fibres in the vicinity of these lesions, which were most prominent in the neighbourhood of joints, were infrequently necrotic, showing myophagic activity. In nine of the ten rats in this group, muscle lesions were present as well in the fore limbs where arthritic changes were much less severe and in pectoral muscles, and consisted of focal muscle fibre necrosis and interstitial infiltrates of small numbers of polymorphonuclear leucocytes and round cells (Fig. 2). Destructive changes appeared in four of the twenty cultures to which serum was added from animals in this group. This rate was only a little higher than in the controls, as follows. Normal (untreated rats): 1 spontaneous 'breakdown'; 1 contaminated by bacteria; 18 unaffected. Rats injected with adjuvant alone: 3 'breakdowns'; 17 unaffected. Rabbit kidney and adjuvant-treated rats: 3 'breakdowns' and 17 unaffected cultures.

Of the forty cultures to which lymph-node cells were added from healthy untreated rats, seven showed 'spontaneous breakdown' of a small proportion of fibres in the culture. The changes were less severe and differed in appearance from those which occurred in cultures treated with cells from the group sensitized to muscle. There were fewer large macrophages, and there was a greater proportion of small cells. Myotubes and young muscle fibres in those cultures became granular and very gradually decreased in size. The morphological changes were similar to those observed in cultures which 'spontaneously' degenerate in the laboratory. Thirty-three of the cultures to which cells were added from normal rats remained intact at the conclusion of the 6-day period of observation (Fig. 3). Muscles were examined histologically from both pelvic and shoulder girdle regions in nine of the ten rats in this group and none showed lesions.

In the control group of cultures to which lymph-node cells from animals treated by three injections of adjuvant alone were added, six of forty broke down after the addition of the cells. The changes in the positive cultures were similar to those which broke down with cells from the untreated group. Muscle sections from hind and fore limbs of all ten animals were examined. In three rats the hind limb muscles, and in two of the three the fore limb muscles, showed lesions similar to those observed in the test group.

In the group of control cultures treated with lymph-node cells from animals sensitized to rabbit kidney and adjuvant by three injections, eight showed destructive changes, two became contaminated with bacteria, and thirty were normal at the end of six days. Hind and fore limb muscles obtained from the ten rats revealed muscle fibre necrosis in only one from a hind limb group. In contrast, all these rats showed kidney lesions. Microscopically, hypercellularity of glomerular tufts, due to epithelial and endothelial cell hyperplasia, was present together with numbers of round cells and polymorphonuclear leucocytes. Adhesions in Bowman's space were numerous and proteinaceous material was found in many renal tubules.

All groups which received adjuvant developed arthritis, mainly of the hind limb joints. Because this process caused impairment of mobility by itself and the fact that no animal became fully paralysed, it was not possible to perceive a difference, during life, between animals which later showed severe microscopic muscle lesions and those which did not. The much higher incidence of necrotic lesions in fore limb muscles of animals sensitized to rabbit muscle was considered a valid sign of effectiveness of the sensitization method. The fore limb muscle lesions did not bear a relationship to the proximity of joints as was the case with the hind limbs, and as a rule arthritic changes were much less severe in the fore limbs than in the hind limb joints.

Table 1

Groups of ten rats	No. and effect on cultures treated with Cells +	Cells −	Serum +	Serum −	Muscle lesions at necroscopy: Hind limb	Fore limb
MF	38	2	4	16	10	9
NR	7	33	1;1*C*	18	—	—
F	6	34	3	17	3	2
KF	8;2*C*	30	3	17	1	—

+, *in vitro* destruction of muscle; −, no effect. *C*, Bacterial contamination; *MF*, group of rats sensitized by intradermal injections of rabbit muscle in Freund's adjuvant; *NR*, untreated rats; *F*, group of rats given intradermal injections of adjuvant alone; *KF*, group of rats given intradermal injections of rabbit kidney in adjuvant.

The results summarized in Table 1 show that lymph-node cells obtained from rats sensitized to muscle are able to destroy muscle fibres, *in vitro*, at a rate much greater than in controls. The findings are presented as evidence that a cell, in certain circumstances, may cause necrosis of muscle and therefore would support a postulate that muscle fibre necrosis, the fundamental lesion of human polymyositis, may also be the result of the action of a cell which has developed this property because of a pathological disturbance of immune mechanisms.

We thank Dr. Raymond D. Adams for discussions and suggestions and Dr. G. F. Winkler and Dr. R. L. Sidman for advice and use of facilities in their laboratories. The work was supported in part by the National Institutes of Health and undertaken during tenure of an Eli Lilly International fellowship in medicine

RESTORATION OF THYMIC FUNCTION IN NEONATALLY THYMECTOMIZED MICE BEARING XENOGENEIC THYMIC GRAFTS

By DR. LLOYD W. LAW
National Cancer Institute, Bethesda, Maryland

DIRECT evidence has been presented to show that the thymus produces a humoral factor which plays a significant part in the development and maintenance of normal immune responses. Neonatally thymectomized mice of several strains carrying thymic tissue in cell-impermeable 'Millipore' diffusion chambers have their capacity restored to reject skin homografts, to form antibodies, both IgG and IgM, to sheep erythrocytes, and to repopulate their lymphoid organs[1–4]. Growth failure has also been prevented in neonatally thymectomized recipients of thymic tissue in 'Millipore' chambers[2].

Adequate control experiments have been carried out to show that these restorative effects are not the result of an adjuvant or of non-specific tissue influences. Lymph node and splenic tissue in 'Millipore' diffusion chambers[5], for example, have been shown to be ineffective in preventing immunological deficiencies in thymectomized mice. Mice with empty diffusion chambers are not restored[5,6].

It has recently been reported that allogeneic (*C57BL*) thymic tissue, enclosed within diffusion chambers, has the capacity to restore immune reactivity in *CBA* mice, showing that thymic humoral factor (THF) is not strain specific[5].

The work reported in this article was designed to determine whether thymic grafts from other species could prevent the growth failure, lymphoid depletion and immunological deficiencies of neonatally thymectomized mice.

F_1 hybrid mice, $(C57BL/Ka \times C3Hf/Lw)F_1$, were thymectomized under ether anaesthesia within 18 h of birth. Either sham-operated or intact litter mates were kept in each litter. Within 24 h of thymectomy one lobe of a thymus from a new-born Osborn–Mendel rat or from a Syrian hamster (*Mesocricetus auratus*) was grafted into the subcutaneous tissues of the lower back. Thus each litter comprised intact or sham-operated controls, thymectomized mice only and thymectomized mice bearing thymic grafts. In our experiments thirty thymectomized mice received rat thymic grafts and thirteen received hamster grafts. Since no particular differences were noted between the groups they were combined for convenience and referred to as mice with xenogeneic thymic grafts.

Body-weights were taken weekly. The absolute lymphocyte levels were determined at 2 months of age, before any other experimental procedures were undertaken. Mice were bled from the retro-orbital sinus. Immunization with sheep erythrocytes was accomplished at 3 months of age by the method described previously[3,7]. Haemolysin antibodies were determined at 7 days and agglutinin antibodies at 10 days.

Allogeneic skin grafts from *AKR* donors were carried out shortly after 2 months of age. Full-thickness homografts were performed using the method of Billingham and Medawar[8]. All mice dying in the course of the experiment or killed at 7 months of age at the end of the experiment were necropsied. Lymphoid tissues were taken routinely and the superior mediastinum was examined for thymic remnants. Histological sections were obtained on all suspected tissue in the retrosternal area.

Neonatally thymectomized $(BL \times C3H)F_1$ mice are subject to the 'wasting' syndrome but the onset is relatively late and the condition relatively chronic. The most striking sign is a loss of subcutaneous fat. The cumulative mortality for the several groups of mice is shown in Table 1. There were seven incomplete thymectomies in the non-grafted group and these were detected at necropsy at 7 months of age. These mice did not 'waste'. On the other hand, there were also six mice bearing thymic remnants which 'wasted' and died from 54 to 150 days of age. Among the thymectomized mice bearing xenogeneic thymic grafts, nearly 50 per cent lived to necropsy at 7 months and did not 'waste'. Seven of the twenty-one restored mice had thymic remnants which were disclosed only on microscopic examination of the retrosternal tissues. It is of interest that six of the twenty-two grafted mice which died from wasting at ages 53 to 115 days also had thymic remnants. Only one intact or sham-operated control died during the period of observation.

Fig. 1 shows the mean weight curves for intact or sham-operated and neonatally thymectomized F_1 mice compared with thymectomized mice bearing xenogeneic thymic grafts which did not waste and die (restored) and the group receiving thymic grafts which wasted and died (not restored).

The survival of skin homografts in neonatally thymectomized F_1 mice in sham (intact) thymectomized and in the thymectomized group grafted with xenogeneic thymuses is shown in Table 2. All the intact group completely rejected *AKR* skin by 20 days, whereas 80 per cent

Table 1. MORTALITY IN THYMECTOMIZED, INTACT AND RESTORED $(BL \times C3H)F_1$ MICE

Group	No. of mice	Number dying (cumulative percentage) at days: 30–60	61–90	91–120	121–150	151–180	181–200
Thymectomized	54	8 (15 per cent)	21 (54 per cent)	6 (65 per cent)	3 (70 per cent)	4 (78 per cent)	5 (87 per cent)
Sham or intact	40	—	—	—	—	1 (2·5 per cent)	0 (2·5 per cent)
Thymectomy plus xenogeneic graft	43	6 (14 per cent)	5 (26 per cent)	5 (37 per cent)	1 (47 per cent)	2 (51 per cent)	1 (51 per cent)

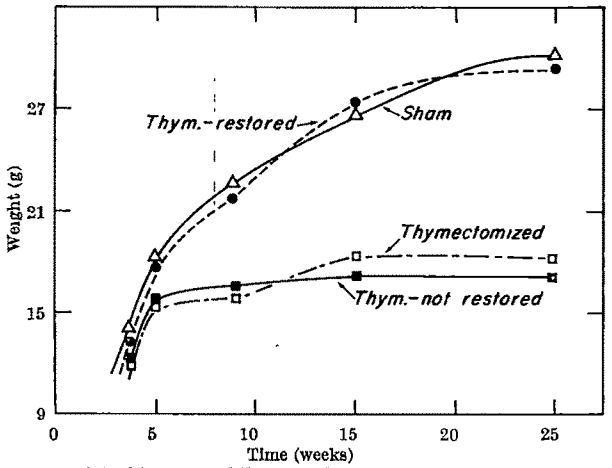

Fig 1. Weight curves of the several groups described in text Both sexes are included but are weighted equally. At the beginning of weighing there were twenty-three in the thymectomized group, eighteen in the sham-operated group, twenty-three in the thymectomized-restored group, and sixteen in the thymectomized-not restored group

of the thymectomized mice retained viable grafts beyond this time, the majority until death. Some of these thymectomized mice which rejected the allogeneic grafts early in the experiment were found at necropsy to be incomplete thymectomies (see Table 1). The presence of xenogeneic thymic tissue in the subcutaneous connective tissues apparently restored the capacity of a large number of the neonatally thymectomized F_1 mice to reject *AKR* homografts; fourteen (64 per cent) of these rejected skin grafts by 20 days. Among the group retaining *AKR* skin grafts until death, four 'wasted' and died and were thus not, in fact, restored.

The antibody responses of the several groups of mice to intraperitoneal challenge by sheep erythrocytes at 3 months of age are shown in Table 3. Very few neonatally thymectomized mice showed haemolysin or agglutinin responses within the range of the sham-operated controls and seven of these were found to have thymic remnants at necropsy. On the other hand, the majority of these neonatally thymectomized F_1 mice grafted with xenogeneic thymic tissue, which did not 'waste' and die, exhibited antibody titres within the range of the sham controls, although the mean titres were somewhat lower.

The mean total lymphocyte count of fifteen sham-operated or intact F_1 mice obtained from peripheral blood at 2 months of age was found to be 8,700/c.c. This represents 70 per cent lymphocytes. Thymectomized litter mates, on the other hand, had a reduced total lymphocyte count of only 3,800 (34·3 per cent lymphocytes), while the mean lymphocyte count of those thymectomized mice with xenogeneic grafts fell between these two figures: the mean total lymphocyte count was 6,250, which represents 47 per cent of the total peripheral leucocytes. The distribution of the individual counts is shown in Fig. 2.

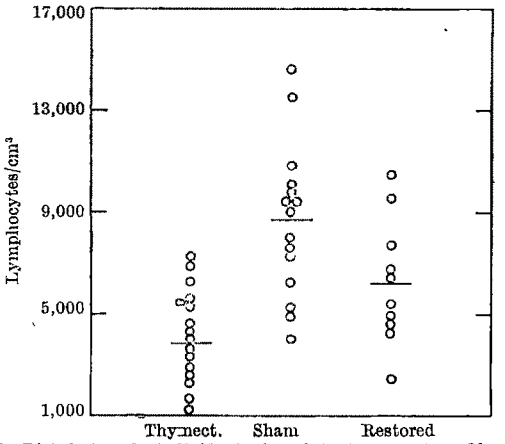

Fig. 2. Distribution for individual mice of absolute number of lymphocytes in neonatally thymectomized F_1 mice, in sham-operated controls and in thymectomized mice bearing xenogeneic thymic grafts (restored)

For the most part, an appreciable difference between the lymphoid tissues of the neonatally thymectomized group and their sham-operated litter mates was found on microscopic examination. There was a reduction in the size of lymphoid follicles and particularly of the germinal centres of the follicles in thymectomized mice dying at various times. The deficiency was extreme, showing nearly complete absence of follicles, in those mice exhibiting severe 'wasting'. In those F_1 mice classed as 'restored' by the several criteria used in this experiment variable histological patterns in the lymph nodes, spleen and Peyer's patches were found. In few of these mice was there a return to a completely normal picture. Lymphoid follicles tended to be smaller but the germinal centres were usually distinct and recognizable. In no case did the tissues of the restored mice show the extreme lymphoid deficiency characteristic of neonatally thymectomized mice.

Xenogeneic thymic grafts were not recovered from the subcutaneous connective tissues of any of the F_1 mice dying from 3 to 7 months of age or from those which lived and were killed at 7 months. These findings are similar to those reported by Miller[9] and Leuchars *et al.*[10]. These investigators found that thymectomized mice bearing allogeneic thymic grafts had their immunological capacity restored but that the graft of thymic tissue was not regenerated and was rejected by the restored host within 10 or 11 days or at the latest within 3 weeks[9] after grafting. Since both groups of investigators observed a persistence of epithelial-reticular cells within the allogeneic thymic graft, they concluded that restoration of immunological function could result from a humoral factor liberated by these cells which acted on host-type lymphoid cells.

Recovery of grafts of thymuses from Osborn–Mendel rats and hamsters into neonatally thymectomized $(BL \times C3H)F_1$ mice was therefore undertaken in a special group of mice at earlier periods, that is at 5-day intervals

Table 2 SURVIVAL OF ALLOGENEIC (*AKR*) SKIN GRAFTS ON NEONATALLY THYMECTOMIZED ($BL \times C3H)F_1$ MICE AND THEIR LITTER MATES GRAFTED WITH XENOGENEIC THYMUSES

Group	No. of mice showing skin graft survival for: 15 days	16–30 days	31–60 days	61–200 days
Thymectomized	6*	2*	6*	16
Sham thymectomy	22	1	0	0
Thymectomy + Xenogeneic thymus	12	2	4	4†

* Six mice were found to be incomplete thymectomies at necropsy, one incomplete retained *AKR* graft to 23 days, another to 53 days.
† All these mice which retained *AKR* grafts eventually 'wasted' and died before 180 days.

Table 3 HAEMOLYSIN AND AGGLUTININ PRODUCTION TO SHEEP ERYTHROCYTES IN ($BL \times C3H)F_1$ MICE NEONATALLY THYMECTOMIZED, SHAM-OPERATED AND RESTORED WITH XENOGENEIC THYMIC GRAFTS

Group	No. of mice	No of mice showing $\log_2$ titres of: 0	1	2	3	4	5	6	7	8	9	Mean $\log_2$ titre
					(haemolysins)							
Thymectomy	29	—	20	3	1	1	1(2)*	—(1)*	—	—	—	1·44
Sham	28				—	4	5	7	10	2	—	6·04

					(agglutinins)							
Thymectomy	30	—	12	2	4	5	1(2)*	2(2)*	—			2·50
Sham	22	—	—	1	—	3	3	4	7	2	2	6·18
Thymectomy + xenogeneic graft	21		(4)†	(1)†	1	3	5	5	2	—		4·73

* Had thymic remnants in retrosternal tissues microscopically at necropsy
† These mice died from 'wasting'

from 5 to 40 days after grafting. The grafts were removed at these times for histological study. The histological picture was similar in both types of grafts. There was degeneration of lymphocytes, but a few persisted until approximately the tenth day. Regeneration into a typical structure was not observed. There was, however, a persistence of epithelial-reticular cells in many grafts to as late as 30 days. Polynuclear cells eventually invaded the periphery, and there was central necrosis and invasion by fibrous tissue. In contrast to these results we were able to confirm the findings of Yunis *et al.*[11] that Holtzmann rat thymuses grafted into neonatally thymectomized mice are regenerated into a typical thymic structure. Neonatal thymic grafts from Holtzmann rats grafted into these F_1 mice were, in most cases, completely reconstituted by the fifteenth day and were found persisting as viable thymic fragments with lymphoid differentiation and organization into cortex and medulla for as late as 50 days. The results of attempts at restoration with these donor Holtzmann thymic grafts will be reported later.

The results reported here show that a considerable number of neonatally thymectomized $(BL \times C3H)F_1$ mice were restored toward normalcy when they were grafted with neonatal xenogeneic thymic tissue. It has been reported that allogeneic thymic grafts are capable of restoring the normal immunological function in thymectomized mice yet viable grafted tissue could not be recovered after 3 weeks[9,10]. Allogeneic thymic tissue in 'Millipore' diffusion chambers has also been shown to promote immunological recovery; splenic tissue and lymph nodes were unable to do so[5]. These findings would seem to indicate that the restoration observed in the present investigation was the result of a humoral factor, THF, dependent on the presence of surviving epithelial-reticular elements of the xenogeneic thymic graft and capable not only of inducing the maturation of residual host (F_1) lymphoid cells but of re-establishing lymphopoiesis. Obviously an unequivocal explanation for restoration cannot be given since adequate controls were not included in this experiment.

If this is the explanation for the restoration seen in our F_1 mice, the thymic-dependent humoral-mediated mechanism is not species-specific.

The lack of effect observed by Yunis *et al.*[11] in *C3H* mice in which there occurred successful rat (Holtzmann) thymic tissue grafts has no ready explanation. The syndrome following neonatal thymectomy in *C3H* mice is rapid and acute, whereas signs of deficiencies in the $(BL \times C3H)F_1$ mice used here appear later and have a more chronic form. It is likely that the residuum of potentially competent precursor lymphoid cells in our F_1 mice represents a more sensitive assay technique.

WATER-SOLUBLE FACTORS WITH VITAMIN K ACTIVITY FROM PIG LIVER AND FROM *Fusiformis nigrescens*

By DR M. LEV and A. W. MILFORD

Departments of Microbiology and Immunology and Surgery, Albert Einstein College of Medicine, Yeshiva University, New York

SINCE its discovery as a blood-clotting factor by H. Dam[1], vitamin K has been accepted as a fat-soluble vitamin of the 2-methyl-1.4-naphthoquinone series which in natural forms are substituted in the 3 position with a phytyl group (in vitamin K_1) or with multiples of isopentoid (in K_2) series. These forms can be readily extracted with fat solvents from plants and from certain aerobic and anaerobic bacteria[2–4]. Recently a 2-dimethyl form of vitamin K_2 has been found in *Haemophilus parainfluenzae*[5].

Many workers have been unable chemically to detect vitamin K in animal tissues such as liver[6,7]. Those who claim to have done so, for example Martius[8], detected extremely low levels—far below those found in biological tests. The paper by Pitt and Morton[9] and the discussion of Martius's paper in a Ciba symposium[10] illustrate the considerable controversy on this subject.

Lev[11,12] reported that an organism, *Fusiformis nigrescens* (*Bacteroides melaninogenicus*), isolated from the bovine rumen, has a specific growth requirement for vitamin K. Various analogues, both natural and synthetic, of vitamin K were assayed microbiologically and the spectrum of activity of these compounds for *F. nigrescens* and animals was found to be close enough to warrant the use of this organism for the assay of vitamin K. Gibbons *et al.*[13] later worked with strains of this organism from the human mouth and studied their vitamin K requirements. Recently they demonstrated[14] the usefulness of the microbiological assay in detecting vitamin K synthesis by *Serratia marcescens*. Martius and Leuzinger[15] using the vitamin K requiring strain of *F. nigrescens* have shown that, when supplied with methionine, the bacterium causes the methylation of 1,4-naphthoquinone to make menadione. The menadione is further converted to vitamin K_2 (45) by the bacterium. Glick, Zilliken and Gyorgy[16] have described a strain of *Lactobacillus bifidus* the growth of which is stimulated by vitamin K. A mutant of *Haemophilus parainfluenzae* has been isolated[17] which requires menadione under certain microaerophilic conditions; the narrow range of specificity of the requirement makes this organism unsuitable for vitamin K assay work.

Although vitamin K activity in the liver has been known for some time on the basis of biological assay in animals on vitamin K-deficient diets[18] the chemical nature of the vitamin in the liver has not been determined. Experiments with a liver faction showing vitamin K activity are described here.

(1) *Liver extracts.* Fresh pig liver from an abattoir was used. For satisfactory results, it was found essential to use liver which was fresh and kept on ice during transportation.

Water-soluble factor was obtained by a procedure summarized in Fig. 1: 100 g liver was emulsified in a Waring blender under an atmosphere of nitrogen with 400 ml. of 0·1 M phosphate buffer, *p*H 8·0, heated at 60° C for 10 min and centrifuged at 8,000*g* for 30 min. The red-coloured fluid thus obtained contained the water-soluble liver factor (LF); when used directly for assay, it was sterilized by filtration through a membrane of pore size 0·45μ.

Lipid extractions for detection of vitamin K in liver (or in bacterial cells) were made by first disrupting the cells (2–3 g dry weight) in a French pressure cell and

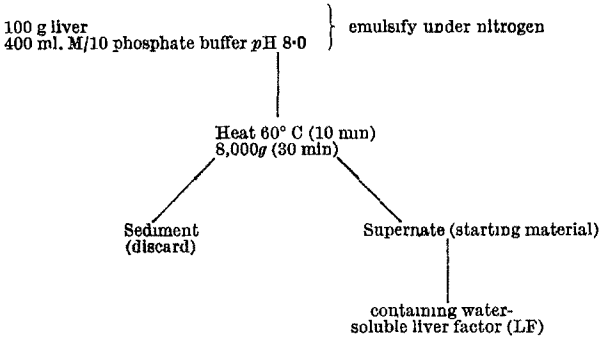

Fig. 1. Extraction procedure for liver factor

lyophilizing the product. The lyophilized samples were then extracted with greater than 100 × volume of dry ethyl ether for 24 h at 5° C. The ether extract was decanted, filtered and taken to dryness under reduced pressure. The residue was taken up in a small volume of ethanol and the solution reduced under vacuum to a final volume of 1 ml. A 1 in 10 dilution of the ethanol extract in distilled water was made and the resulting emulsion used for microbiological assay.

(2) *Bacterial cells.* *F. nigrescens* was cultured for 2 days in trypticase-yeast extract broth (see later) containing 0·1 μg/ml. vitamin K_1, after which the cells were collected. Vitamin K-deficient cells were obtained from 10 l. of culture in trypticase-yeast extract medium which was not supplemented with vitamin K but which was inoculated with 6 ml. of a 48-h culture of *F. nigrescens* grown in trypticase blood broth containing vitamin K_1 (see later); the cells were gathered after 2 days and in some instances 4 days incubation. For all large volume cultures vessels were aseptically filled to the top with medium to exclude oxygen.

(3) *Assay.* The basal medium for *F. nigrescens* consisted of 3 g trypticase (BBL), 0·3 g yeast extract (Difco), 0·3 g and 0·5 g sodium chloride (per 100 ml.); *p*H 7·0. This was tubed in 10-ml. amounts, sterilized by autoclaving and, immediately prior to inoculation, heated in boiling water for 15 min and cooled. For stock culture maintenance, 0·1 ml. of a 1/200 dilution of horse red blood cells in sterile distilled water and 0·1 μg vitamin K_1 were added to each 10 ml. of medium. For assays of growth factor from liver, an inoculum of 0·1 ml. of a 1/10 dilution of a 48-h culture of *F. nigrescens* was used for each 10 ml. medium. Assay cultures were incubated anaerobically in Fildes-McIntosh jars (A. Gallenkamp and Co., Ltd., London) for 2 days under an atmosphere of 95 per cent hydrogen and 5 per cent carbon dioxide, at 37° C.

Because most contaminating micro-organisms are aerobic and many aerobic bacteria synthesize vitamin K_2, all assay tubes showing growth were routinely subcultured in trypticase broth and incubated aerobically for 2 days. The rare flask or tube of medium showing growth aerobically was excluded.

(4) *Results.* Good growth of *F. nigrescens* occurred after addition of 1·0, 0·5, 0·25 and 0·1 ml. of the watery liver extract to the assay system, Inoculated but unsupplemented assay medium failed to support growth. Growth was ascertained by turbidimetric measurement relative to control tubes and by microscopic examination. *F. nigrescens* could be cultured serially in broth containing the water-soluble liver factor. A precipitate was formed in addition after 3 days incubation in all tubes, including the uninoculated control tubes.

Vitamin K_1 and liver factor were compared microbiologically. The minimal amount of vitamin K_1 giving a response was found to be 0·025 μg/10 ml. tube. Since 0·1 ml. of extract containing liver factor give a similar growth response, the extract had the activity equivalent of about 0·25 μg of vitamin K_1 per ml.; thus, 1 g of fresh pig liver contains a soluble growth factor for *F. nigrescens* equivalent in activity to 1 μg vitamin K_1. It is of interest to note that Dam and Schoenheyder[19] found fresh hog liver contained the equivalent of 0·6–0·9 μg of menadione per gram by chick assay and Green *et al.*[18] found beef liver contained 0·71 μg/mg of menadione activity by chick assay.

The heat stability of liver factor was examined by heating aqueous extracts at 60° C for 10 min, 80° C for 10 min and 120° C for 15 min. The first condition produced a heavy precipitate, but essentially undiminished activity remained in the red-coloured supernatant. Preliminary 'pasteurization' at 60° for 10 min, therefore, was adopted as a routine final step in the extraction procedure (see sections 1–3). Heating at 80° C for 10 min diminished activity by more than 50 per cent; autoclaving for 15 min abolished the activity.

Extracts containing liver factor were dialysed against distilled water (100 × volume of extract) for 18–24 h. The dialysate and remaining fraction were brought to original volumes under reduced pressure, sterilized by filtration and assayed. The active component did not penetrate the dialysis membrane.

Attempts were made to purify liver factor by ammonium sulphate fractionation. Aqueous liver extracts were first defatted with ether, and fractions successively precipitated by 20, 30, 45 and 50 per cent saturated salt were prepared at 5° C; together with the supernate these were dialysed against 0·1 M phosphate buffer *p*H 8·0. All fractions were made up to the original volume of liver factor, sterilized by filtration and assayed microbiologically. The main activity was found to be associated with the material precipitated between 20 per cent and 30 per cent saturation. This material was used for certain experiments (see later) because it was easily sterilized by filtration. Large volumes (*c.* 1 l.) of crude extract containing liver factor were difficult to sterilize satisfactorily.

In order to gain information on the nature of the active component, portions of extracts containing liver factor were incubated individually with 0·1 per cent twice recrystallized trypsin, 0·1 per cent 'Pronase' (Calbiochem Grade *B*: 'Pronase' is a proteolytic enzyme from *Streptomyces griseus*), 0·1 per cent pancreatic lipase (Mann), 0·1 per cent twice recrystallized chymotrypsin and 0·01 per cent ribonuclease (Worthington). All solutions used were previously sterilized by membrane filtration and all enzyme-extract mixtures were incubated for 2 h at 37° C at *p*H 8·0. A comparison of the properties of liver factor with vitamin K_1, and the results of assay of the digest mixtures are summarized in Tables 1 and 2.

'Pronase' and pancreatic lipase completely abolished activity of liver factor, although in control assays these enzymes at this concentration did not diminish the growth-stimulating effect of vitamin K. Proteolytic action was found in the preparation of pancreatic lipase. Incubation with trypsin reduced the activity of liver factor; that is, growth occurred when 1·01 ml. or 0·5 ml. but not when 0·25 ml. of trypsinized extract was included in 10 ml. medium. Untreated liver factor showed growth at 0·25 and 0·1 ml. levels.

Table 1. Comparative Properties of Liver Factor and Vitamin K_1

	Liver factor	Vitamin K_1
Solubility in lipid solvents	−	+
Solubility in water	+	−
Heat stability (121° C, 15 min)	−	+
Sensitivity to certain hydrolytic enzymes	+	0
Stimulation of growth of *F. nigrescens*	+	+
Activity in blood-clotting mechanism	Not tested	+

Table 2 Effect of Enzymes on Growth-stimulating Property for *F. nigrescens* of Liver Factor

Enzymes	Activity after digestion
'Pronase'	0
Pancreatic lipase	0
Trypsin	Reduced *c.* 50 per cent
Chymotrypsin	Undiminished
Ribonuclease	,,

Chymotrypsin had no apparent effect on the activity of liver factor although treatment of liver factor with it prevented formation of precipitate in the uninoculated controls (as did trypsin treatment). Ribonuclease had no effect on the growth-stimulating effect of liver factor. The inclusion of either trypsin or pronase in levels greater than 0·1 per cent were inhibitory for *F. nigrescens*.

The foregoing experiments suggest that liver factor is a protein, possibly a protein containing vitamin K bound in some manner. Several attempts were made to dissociate vitamin K from liver factor. As mentioned previously, when 250 ml. of liver factor was lyophilized and extracted with ether (5° C, 24 h) no growth stimulatory activity for *F. nigrescens* was found in the ether extract; full activity remained in the extracted water-soluble fraction. Moreover, after incubation of aqueous extract containing liver factor with trypsin, pronase or pancreatic lipase, no activity was found in the ether-soluble fractions. Finally, liver factor was incubated with a cell-free extract of *F. nigrescens*; no active ether-soluble form was detected after this treatment. Thus all attempts to dissociate a lipid form of vitamin K from extracts containing liver factor have so far been unsuccessful.

It seemed of interest to determine whether *F. nigrescens* grown with vitamin K is able to produce a water-soluble protein resembling that from liver in capacity to replace vitamin K as a growth factor for *F. nigrescens*. Experiments were made using cells (2·43 g dry weight) from a 2-day growth in 3 l. of vitamin K-supplemented medium. The cells were broken in a French pressure cell, lyophilized, ether extracted continuously in a Soxhlet apparatus for 18 h, and resuspended in distilled water to their original volume. After 'pasteurizing' at 60° C for 10 min and centrifuging, the resulting turbid grey solution was sterilized by membrane filtration; it was highly active for *F. nigrescens*.

Vitamin K-deficient cells were similarly prepared by inoculating 10 l. of unsupplemented medium. The yield of dry cells was 0·34 g and these were treated in the same way as the cells grown with vitamin K. The lyophilized and ether-extracted deficient cells were made up to the same concentration as the supplemented cells, that is, 0·034 g/ml. After pasteurizing, the supernate from the deficient cells yielded a straw-coloured clear solution quite distinct from the grey turbid extract of the supplemented cells. The extract of the deficient cells was not active in the microbiological assay.

It was of interest to determine in what form vitamin K activity was represented in cells of *F. nigrescens* grown with vitamin K_1, without vitamin K (that is, deficient), and with liver factor. Cells from 3 l. of medium containing 0·1 μg K_1 per ml., from 10 l. without K, and from 10 l. of culture grown with a fraction of liver extract precipitated between 20 and 30 per cent ammonium sulphate equivalent to 100 ml. of liver extract were used in this experiment. The cells were broken, ether extracted as already described and assayed. Activity associated with ether-soluble material was detected only in the case of cells grown with vitamin K and, although a smaller weight of deficient cells (1 g) was used than of K_1-grown cells (2·6 g) and liver factor-grown cells (3·25 g), this does not account for the lack of activity. (The liver factor cell weight is not meaningful as a precipitate is formed in the medium and is collected with the cells during centrifugation.) Activity associated with ether-insoluble material was produced by cells grown either with vitamin K or with liver factor but were not detected in deficient cells. The grey-coloured extract from the K-grown cells was highly active while the material from the liver factor-grown cells was similar to that from K-grown cells and was active although considerably less so than the K material. These results are summarized in Table 3.

The pig liver factor described here is radically different from classical vitamin K. A similar factor has been found in rat and chick liver too, suggesting a wide distribution.

Table 3. VITAMIN K ACTIVITY (MICROBIOLOGICAL ASSAY)

Cells	Ether extractable	Water extractable
K grown	+ +	+ + + +
Deficient	−	−
LF grown	−	+ +

The pig liver factor is water soluble, heat labile and sensitive to certain hydrolytic enzymes. This may explain why it has not been possible to detect vitamin K chemically in tissue such as liver although K activity is readily assayed by the use of vitamin K-deficient animals. This liver factor may be the active form of vitamin K in animals—possibly a conjugated form of vitamin K. Although preliminary experiments failed to detect vitamin K in ether extracts of liver factor or of enzyme-treated liver factor, possibly more refined techniques may be successful.

There is an interesting relationship between substances with the microbiological assay properties of vitamin K in pig liver and in *F. nigrescens*. In liver, vitamin K microbiological activity appears to exist entirely in the protein form. In *F. nigrescens* substitution of liver factor for vitamin K in culture medium stimulated the synthesis of a water-extractable factor but not of an ether-soluble factor. A factor resembling liver factor has been found in cells of *F. nigrescens* grown with vitamin K_1, but it is usually possible to extract a lipid form of vitamin K from these cells also. When vitamin K-deficient cells of *F. nigrescens* were tested, no liver factor-like material was detected, and no lipid-soluble form of vitamin K found. The liver factor-like protein from *F nigrescens* is very active for the micro-organism and it is possible that some degree of specificity exists, that is to say, that the factor from liver may be more active for animals than for the micro-organism.

These proteinaceous substances with vitamin K activity for *F. nigrescens* may be stages in the metabolic pathway of vitamin K_1. It is interesting that the only known function of vitamin K in animals is in the synthesis of specific proteins, prothrombin, factors VII and X.

Tests of the ability of liver factor to restore the blood-clotting picture of animals are in progress. Since it is difficult to deplete animals such as rats of vitamin K due to the contribution of the bacterial flora, experiments have been instituted to test the vitamin K activity of liver factor using germ-free rats fed a vitamin K-depleted diet. The possibility exists that liver factor-like substances may be present also in tissues other than liver since the feeding of irradiated beef has resulted in vitamin K deficiency.

We thank Drs. E. J. Hehre and S. M. Levenson for much helpful criticism and discussion. This work was supported by a grant to the Albert Einstein College of Medicine by the National Institutes of Health, Bethesda, Maryland.

PERITONEAL FLUID VOLUME AND THE OESTRUS CYCLE IN MICE

By Dr. F. HARTVEIT and Dr. S. THUNOLD
The Gade Institute, Department of Pathology, University of Bergen, Norway

IT has recently been reported that the amount of fluid found in the peritoneal cavity following the intraperitoneal injection of saline is greater in female mice than in males[1]. It has since been found that the peritoneal fluid volume is greater in normal female mice than in normal males[2]. At the same time the scatter in peritoneal fluid volume is great, particularly in the females.

As changes in body water related to the female sex cycle are well documented in women, these observations suggested to one of us (F. H.) that the variations in peritoneal fluid volume in female mice might be related to the oestrus cycle. As the volume of peritoneal fluid originally present may be of importance in assessing the reaction to substances injected intraperitoneally, and not least in determining the degree of scatter in the values obtained within a group of females, the following investigation was set up to test this hypothesis.

Mice of the closed colony kept at this Institute[3] were used. A group of ten males (mean weight $\pm$ *S.D.* = 30·1 $\pm$ 2·2 g) and a group of thirty virgin females (mean weight $\pm$ *S.D.* = 25·0 $\pm$ 1·9 g) of similar age were set up.

All the mice were killed by cervical dislocation. The peritoneal cavity was opened, the fluid removed and its volume measured directly.

In the females, vaginal smears were taken using the lavage method. Short Pasteur pipettes with rounded ends were used. One drop of saline was taken up in the pipette which was then inserted into the vagina. The fluid was sucked in and out three times. The character of the fluid was recorded. It was then placed on a slide and spread out with the pipette. The smear was air-dried and stained with Leishman's stain. The vagina was removed and fixed in formalin. Sections were made and stained with haematoxylin and eosin and with alcian blue–periodic acid–Schiff. The stage in the oestrus cycle was determined according to a modification of the criteria outlined by Snell[4], being briefly as follows:

Prooestrus smears were characterized by a smear containing few cells, mainly epithelial, some of which were cornified, and a few leucocytes; oestrus by a more cellular smear containing mainly cornified epithelial cells; metoestrus by a very cellular smear made up of cornified cells and dioestrus by a cellular smear consisting mainly of leucocytes and some epithelial cells.

Prooestrus sections were characterized by an epithelium with many layers, the outer four nucleated and a distinct stratum granulosum. Oestrus was characterized by about 12 nucleated layers covered by a cornified layer. In metoestrus the cornified layer had delaminated and leucocytes were present. In dioestrus only a few epithelial cell layers were present and these were infiltrated by leucocytes.

For both smears and sections prooestrus, oestrus, metoestrus and dioestrus were recorded as stage 4, 3, 2 and 1, respectively.

The amount of mucus in the vaginal sections was judged from the alcian blue–periodic acid–Schiff stained sections, and recorded as present in more than the top three layers of the epithelium, present in the top two or three layers, present in the top layer, or absent. These different amounts of mucus were recorded as 4, 3, 2 and 1, respectively.

The peritoneal fluid volume in both male and female mice is detailed in Fig. 1, which shows the sex difference and the scatter in the values. The mean peritoneal fluid volume ($\pm$ *S.D.*) was greater in the female mice (0·10 $\pm$ 0·05 ml.) than in the males (0·02 $\pm$ 0·01 ml.). This difference is statistically significant ($P < 0·05$). The standard deviation in the female values was five times as great as that in the males.

The vaginal lavage fluid was found, macroscopically, to be either cloudy (containing fine particulate matter; type 1), or flocculent (containing coarse particulate matter; type 2) or else the specimen consisted mainly of mucus (type 3). It was found that eleven of the specimens were cloudy, four flocculent and fifteen consisted of mucus.

Fig. 2 shows the results of correlating the macroscopic appearance of the lavage specimen to the peritoneal fluid volume. The positive correlation between these two characteristics is statistically significant ($P < 0·001$), less fluid being present in the peritoneal cavity when the lavage specimen was cloudy than when mucus was present. The flocculent specimens lay between these two extremes.

The quality of the vaginal smears containing mucus was not all that could be desired, but air-drying proved

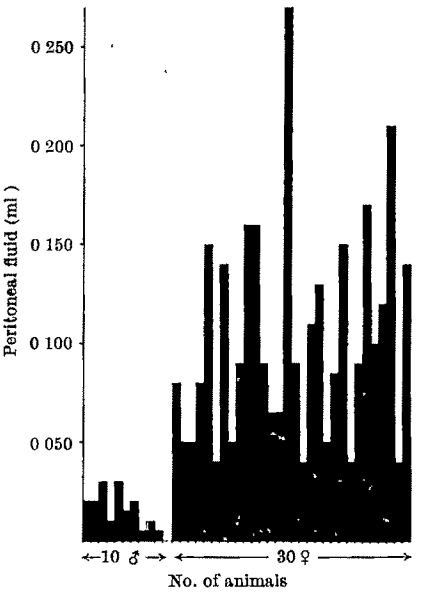

Fig. 1. The peritoneal fluid volume in male and female mice

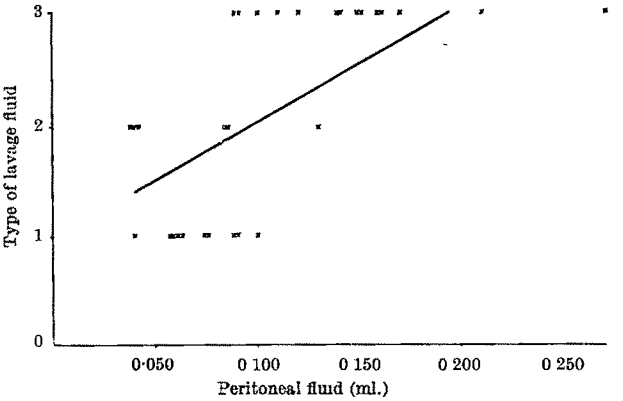

Fig 2. The correlation between the peritoneal fluid volume and the macroscopical appearance of the vaginal lavage fluid (see text)

otherwise satisfactory. In the sections stained with haematoxylin and eosin the stratum granulosum was at times difficult to define. It was, however, clear in the alcian blue–periodic acid–Schiff sections, and these were therefore used for the final classification. In some specimens the vaginal epithelium presented a combination of two adjacent stages and occasionally different stages were seen in different sections from the same vagina. In such borderline cases the predominant stage was recorded. The result of these classifications is shown in Table 1.

Table 1. NUMBER OF MICE IN DIFFERENT STAGES OF THE OESTRUS CYCLE AS DETERMINED BY VAGINAL SMEARS AND HISTOLOGICAL SECTIONS OF THE VAGINA

Stage	Smears	Sections
Proœstrus	15	12
Oestrus	2	4
Metoestrus	5	4
Dioestrus	8	10
Total	30	30

Fig. 3 shows the results of correlating the stage of the oestrus cycle as judged from smears to the peritoneal fluid volume. The positive correlation between these two characteristics is statistically significant ($P < 0{\cdot}001$), least fluid being present in dioestrus and most in proœstrus.

Fig. 4 shows the correlation between the stage of the oestrus cycle judged from the sections and the peritoneal fluid volume. A statistically significant positive correlation was found here also ($P < 0{\cdot}01$), though the correlation was not so high as that obtained with the smears.

Fig. 5 shows the correlation between the amount of mucus present in the vaginal sections and the peritoneal fluid volume. Most mucus was present when the peritoneal fluid volume was highest. This positive correlation was also statistically significant ($P < 0{\cdot}01$).

Fig. 6 shows the result of correlating the macroscopical appearance of the lavage fluid to the stage of the oestrus cycle as determined from the smears. The positive correlation in this case was also significant ($P < 0{\cdot}01$), cloudy fluids being clearly related to dioestrus and the presence of mucus to proœstrus.

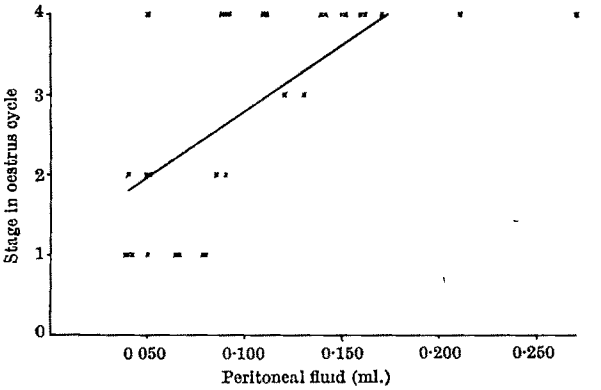

Fig. 3. The correlation between the peritoneal fluid volume and the stage of oestrus cycle judged from vaginal smears (see text)

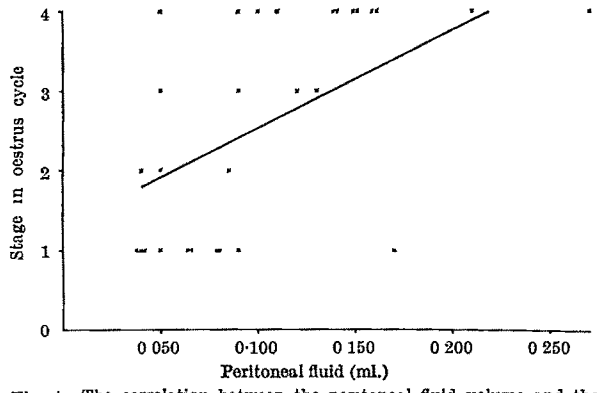

Fig. 4. The correlation between the peritoneal fluid volume and the stage of oestrus cycle judged from vaginal sections (see text)

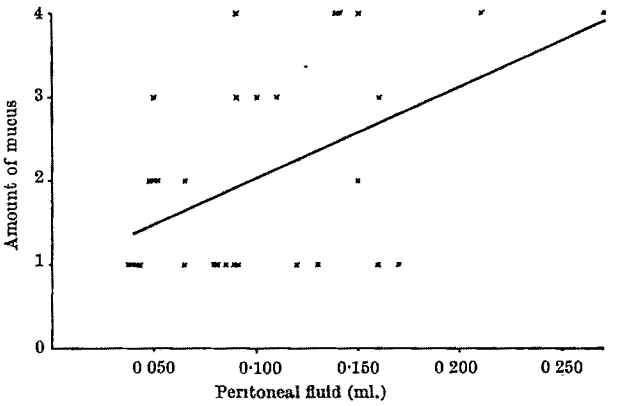

Fig. 5. The correlation between the peritoneal fluid volume and the amount of mucus present in the vaginal sections (see text)

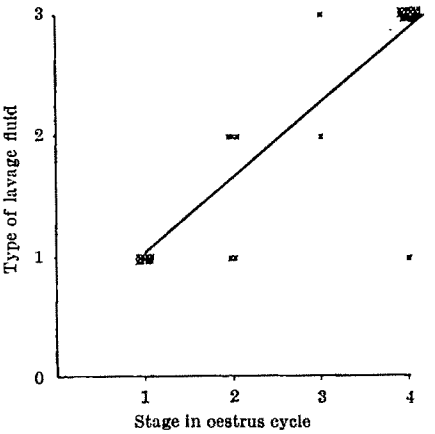

Fig. 6 The correlation between the stage of oestrus cycle judged from vaginal smears and the macroscopical appearance of the vaginal lavage fluid (see text)

The present investigation confirms our previous impression that the volume of peritoneal fluid is greater in female than in male mice of our closed colony. It also confirms that the scatter in the female values is greater than that in the males. These variations in peritoneal fluid volume in the females are clearly shown to be related to the different stages in the oestrus cycle. The correlation obtained from the vaginal smears was higher than that obtained from vaginal sections. The explanation here may be that the sections were taken from the vagina immediately after lavage had been carried out. Thus the possibility that the top layer of cells had been washed off cannot be excluded. Indeed it may be this that has accentuated the variations in histology from section to section that are normally to be expected.

The finding of a high correlation between the macroscopical appearance of the lavage fluid and the peritoneal fluid volume provides a quick and simple way of sorting a group of females into those in which the peritoneal fluid volume can be expected to be high and those in which it can be expected to be low. This may enable us to reduce the scatter in experimental results in female mice following, for example, the intraperitoneal transplantation of ascitic tumours, and thus facilitate the assessment of differences due to treatment.

The finding that the presence of mucus in the lavage fluid coincides with proœstrus in our mice may also be of practical use in breeding experiments. It is, however, at variance with data obtained from other strains in which mucus is said to be present in dioestrus smears[4]. However, the histology in this investigation, the findings of which

are in full agreement with those outlined by Snell for other strains, shows that most mucus was present when the peritoneal fluid volume was greatest, that is, in pro-oestrus. It is suggested on the basis of the present investigation that as the presence of "epithelial cells sometimes more or less filled with mucus"[4] is characteristic of prooestrus, it is more reasonable to expect mucus in the lavage fluid and in smears in prooestrus than in dioestrus, when the epithelial cells are quiescent.

The present findings therefore support the hypothesis that water retention as evidenced by an increase in peritoneal fluid volume occurs in prooestrus. It is tempting to suggest that this fluid may play its part in facilitating the transport of the ova to the oviducts when ovulation occurs in early oestrus. The mechanism of this increased fluid production may lie in the increased vascularity that accompanies the proliferative changes characteristic of prooestrus.

We thank Prof. E. Waaler for his interest in this work.

ANTI-TRANSFERRIN-DEPENDENT HAEMAGGLUTINATION IN ADULT C_3H MICE DURING INJECTIONS OF CASEIN AND IN UNTREATED SUCKLING C_3H AND *DBA*/2 MICE

By DR. P. EBBESEN
Department of Biochemistry A, University of Copenhagen, Denmark

THE attachment of serum proteins to the surface of red blood cells may be detected by use of a direct haemagglutination test (HT), based on principles outlined as early as 1908[1]. The anti-globulin test was developed in 1945 by Coombs *et al.*[2] with the purpose of detecting the presence of incomplete Rhesus antibodies on red blood cells. It has since been shown[3,4] that both gamma and non-gamma globulins may cause a positive reaction, when the test is performed with wide-spectrum antiserum produced in animals by immunization with whole serum. The work of Jandl[5] and Nelken[6] showed that the reticulocytes in adult humans, when present in large numbers, could be agglutinated with wide-spectrum antiserum, and the same was later shown to be the case in mice[7]. This agglutination was at least in part due to attachment of transferrin to the reticulocytes[8]. It was shown earlier that circulating antibodies against liver, spleen and kidney[8,9] can be demonstrated after injections of casein. In the course of investigations on the agglutinability of mouse red blood cells in an anaemia of unknown aetiology[10], the present investigation was undertaken in order to find out, using the direct HT, if the anaemia which accompanies the development of amyloidosis in casein-treated mice[11] may be caused by antibodies against their own red blood cell antigens. The possible role of reticulocytes in the positive HT in casein-treated anaemic mice was evaluated in suckling mice, in which a high percentage of reticulocytes is known to exist[12].

Twenty-six 2-month-old C_3H mice of both sexes were injected daily subcutaneously with 0·5 ml. of a 5 per cent casein solution; eleven mice were injected for 3 weeks, seven for 6 weeks and eight for 8–12 weeks. During the first 2–3 weeks of treatment and for 2–3 weeks after cessation of treatment the animals were tested every third day with a direct HT. Red blood cell and reticulocyte counts were made before treatment and after 3 and 6 weeks of treatment. The animals were autopsied at the end of the scheduled investigations. In addition, untreated C_3H and *DBA*/2 mice, five in each group, were bled at 1 day and 1, 2, 3, 4 and 5 weeks of age for HT and reticulocyte counts.

The procedure for the HT was as follows: Blood was taken from the retrobulbar venous plexus in glucose citrate. The red blood cells were washed four times with saline and made into a 5 per cent suspension in saline. One drop of this suspension was added to one drop of antiserum on a glass tile, and the tests were read macroscopically after 20 min at room temperature. The antisera used were pure rabbit mouse-gamma-globulin antiserum (batch *CS*-1498 Colorado Serum Company, Denver), diluted 1 : 50, and a wide spectrum rabbit mouse-serum antiserum diluted 1 : 7 and 1 : 50. The wide-spectrum antiserum was produced by immunization with mouse whole serum. After inactivation of complement by heating to 56° C for 40 min the antiserum was absorbed twice with two volumes of packed washed normal mouse red blood cells, first 1 h at 37° C and then overnight at 4° C. Controls in each series of tests included the use of saline in place of antiserum and testing of both positive and negative reacting cells. The positive cells were prepared by coating normal red cells with isoimmune sera as described by Garfein *et al.*[7]. Isoimmune sera for coating C_3H and *DBA*/2 red blood cells were obtained by immunizing *CBA* and $C_{57}Bl$ mice with C_3H and *DBA*/2 spleen cells. *CBA* and *DBA*/2 red cells incubated with non-immune sera served as negative cells to this latter test. Serial dilution experiments with the antisera diluted in saline from 1/1 to 1/1,024 were used to observe the prozone and to find the optimal dilutions.

Results of casein injections. All twenty-six adult mice showed a negative HT when tested with the pure anti-mouse-gamma-globulin antiserum irrespective of the duration of the casein treatment, whereas the HT performed with wide-spectrum antiserum became positive during the injection period. Thirteen of fourteen mice showed a positive HT after 14 days of treatment (Table 1) and the reaction remained positive so long as the injections were continued. Regardless of the duration of treatment the agglutinability disappeared about 2–3 weeks after the last of the casein injections (Table 2).

The number of red blood cells decreased during the casein treatment to an average of $6{\cdot}9 \pm 1{\cdot}1 \times 10^6$ with a range of $5{\cdot}2$ to $9{\cdot}2 \times 10^6$. After 8–12 weeks of casein treatment all eight mice of this group showed less than $6{\cdot}2 \times 10^6$ red cells. The average of red blood cells of thirteen untreated adult (2–4 months) C_3H mice was $9{\cdot}6 \pm 1{\cdot}0 \times 10^6$ with a range of $7{\cdot}9$ to $11{\cdot}5 \times 10^6$.

* Mean value in five mice.

Reticulocyte counts determined in fifteen animals before onset of treatment were $1·9 \pm 0·9$ per cent; this was slightly increased after 3 weeks of casein injections and was normal again after 6 weeks of treatment (Table 3). Immediate microscopic examination of red blood cells agglutinated in the antiserum usually showed half the cells in the agglutinates.

When the mice were killed, the microscopic examination revealed a slight haemosiderosis in the liver and spleen. After 8 weeks of treatment, amyloidosis occurred in the liver, spleen and kidneys in all eight mice of this group. At this time a definite atrophy of the thymic cortex was noted. The peripheral lymph nodes showed no abnormalities.

Results in suckling mice. The influence of an increased percentage of reticulocytes on the result of the HT was examined on red blood cells of untreated suckling *C₃H* and *DBA*/2 mice with the wide-spectrum antiserum. A positive HT was present in the neonatal period so long as the percentage of reticulocytes was in the range of 5–10, that is, in the first 3 weeks of life (Table 4). The mothers of these mice showed negative HT.

Inhibition tests were performed to identify the antigen on the red blood cells with which the antibody in the wide spectrum antiserum was reacting. It was found that the agglutination of red cells from casein-treated as well as from suckling mice was only slightly inhibited by the addition of one drop of 1 per cent solution of mouse gamma globulin to one drop of antiserum diluted 1 : 7 before the test cells were added, whereas the agglutination of isoimmune-serum-coated red cells was clearly inhibited under these circumstances. This gamma globulin solution also inhibited a positive Coombs test in seven mice of the *NZB* strain, which is known to develop a Coombs positive anaemia spontaneously[13]. The results of the inhibition tests made a sensitization of the red blood cells of the casein-treated and suckling mice with ordinary warm gamma auto-antibodies improbable. Therefore, the possible presence of cold agglutinins was investigated. Tests for complete cold agglutinins were negative, and the HT was not potentiated at 4° C. HT carried out on blood collected into 37° C glucose citrate to avoid sensitization with incomplete cold antibodies gave the same results as when carried out at room temperature. Since no evidence could be found for cold agglutinins, further inhibition tests were made. The addition to the wide-spectrum antiserum of an equal quantity of a 5 per cent casein suspension in saline, of a 1 per cent solution of mouse gamma-*A* myeloma globulin[14], of a 1 per cent myeloma macroglobulin[15] or of undiluted guinea-pig serum as a source of complement did not show more than a slight inhibitory effect on the HT. The addition, however, of an equal quantity of a 1 per cent solution of mouse transferrin inhibited the positive HT of the red cells from casein-treated and suckling mice but had no effect on isoimmune-serum-coated red cells.

The transferrin and the gamma globulin used in inhibition tests were isolated by DEAE-cellulose column chromatography and the mixture separated by 1·6 M ammonium sulphate. The purity of the various serum proteins was examined in agar immune diffusion experiments using the technique of Wadsworth[16]. The transferrin solution was found to contain a slight contamination of gamma globulin and the gamma globulin solution a slight contamination of transferrin. The pure mouse-gamma-globulin antiserum reacted only with gamma globulin, while the wide-spectrum antiserum reacted with several mouse serum proteins, including transferrin. After absorption with red blood cells from casein-treated or suckling mice the wide-spectrum antiserum no longer reacted with transferrin, but still reacted with gamma globulin. The results of both the absorption and the inhibition tests point toward transferrin as the substance coating the red cells. The wide-spectrum antiserum gave no precipitation lines in agar gel diffusion experiments with casein, which would appear to be evidence against casein as the source of the antigen in the HT. Agglutination with the wide-spectrum antiserum was found to be optimal in a dilution of 1 : 7 against the red blood cells from casein-treated and suckling mice; it was, however, also marked with undiluted antiserum, confirming that the HT was not an ordinary anti-gamma globulin reaction[17].

The observed correlation between agglutination in the wide-spectrum antiserum and the high percentage of reticulocytes in the suckling period of mice is in accordance with the findings of Garfein *et al.*[7] in mice with reticulocytosis caused by X-ray treatment. It is unlikely that the agglutination of red blood cells from casein-treated mice is caused by the reticulocytes, since their percentage in the majority of these mice was normal, and the agglutinates were found to contain considerably more red cells than the reticulocytes. The antigen coating the red cells from casein-treated mice seems to be identical with the one responsible for haemagglutination of the reticulocyte-rich blood from suckling mice, since the HT was negative in both cases, when carried out with antiserum absorbed with either type of cells. Since anti-transferrin is known to agglutinate reticulocytes[5,6] the agglutination of red cells from casein-treated mice may also be caused by coating with this protein. The lack of anti-transferrin activity in the absorbed sera and the inhibitory effect of transferrin on the HT also point toward transferrin as the protein causing the haemagglutination by reaction with the anti-transferrin in the wide-spectrum antiserum. The high sensitivity of the HT[18] does, however, leave open the possibility that the factor acting in this test is not made evident by the less sensitive agar diffusion method. Coating the red cells with bovine transferrin contained in the casein solution and thereby causing the agglutination reaction is unlikely judging from the weak inhibitory effect of casein on the HT and the lack of precipitation in the agar gel diffusion experiments. The reason for the observed adsorption of transferrin to the red cells after casein treatment is unexplained. The present article, however, supports the view that the positive HT in casein-treated mice is due to transferrin.

Red blood cells from adult *C₃H* mice during injections of casein and from suckling untreated *C₃H* and *DBA*/2 mice were found to be agglutinable by a rabbit wide-spectrum mouse-serum-antiserum, but not by a pure mouse-gamma-globulin antiserum. This haemagglutination was inhibited by addition of mouse transferrin, but not by addition of mouse gamma globulin to the antiserum, and in the casein-treated mice it was found to be independent of the number of reticulocytes.

This work was supported in part by a grant from the Carl og Ellen Hertzs Legat til Dansk Læge og Naturvidenskab. I thank Dr. Ragna Rask-Nielsen for discussions and valuable help with the manuscript, Dr. Hans Flodgård

for the mouse serum proteins and Dr. Hans Wigzell for his gift of the pure rabbit mouse-gamma-globulin antiserum.

DEPENDENCE OF SYNAPTIC TRANSMISSION ON PROTEIN METABOLISM OF NERVE CELLS: A POSSIBLE ELECTROKINETIC MECHANISM OF LEARNING?

By DR. RAFAEL ELUL*

Space Biology Laboratory, Brain Research Institute, and Department of Anatomy, University of California, Los Angeles, and the Pasadena Foundation for Medical Research, Pasadena, California

BY analogy with the mechanism of the genetic code, the suggestion has frequently been made that nucleic acids of brain tissue may be the repositories of the permanent trace of memory. According to this hypothesis, learning is accompanied by an altered metabolism of DNA and RNA which, in turn, affects the general metabolism of the brain[1]. A specific aspect of the hypothesis, for which considerable experimental evidence has been gathered, is the correlation with learning of changes in protein metabolism of the brain[2–4]. Thus, for example, it was found that learning is made easier after administration of exogenous RNA[5] and, conversely, that learning is impaired by substances interfering with protein metabolism[6–8]. However, such experiments provide no clue as to how metabolic processes may affect the elaboration of information in the nervous system[3].

It is known that information is encoded in sensory receptors as trains of nervous impulses, the frequency of which is modulated by oncoming stimuli[9,10]. These impulses converge on neurones in higher centres only after having been transmitted through several relay stations. Because each relay involves synaptic transmission, which may or may not activate the next neurone in the chain, a profound modification in the pattern of response may follow even a modest increase or decrease in efficacy of these synapses. For this reason it is generally supposed that a modification of the response to synaptically transmitted impulses must be an important step in learning. If changes in protein metabolism are indeed related to memory, it must be expected that modification of DNA and RNA structure will be coupled with changes in synaptic activity, but there are no experimental findings reported to corroborate this postulate.

This article reports some observations on electrokinetic displacement of nerve cells and proposes a mechanism whereby a regulatory influence on synaptic transmission may be exerted by movement with such an origin. It is also shown that changes in DNA and RNA structure can be expected to modulate the electrokinetic effect on the synapse, and the mechanism proposed here may thus provide a link between the neurochemical and electrophysiological aspects of learning. It should be clear that the hypothesis that DNA in brain cells may become imprinted by experience is not considered here from a critical point of view, and the reader is referred to the reviews cited[3–5] for an evaluation of the experimental evidence. Instead, with imprinting as a starting point, the present article is concerned with tentatively providing a read-out mechanism by which imprinting might influence nervous activity.

Electrokinetic Displacement in the Synapse

The displacement of nerve cells in a focal electric field has recently been demonstrated in tissue-culture experiments[11,12]. A localized electric field was established by passing current from a micropipette placed near a cell. The resulting movement is apparently related to the extensively studied electrophoretic migration of cells in a uniform electric field[13,14], and results from the interaction of the field with a polarized ionic layer around the cell surface[15]. Besides the study of the displacement of the entire cell, however, the use of a focal field also makes possible an exploration of the electrokinetic behaviour of small segments of the cell membrane. Of particular interest is the situation in which cultured cells have become attached to the walls of the culture chamber and to one another, and are therefore unable to migrate under influence of the field. As shown in Fig. 1, under these conditions the electrokinetic force can produce a local deformation of the cell membrane. The effect of the electric field may be seen even more clearly with isolated cells (Fig. 2). (Photomicrographs can unfortunately provide only a static representation of the effect; a ciné film has, however, been prepared in which the development and time-course of the electrokinetic movement may be observed[62].) Passage of current out of the electrode (that is, electrode tip positive in respect to surface of the cell) usually causes attraction, while current flowing into the electrode results in movement of the membrane in the other direction[11]. The current necessary to cause this effect varies from 5×10^{-7} to 5×10^{-6} amp, and because the electrode is 5–10μ away from the nearest point of the cell, the current density at the surface of the cell may be calculated as 4×10^{-10}–$1{\cdot}7 \times 10^{-7}$ amp/μ^2 (ref. 11). A direct measure is thus available of the current density required to deform the membrane of intact living cells.

Although this effect is not limited to nerve cells (Fig. 2)[11,12], it seems that synapses between neurones or between neurones and muscle cells are the only places at which a current of such a density is generated in most living organisms. (The exceptions are some electric fish.) After the release of transmitter substance from the presynaptic terminal, the conductance of the subsynaptic terminal is briefly increased about 100 times[16]. Since the interior of the cell is negative with respect to the outside, current flows into the cell through the conducting region of the sub-synaptic membrane. Direct measure-

ments on spinal motoneurones have revealed a synaptic current of 2×10^{-8}–$1{\cdot}5 \times 10^{-7}$ amp[17,18]; in the neuromuscular junction the current intensity has been estimated at $1–3 \times 10^{-6}$ amp[19–21]. A low-resistance path for the flow of this current is available only at the fraction of the cell surface activated by transmitter substance, and a remarkably high current density across the synapse is therefore attained. From the data given by Eccles and Jaeger[20], the current density at the neuromuscular junction can be calculated as 3×10^{-10} amp/μ^2; the current density estimated for motoneurone synapses is even a little higher[22].

From these estimates it would appear that the current density during normal synaptic activity approaches that required for the displacement of cells in tissue culture, and an analogous displacement due to the flow of synaptic current is therefore postulated. The duration of the synaptic current (1–2 msec)[16] is also comparable with the 3-msec duration of the pulses used in the tissue culture experiments. Admittedly, the estimates of current density at the synapse may be too high because of the absence of direct experimental data on the area of membrane involved in synaptic activity, but the measurements of current required for this displacement of cells in tissue culture should also be regarded as an upper limit because of the necessarily limited sensitivity of this optical viewing system (2–3μ). Indeed, because of the linear relationship between current density and displacement[11], even if the density of the synaptic current is smaller than the aforementioned by two orders of magnitude, a displacement of several hundred Å may still reasonably be expected during synaptic activity.

These considerations permit a consideration of electrokinetic displacement within the synapse. Electrokinetic displacement results from interaction of electric field with the polarized ionic envelope formed by adsorption around any organic or inorganic surface placed in an electrolyte solution[15,23]. In excitatory synapses, current drawn to the sub-synaptic membrane from the extracellular space interacts with the ionic envelope of the presynaptic component of the synapse as it flows through the synaptic cleft. So far as the presynaptic component is concerned, the situation is analogous to that when a negative electrode is placed in its vicinity; it should therefore be displaced away from the sub-synaptic element, thus increasing the width of the synaptic cleft. The synaptic cleft is quite narrow (100–500 Å (ref. 24)), but still far thicker than the ionic envelope responsible for electrokinetic movement which, for physiological ion concentrations, is estimated at 5–10 Å (refs. 25 and 26). Extrapolation of the findings on electrokinetic movement in tissue culture should therefore be valid even for this comparatively narrow space.

Electrode tip slighly out of focus (arrow); current pulses (3 msec, 30/sec) passed out of electrode in *B*. Current intensity 1×10^{-6} amp, electrode tip positive. Calibration, 50μ

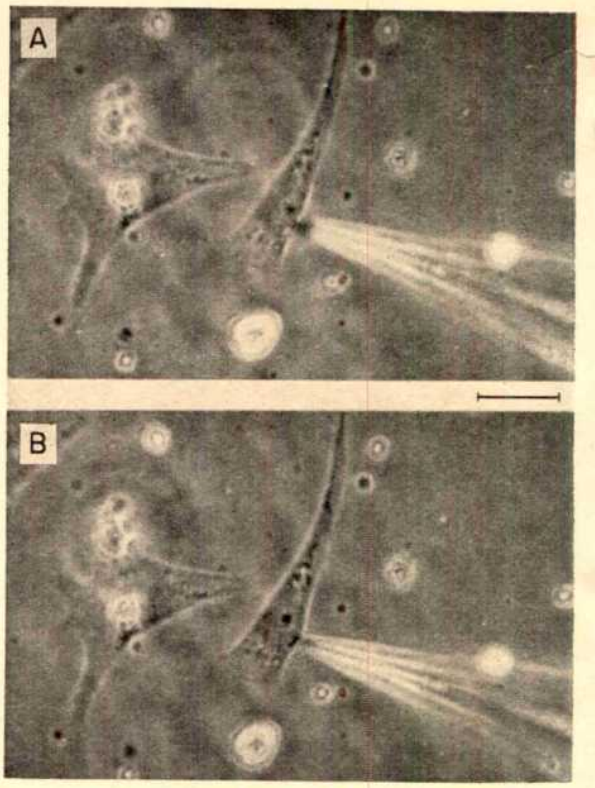

Fig. 2. Deformation of fibroblast membrane by a focal electric field. Seven-day rat, cerebellum culture, fifteenth day. Fibroblast shown has migrated from main explant and is now attached to floor of the chamber. *A*, Control photograph. *B*, Photograph taken during passage of current pulses as in Fig. 1*B*, electrode tip positive, current intensity 5×10^{-4} amp. Phase contrast. Calibration, 50μ

With regard to the sub-synaptic element, the situation is more complex: the effect of current flow is similar to that of a positive electrode, tending to constrict the synaptic cleft, and thus counteracting the movement of the pre-synaptic element. However, because the electrokinetic force is diminished in conducting, as compared with insulating, particles[27,28], the displacement of the sub-synaptic element, through which flows the synaptic current, will be far smaller than that of the non-conducting pre-synaptic membrane. It has been suggested that activity of the synapse might give rise to osmotic pressure across the sub-synaptic membrane[22], but this force would not be in the direction required to compensate for electrokinetic displacement of the presynaptic ending, nor is it very probable that its magnitude would be similar.

For these reasons, a net increase in width of the synaptic cleft can be expected in excitatory synapses; in inhibitory synapses, where the current flow is opposite, the synaptic cleft should become narrower. Even if the reaction to electric field of the specialized synaptic surfaces differs from that of non-synaptic neurone membrane, flow of synaptic current should still cause movement, except that the width of the cleft may perhaps decrease where it was expected to increase and vice versa. For the argu-

ments presented here, however, the direction or magnitude of the change in the synaptic cleft is irrelevant; the only assumption required is that the width of the synaptic cleft is altered during synaptic activity.

Electrokinetic Displacement and Synaptic Efficacy

Operation of the synapse is critically dependent on the dimensions of the synaptic cleft. According to the analysis reported by Eccles and Jaeger[20], two opposing factors are at play: stricture of the cleft should reduce the distance of diffusion of the released transmitter, thus allowing additional transmitter to reach the sub-synaptic membrane and to augment the synaptic potential; on the other hand, stricture of the cleft should increase the impedance to flow of synaptic current of the extracellular path, resulting in reduction of the postsynaptic potential. Although information on the relative importance of each of these factors in various synapses is not as yet available, theoretical reasoning indicates that the net effect of a given change in width of the synaptic cleft might significantly differ in synapses of 1 and 10μ diameter[20]. It is likely, therefore, that electrokinetic effects will at least be present in synapses of some types.

It might be argued that the synaptic potential will be well under way before the beginning of the electrokinetic movement, which is due to the flow of synaptic current; thus the potential cannot be much affected by the movement. This criticism is certainly valid for an isolated synaptic event but, as already mentioned, messages in the nervous system are transmitted as trains of closely spaced impulses, at a rate close to that used in our tissue-culture experiments (30/sec). Because a sustained displacement without relaxation was found in tissue culture at this repetition rate, it is likely in the synapse also that complete recovery of the cleft from preceding deformation would not take place before the onset of the next impulse. Electrokinetic deformation of the synapse would thus influence not only the flow of synaptic current, but also diffusion of the transmitter generating subsequent synaptic events. Although further consideration shows that this process must tend towards an equilibrium, because excessive stricture of the synaptic cleft depresses the current and thus also proportionately diminishes the electrokinetic force, the mechanism is important in so far that it allows simultaneous control by the electrokinetic effect of transmitter diffusion as well as synaptic current, both of which determine the amplitude of the postsynaptic potential, and thus also triggering of spikes.

Protein Metabolism and Electrokinetic Displacement

The electrokinetic effect has been discussed up to now solely as a function of density of the current. There are, however, several other factors which also determine the extent of electrokinetic movement, and which must be considered in relation to its effect on the synapse. These factors explicitly appear in the equation of electrophoretic velocity[15]:

$$\text{electrophoretic velocity} = \frac{\varepsilon\zeta E}{\eta} A$$

from which displacement may be found as the product of velocity and duration of the current. The intensity of the electric field E essentially is a function of the current density[29] (see also ref. 11) which has already been considered; A is a constant for any given surface configuration[14,15,23]; the viscosity η is also generally assumed to be constant, although it may increase when the width of the synaptic cleft falls below 100 Å (ref. 30) and could thus appreciably attenuate the electrokinetic effect; the dielectric constant ε is determined by physical properties of the extracellular fluid and may also be treated in the present context as a constant.

On the other hand, the electrokinetic potential ζ, known also as zeta potential, varies markedly with changes in protein metabolism. The zeta potential is an expression of the preferential adsorption from the solution of particular polar groups[15,23], and obviously the chemical nature of the surface determines its affinity for specific ions, and the quantity of ions adsorbed. Since cellular membranes are apparently coated with protein[31], it is most probable that changes in the composition and configuration of cellular proteins exert a dominant influence on the zeta potential. It is at present believed that nucleic acids serve as a template for formation of cellular protein[32–34]; and it is easy to see that changes in DNA or in RNA might lead to alteration of the zeta potential, and thus to augmentation or reduction of the electrokinetic effect on synaptic potentials.

Learning and Electrokinetic Displacement in the Synapse

The two main premises on which is based the proposed mechanism of memory read-out can now be stated: (1) The electrokinetic force generated by synaptic current flow alters the width of the synaptic cleft during repetitive activity of the synapse. Because spike firing is determined by the amplitude of synaptic potentials, and these in turn depend on the width of the synaptic cleft, electrokinetic movement could modulate the firing of the postsynaptic neurone. (2) Modification during learning of DNA and RNA has been shown by other investigators; changes in membrane structure, which is under DNA control, can therefore be expected following learning in neurones. Such changes in pre- and post-synaptic cells would affect the magnitude of electrokinetic force, and hence also the width of the synaptic cleft and the amplitude of synaptic potentials. As a result, the effect on the postsynaptic neurone of a given synaptic input would differ from that prior to learning.

Experimental evidence in support of proposition (1). Numerous investigations have been undertaken of the displacement of isolated living cells in a uniform electric field[13,14]. The current density required is of the same order as that necessary for deformation of cell membranes by focal electric field in tissue culture[11,12]. It would seem, therefore, that the mechanism in both cases is identical—local deformation of the membrane ensues when displacement of the cell *in toto* is impeded. It may be questioned whether extrapolation of these data to cell membranes *in situ* is permissible. Experiments bearing directly on this point would encounter obvious difficulties, but some suggestive evidence is available. Thus, in the spinal ganglion of the toad and also in brain-stem of the cat, pulses of 2×10^{-8} amp and 100 msec duration delivered through a micropipette may often result in penetration of neurones close to this electrode[35,36]. Penetration of cortical neurones in the cat also is facilitated by brief pulses (5 msec, 3–5 $\times$ 10^{-8} amp), and reversal of current polarity before completing penetration may lead to withdrawal of the electrode from the cell membrane[37]. The most satisfactory interpretation for these observations is that cell membranes are either attracted or repelled from the electrode during passage of current, according to the direction of current flow.

The data presented here indicate that in normal synaptic activity the current density might be sufficient to reproduce the effect of an extraneous field on synaptic membranes; also the rate of repetition of synaptic discharge is adequate to prevent relaxation of the displaced membranes between impulses. The feasibility of such changes in the spatial relationship of the pre- and postsynaptic elements *in vivo* has already been noted: based on the electron microscope observations by Palay[38] and on Ranck's theoretical considerations[22]. However, even though the width of the synaptic cleft may change electrokinetically, it does not necessarily follow that this mechan-

ism has any functional importance. Experiments bearing directly on this question have yet to be designed and carried out, but some circumstantial evidence for electrokinetic effects in the synapse may be mentioned.

Of special interest in this context is the post-tetanic potentiation found in many synapses and in the neuromuscular junction. Since repetitive synaptic activity results in a maximal electrokinetic effect, it is tempting to suggest that such potentiation may be due, at least in part, to electrokinetic deformation of the synapse. One of the principal mechanisms invoked in relation to post-tetanic potentiation is hyperpolarization of presynaptic terminals[39], but although this mechanism plays an important part in certain synapses[16,40,41] post-tetanic potentiation is equally present in synapses which do not show it[42]; for these synapses, the possibility of electrokinetic post-tetanic potentiation cannot be rejected. Another concept which has been successfully used to explain certain features of post-tetanic potentiation is mobilization of transmitter substance[43,44], but again some observations cannot be accounted for by this postulate[45]. Another example is the effect of calcium: increase in the extracellular concentration of calcium is associated with increased synaptic current[46]; since calcium changes the configuration of proteins[47], the resulting electrokinetic force could alter the resistance of the synaptic cleft. Investigations of the effect of extraneous polarizing currents on synaptic transmission are also relevant. With a focal electric field, a slowly developing facilitation (20–120 sec time-course) was found[48,49] even when the frequency of the spontaneous miniature end plate potentials was not changed[48]. It should be borne in mind that the neuromuscular junction, which features an exceptionally wide synaptic cleft (500 Å) (ref. 24), may scarcely provide an ideal background for detection of electrokinetic displacement, because a change in width of the cleft would have a far less critical effect on transmission than in narrower synapses[20]. Indeed, results recently obtained in the cerebral cortex with focal currents were far more dramatic; changes in firing pattern of neurones were found which outlasted the current by more than 3 h (ref. 50).

Experimental evidence in support of proposition (2). Variations under various environmental conditions in the electrokinetic potential have been extensively explored[51,52]. The relationship of protein configuration to the electrokinetic potential will therefore be illustrated only briefly. The mobility of proteins, which is linearly related to their zeta potential, can be varied over a 1 : 3 range by changing the *p*H (ref. 53). Similarly, mobility of viruses[14], bacteria[54] and blood cells[55] varies with the *p*H. Even more suggestive are the experiments in which addition of a virus which adsorbs on the cell surface reduced the mobility of erythrocytes to half its previous value[56]; tumour cells were similarly affected by homologous serum[14]. Changes in the chemistry of the surface of the cell thus result in substantial changes in electrokinetic force.

Conclusion

One of the important attributes of the present hypothesis is its generality: it does not require a complex synaptic membrane, which undergoes highly specific structural modifications during learning; neither does it necessitate correlation of firing of the pre- and post-synaptic cells. In fact, almost any change in protein structure, even if not restricted to the synaptic area, might serve the requirements of this hypothesis. Also, so long as additional modifications in protein metabolism have not occurred, the effect should persist regardless of the frequency of activation of the synapse. However, the very generality of this mechanism makes it impossible to interpret learning in terms of the present hypothesis alone. Clearly, any change in the electrokinetic potential affects all synaptic endings of the same cell to an equal degree; neuronal connectivity patterns must therefore be relied on appropriately to channel the adaptive changes.

It cannot be over-emphasized that the hypothesis outlined here may only account for the read-out of information previously stored in nucleic acids and in proteins. A complementary mechanism has to be postulated which alters the composition of DNA and thereby of the membrane, and the principle of operation of this imprinting process obviously must be quite distinct from the read-out mechanism outlined here. Certain data suggest imprinting in protein metabolism[57–59], but they shed no light on the mechanism involved. The recent report of the effects on protein synthesis of changes in potassium concentration[60,61] raises the possibility that potassium extrusion associated with the action potential may affect the protein metabolism of neurones, but the practical importance of this mechanism remains to be determined.

At the basis of the present hypothesis are the experimental observations on displacement and deformation of living cells by focal electric field[11,12]. It is necessary to introduce a series of accessory assumptions, extrapolated from other data, however, and the conclusions reached are far from being unequivocal. Thus, it cannot be claimed that the hypothesis is unique. It is hoped, however, that compared with certain other theoretical approaches to learning, it is more accessible to direct experimental testing of each individual underlying extrapolation. Even though such experiments may fail to confirm the hypothesis, some purpose may be served in directing attention to a hitherto neglected class of biological phenomena—that of electrokinetic processes.

I thank Prof. W. R. Adey for his advice and Mr. J. F. Massey for his assistance in maintaining tissue cultures and taking microphotographs.

This investigation was supported in part by the Air Force Office of Scientific Research of the Office of Aerospace Research, and in part by a grant from the National Institute of Neurological Diseases and Blindness, Public Health Service.

PROTECTION OF PHAGOCYTIZED BACTERIA FROM THE KILLING ACTION OF ANTIBIOTICS

By BEULAH HOLMES, Dr. PAUL G. QUIE*, Dr. DOROTHY B. WINDHORST, Dr. BERNARD POLLARA and Prof. ROBERT A. GOOD†

Pediatric Research Laboratories, Variety Club Heart Hospital, the Departments of Pediatrics and Microbiology, and the Division of Dermatology, University of Minnesota Hospitals, Minneapolis, Minnesota

PHAGOCYTIC cells ingest and destroy a variety of micro-organisms[1–3]. Many of the analyses of these activities are made *in vitro*, in culture media prepared with antibiotics to prevent multiplication of extracellular organisms. The killing of extracellular bacteria with antibiotics facilitates long-term investigation of the fate of intracellular bacteria and would reveal a defect in ability to digest intracellular organisms which ordinarily would be obscured by extracellular multiplication. Some antibiotics are known to be relatively ineffective against intracellular parasites such as tubercle bacilli and brucella[4–6], bacteria which survive intracellularly but are killed by the same antibiotics when not within the cells. Despite this evidence, the use of antibiotics is often deemed disadvantageous[1]. The interpretation of results obtained in investigations where antibiotics are used and the evaluation of the contribution of antibiotics to bacterial inactivation are particularly difficult when the bacterial strain used is rapidly killed by an isolated cell population. Mackaness[7] clearly demonstrated using rabbit peritoneal macrophages and *Staphylococcus aureus* in a solid medium containing penicillin that the antibiotic did not contribute to the intracellular killing of the bacteria. On the other hand, Jenkin and Benacerraf[8], using mouse peritoneal macrophages and *Salmonella enteritidis*, observed a rapid drop in the number of bacteria at the end of a 3-h sampling period which was attributed to the presence of streptomycin in the tissue culture medium.

This article presents evidence that ingested *Staphylococcus aureus* is protected for as long as 24 h from the action of penicillin and streptomycin in the culture medium. This investigation was made possible by the availability of cells from a population of children in our clinic who suffer from a disease based on a defect of intracellular digestion of certain micro-organisms.

We have recently had the opportunity to investigate the phagocytosis and digestion of bacteria by the peripheral white blood cells of three boys with fatal granulomatous disease. This disease, described by Berendes, Bridges and Good[9,10], by Landing and Shirkey[11] and by Carson *et al.*[12], is characterized by chronic draining adenopathy, pulmonary disease, hepatosplenomegaly and dermatitis. The disease has been described only in boys and is familial, and presumably is based on a sex-linked recessive defect. Extensive investigations have failed to reveal the nature of the metabolic fault which underlies the chronic granulomatous infections in these children.

In recent investigations of all three cases, the patients' peripheral white blood cells phagocytize bacteria normally but, in a tissue culture medium containing antibiotics, do not digest the bacteria. This suggests that the metabolic abnormality underlying the tendency to granuloma formation in these children is indeed a failure to digest bacteria following phagocytosis. Perhaps of equal significance, the results provide evidence that the presence of antibiotics in the tissue culture medium does not significantly affect the viability of certain intra-cellular organisms.

Venous blood was collected in a heparinized syringe and placed in a siliconized tube containing a solution of dextran (6 per cent) in saline. After 1 h at room temperature, the leucocyte-rich plasma was withdrawn and the cells were sedimented at 800*g* for 8 min. The cells were washed once in heparinized saline (0·5 u./ml.) and resuspended in Hanks's balanced salt solution or gel-Hanks (0·1 per cent gelatine). An 18-h broth culture of coagulase-positive *Staphylococcus aureus* was centrifuged at 1,500*g* for 10 min and washed twice with normal saline. The deposit was resuspended in Hanks's balanced salt solution or gel-Hanks so that the final suspension had an optical density of 0·6 at 650 mμ, and the bacterial suspension was diluted 1 : 50 before addition to the white blood cell culture. A suspension of white blood cells (1×10^7 cells per ml.) was delivered into 15 × 120 mm siliconized screw-cap test-tubes. Pooled normal human serum and bacterial suspensions were then added to give a final serum concentration of 10 per cent and approximately equal numbers of cells and bacteria (5×10^6 per

* John and Mary R. Markle Scholar in Academic Medicine. Career development awardee of the National Institute of Allergy and Infectious Disease.
† American Legion Memorial heart research professor of paediatrics and microbiology.

ml.). The mixtures were incubated in a reciprocating water bath shaker at 37° C for 20–30 min to allow phagocytosis to occur. The tubes were removed from the water bath and centrifuged at 800*g* for 8 min and resuspended in tissue culture medium containing 100 U. of penicillin per ml. and 100 U. of streptomycin per ml. The medium consisted of Hanks's balanced salt solution plus 50 per cent foetal bovine serum and 1 per cent chick embryo extract. Samples were removed at prescribed intervals, centrifuged at 800*g* for 5 min, and the cellular pellet washed twice in Hanks's balanced salt solution. The deposit was suspended in 1 ml. distilled water and vigorously pipetted for about 30 sec. Appropriate dilutions were made and equal portions removed for the determination of total number of viable bacteria by the pour plate method using nutrient agar. A simultaneous control patient assay was performed with each assay for patients with granulomatous disease.

In Fig. 1, counts of viable bacteria have been plotted from representative experiments showing the survival of *Staphylococcus aureus* in peripheral white blood cells of the three patients with the chronic granulomatous disease and of three control patients. In most instances, control cells were obtained from children of about the same age as the patients, although age does not seem to be a factor in this system. It can be seen that after 120 min the number of viable bacteria has decreased by less than 0·5 $\log_{10}$ in cultures using cells from the granulomatous patients. The control cultures consistently showed a decrease of 1 to 1·5 $\log_{10}$. When samples were taken at longer intervals (5 to 24 h) there was no significant decrease in numbers of viable bacteria in cultures from patients with granulomatous disease, while a continuing decrease was noted in the control cultures (Fig. 2). Air-dried smears were made at sampling intervals between 0 min and 120 min and stained with Wright's stain. In all smears, large numbers of intracellular bacteria were seen in polymorphonuclear leucocytes and macrophages and appeared to be morphologicallly intact (see Fig. 3).

Summarizing these findings: (1) the peripheral white blood cells of three patients with fatal granulomatous disease of childhood, when cultured in a medium containing antibiotics, fail to destroy intracellular *Staphylococcus aureus* at a normal rate; (2) the survival of intracellular bacteria is not affected when the fluid cultures are shaken for long periods of time in the presence of antibiotics.

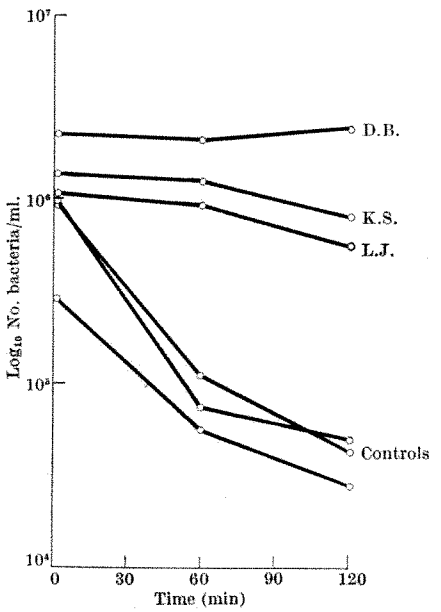

Fig. 1. A comparison of the destruction of *Staphylococcus aureus* by peripheral white blood cells of patients with fatal granulomatous disease (L.J., D.B., and K.S.) and of control patients

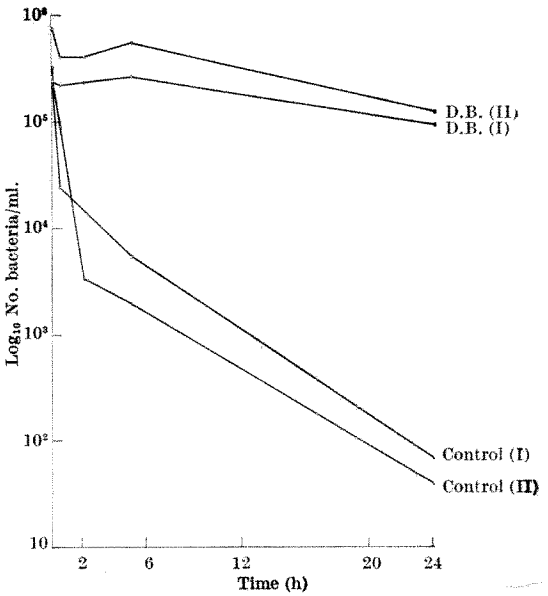

Fig. 2. Viable bacterial counts from two separate experiments (I and II) showing the fate of *Staphylococcus aureus* during prolonged incubation in the presence of peripheral white blood cells from a patient with chronic granulomatous disease (D.B.) and control patients

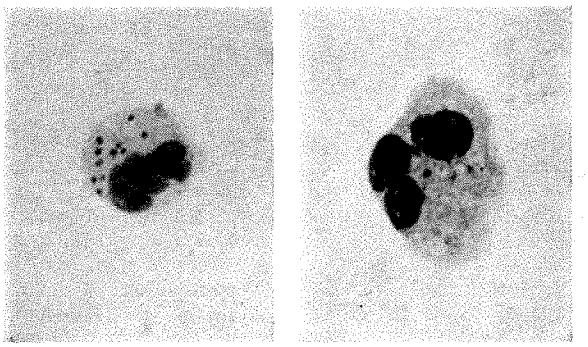

Fig. 3. *a*, A neutrophil from a patient with chronic granulomatous disease (K.S.) 30 min after infection *in vitro* with *Staphylococcus aureus*. *b*, A neutrophil from the control patient 30 min after infection *in vitro* with *Staphylococcus aureus*

Because the clinical disease of the patients investigated seemed to arise from faulty digestion of phagocytized micro-organisms, the latter finding indicates that phagocytized staphylococci are protected from bactericidal action of penicillin and streptomycin in the media. This suggests that when a search is made for abnormalities of intracellular digestion due, for example, to abnormalities of lysosomal content or structure, it may be useful to investigate the degradation of organisms located entirely within the cell while killing the extracellular micro-organisms with an appropriate antibiotic.

POLYSOME PATTERNS AND PROTEIN SYNTHESIS DURING THE MITOTIC CYCLE OF *Physarum polycephalum*

By DR. C. MITTERMAYER*, DR. R. BRAUN†, T. G. CHAYKA and PROF. H. P. RUSCH
McArdle Laboratory for Cancer Research, Medical Center, University of Wisconsin, Madison

MITOSIS is synchronous in the plasmodium of *Physarum polycephalum* and RNA is synthesized in two distinct peaks, one premitotic and one postmitotic[1].

Since RNA is intimately associated with protein synthesis, it was of interest to determine the characteristics of protein synthesis and of polysome patterns during the mitotic cycle. A disappearance of polysomes during mitosis would suggest that certain cytoplasmic functions cease at the end of one cycle and start afresh with the beginning of each new cycle.

Sucrose was obtained from Baker and Adamson, and sodium deoxycholate (DOC) from Matheson, Coleman and Bell (Norwood, Cincinnati). L-lysine-^{3}H (specific activity 800 mc./mmole) was purchased from Schwarz Bioresearch Inc. (Orangeburg, New York). RNase (pancreatic ribonuclease, *EC* 2.7.7.16) came from Boehringer und Soehne (Mannheim, Germany). Medium *A* consisted of 0·25 M sucrose, 0·05 M potassium chloride and 0·005 M magnesium chloride, *p*H 5. Medium *B* consisted of 0·2 M sucrose, 0·05 M potassium chloride, 0·0015 M magnesium chloride and 0·1 M *tris* buffer, *p*H 7·2.

Growth and maintenance of the organism. Methods of cultivation of the organism have recently been reviewed by Daniel and Baldwin[2] and by Guttes and Guttes[3]. A detailed account of the growth and of the microscopic procedures has been given previously[4]. In this work the sub-line *M3C* was used.

Determination of total protein content in vivo. Plasmodia, each derived from 0·3 ml. of a shaken culture, were collected at different times of the cycle between mitoses 3 and 4 into 10 ml. of trichloroacetic acid–acetone (4 per cent trichloroacetic acid, 48 per cent acetone, 48 per cent water), and shaken. After centrifugation at about 1,000*g*, the pellet was resuspended and this procedure was repeated to remove all pigment. Three washes with 10 ml. 0·25 M perchloric acid (PCA) followed. The colourless precipitate was dissolved overnight in 3 ml. 0·4 N sodium hydroxide, and aliquots were taken to determine protein content by the Biuret methods[5].

Determination of the rate of amino-acid incorporation. Plasmodia at different stages of mitosis were incubated for 10 min on 13 ml. nutrient medium containing 20 μc./ml. lysine-^{3}H and processed as indicated earlier. The radioactivity of 0·5 ml. of the alkaline solution was determined in a liquid scintillation counter.

Preparation of ribosomes. Three plasmodia, taken about 2 h before mitosis 3, were homogenized in 30 ml. of either Medium *A* or Medium *B* with 15 strokes in a Potter–Elvehjem homogenizer with a 'Teflon' pestle. All steps were performed in the cold. To precipitate unbroken plasmodia and nuclei, the suspension was centrifuged for 10 min at 1,400*g*. The supernatant was then centrifuged at 7,500 r.p.m. in a 'Spinco' rotor 30, at an average of 5,000*g*. This pellet was designated 'mitochondria'. The 5,000*g* supernatant was divided into two halves: one was brought to a final concentration of 0·1 per cent DOC with 0·3 ml. aqueous DOC solution; the other received no additions. Both supernatants were then centrifuged for 1 h at 100,000*g* in a 'Spinco' centrifuge. The 100,000*g* pellet that had not been subjected to DOC was called 'microsomes', while the DOC-treated pellet was designated 'ribosomes'. The 100,000*g* supernatant was discarded. All three pellets (mitochondrial, microsomal and ribosomal) were washed three times with 10 ml. 0·25 M PCA, being carefully suspended and centrifuged each time as indicated above.

The RNA was hydrolysed with RNase in all pellets according to the method previously described[1], and the radioactivity and ribose contents were determined in the supernatant. A conversion factor of 2·1 was used to calculate μg RNA from μg ribose.

Preparation of polysomes without radioactive labelling. Plasmodia at about mitosis 3 were incubated for 1 h in fresh nutrient medium. At the desired times of the mitotic cycle they were placed in liquid nitrogen. This step had to be done rapidly, great care being taken to ensure that no cooling of the cultures took place in the air outside the 26° C incubator. Once collected, the samples could be kept for at least 5 h without destruction of polysomes. The next step included homogenization in a Potter–Elvehjem all-glass homogenizer (Kontes Glass Co., Vineland, New Jersey, type *B*). Homogenizer and pestle, as well as the vessel containing 2·5 ml. Medium *B*, were pre-cooled to 0° C, and the subsequent steps were performed in the cold room at 4° C. The frozen sample was placed in the homogenizer and immediately homogenized with ten strokes at 1,100 r.p.m. As soon as the frozen plasmodium was broken, five additional strokes followed, while the homogenizer was held in a cold mixture at −6° C. From then on the homogenate was kept in a glycerol–water–ice mixture at −6° C. The homogenate was centrifuged for 5 min at 3,500 r.p.m. in a 295 rotor of an International centrifuge at −6° C. The pellet was discarded, and the supernatant was brought to a final concentration of 0·4 per cent DOC with 0·2 ml. of a 5 per cent aqueous DOC solution. After being briefly shaken in the cold, 0·5–1·5 ml. of this supernatant was layered with pre-cooled pipettes over a sucrose density gradient. A 2-h run in an '*SW*25' bucket in a Spinco model *L* centrifuge at 25,000 r.p.m. followed, with the temperature in the centrifuge set at 10° F. After the centrifuge was stopped by braking, the tubes were punctured and the effluent passed through a flow-through cell (Beckman No. 96160) of cylindrical shape, 10 mm path length and 0·5 ml. volume. The whole flow-through assembly was filled with 0·5 M sucrose at the start. The ultra-violet absorption of the effluent was measured in a Beckman '*DB*' model at 260 mμ and registered continuously with a Sargent strip chart recorder. 0·5 M sucrose served as a blank.

Linear sucrose density gradients were prepared by mixing a 10 per cent sucrose solution with a 51 per cent sucrose solution, both containing 0·025 M potassium chloride, 0·005 M magnesium chloride, and 0·05 M *tris*, *p*H 7·3. The mixing procedure was performed in a gradient apparatus consisting of two 20-ml. syringes filled up to the 17-ml. mark, which were pushed with equal speed, resulting in a 28-ml. linear gradient.

Preparation of polysomes after radioactive labelling. 1 h before labelling, the cultures were transferred to a lysine-free, fully defined medium (*AV*-40)[2]. At the desired time in the mitotic cycle these cultures were transferred into a lysine-free *AV*-40 medium containing 20 μc./ml. lysine-^{3}H and were incubated for the specified times. Care was taken to bring the incubation medium

* Present address: Pathologisches Institut der Justus Liebig Universität, Giessen, Germany.
† Present address: Swiss Institute for Experimental Cancer Research, Lausanne.

to 26° C prior to use. After incubation the plasmodia were chilled rapidly in liquid nitrogen and processed as described above. Collection and precipitation of the radioactive samples were done as follows: twenty drops (about 2 ml.) were collected by a fraction collector into 0·5 ml. albumin solution (1 mg/ml.) and immediately precipitated in the cold with 1·5 ml. 0·5 M PCA or 0·6 ml. 100 per cent TCA (w/v). The samples were then filtered *in vacuo* through 'Millipore' filters, type *HA*, of 2·8 cm diameter with a pore size of 0·45μ. After being dried in air the radioactivity of these filters was measured in a liquid scintillation counter.

Determination of the load on the gradients. A direct and fast measurement of the RNA content of the sample loaded on the gradients was not possible, because of its contamination with non-ribosomal, ultra-violet-absorbing material. We therefore looked for a fast and accurate but indirect measurement of the RNA content of the load. This was found in the direct proportionality of pigment and RNA content of the postmitochondrial supernatant, as illustrated in Fig. 1. The routine procedure followed was to load a certain amount of postmitochondrial supernatant on the gradient, and to mix the same amount thoroughly with TCA-acetone in the cold and centrifuge this at 1,400*g* for 10 min. The optical density of the supernatant was measured at 415 μm, the spectral maximum of the yellow pigment. The sediment was washed three times with 10 ml. 0·25 M PCA and the RNA determined as described elsewhere[1]. When RNA was not determined in the sediment, its amount was calculated from the graph (Fig. 1).

Calculation of the amount of ribosomes and polysomes. Since the observed heights of the peaks are the result of overlapping of neighbouring peaks, all methods of comparing single ribosomes with polysomes are approximations[6]. The method we followed was to measure the areas below the single ribosome peak and the polysome peaks, having separated the two by a vertical line going through the trough between single ribosomes and dimer peaks. The ratio polysomes to single ribosomes was calculated from these figures.

Protein synthesis during the mitotic cycle. The total protein content of plasmodia during the mitotic cycle is shown in Fig. 2. The protein almost doubled between mitosis 3 and mitosis 4. In contrast to the more or less steadily increasing amount of total protein, the rate of incorporation of lysine-^{3}H into protein showed a biphasic pattern. The premitotic and postmitotic peaks parallel those of RNA synthesis. In contrast to RNA synthesis, however, the lysine-^{3}H incorporation exhibited a distinct lag phase of about 1 h after mitosis compared with the postmitotic rise in uridine incorporation.

Ribosomes. To determine optimal conditions for preparing ribosomes and polysomes, the influence of *p*H during the isolation procedure was investigated and

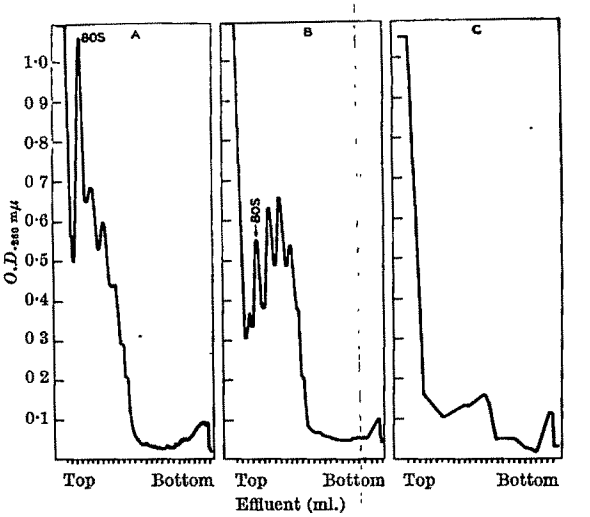

Fig. 3. Effect of temperature and RNase ion the polysome pattern. (*A*) The frozen plasmodium was homogenized at 0° C. Most of the polysomes were broken down. (*B*) The frozen plasmodium was homogenized with a rough-surfaced, all-glass homogenizer, and all steps were performed at −6° C. Polysomes prevail. (*C*) After homogenization the 16,000*g* supernatant was incubated at 37° C for 10 min with 2·5 μg RNase. This resulted in total disappearance of ribosomal structures. Load expressed in μg RNA. *A* = 45, *B* = 40, *C* = 42

the RNA contents of the ribosomes was compared with that of fractions containing mitochondria and microsomes. It will be noted from Table 1 that the amount of RNA in the microsomes obtained at *p*H 7·2 (145 μg) was greater than the amount obtained at a lower *p*H (84 μg). Fractionation at *p*H 7·2 in the presence of DOC resulted in further purification (168 μg RNA), yielding a fraction designated as 'ribosomes'. The mitochondrial pellet obtained at *p*H 5 contained more RNA (104 μg) than the fraction prepared at *p*H 7·2; this suggests that microsomes adhered to the mitochondria at the lower *p*H.

Polysomes. The critical phase in the isolation procedure of polysomes from the plasmodium is the prompt application and maintenance of low temperatures. As seen in Fig. 3*B*, only the plasmodia which were frozen in nitrogen and homogenized in this frozen state gave the characteristic pattern of polysomes. If the plasmodium was not converted from the solid frozen state directly into a homogenate, breakdown took place; melting or softening of the solidly frozen plasmodium in the homo-

The figures given represent the averages of two independent experiments. See text for the preparation of the various fractions.

genizing medium caused breakdown. The selection of the proper homogenizer was also crucial. Only glass homogenizers with a rounded tip and rough inner surface were satisfactory. Homogenizing at 4° C resulted in the breakdown of polysomes (Fig. 3*A*). The breakdown of all ribosomal structures could be induced by adding 2·5 μg RNase to the postmitochondrial supernatant and incubating it for 10 min at 37° C (Fig. 3*C*). In the RNase-treated samples we regularly found a slight peak at about the position of the decamer. This peak did not disappear with higher RNase concentrations. The standard optical density pattern (Fig. 3*B*) showed a large amount of non-ribosomal material at the top. This was not surprising since no 'purification step' was used. The lightest particle to be recognized in the standard 2-h centrifugation was the 50*S* ribosomal subunit, the 30*S* subunit remaining in the highly absorbing material at the top of the sucrose gradient. Both subunits could be resolved with an 8-h centrifugation, and their amounts could be increased by omitting magnesium from the isolation medium. In the standard centrifugation, the second lightest peak was caused by 80*S* particles (single ribosomes); thereupon followed the polysomes, with the dimer, trimer, tetramer, pentamer, and hexamer peaks showing up at regular intervals (Fig. 3*B*).

In Fig. 4*A*, a better resolution was achieved owing to a smaller load; polysomes were separated in peaks up to heptamers. In other experiments with still smaller loads, nonamer peaks could be detected. However, the region comprising ten to twenty unit-aggregates is represented in *P. polycephalum* only by a low, broad peak. Fig. 4*B* shows the polysome pattern of a 48-h culture. This stage is characterized by movement of the plasmodial masses owing to lack of nutrients. The sedimentation pattern showed predominantly the single ribosome peak with a small polysome portion.

The effect of DOC at different concentrations on the polysome pattern is shown in Fig. 5. When no DOC was added to the postmitochondrial supernatant (Fig. 5*A*), single ribosomes prevailed. With increasing DOC concentrations (Fig. 5*B*, 0·1 per cent; Fig. 5*C*, 0·3 per cent) more polysomes were found. This indicates that polysomes were being liberated, on the assumption that the single ribosome population was not altered by DOC. A high concentration of DOC (1 per cent), as used by investigators with liver preparations[6–8], destroyed the entire patterns (Fig. 5*D*).

Polysome pattern during the mitotic cycle. Fig. 6 shows polysome preparations at different stages in the mitotic cycle. The optical density pattern is remarkably uniform at most times of the mitotic cycle. There was no rapid change during and immediately after mitosis (Fig. 6*A*). There was, however, a steady decline in the number of

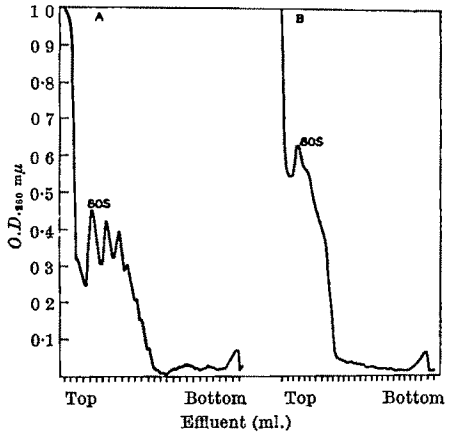

Fig. 4. Influence of age of plasmodium on the polysome patttern. (*A*) Standard polysome pattern of a plasmodium 23 h after inoculation of the culture. (*B*) Polysome pattern of a plasmodium 48 h after inoculation of the culture

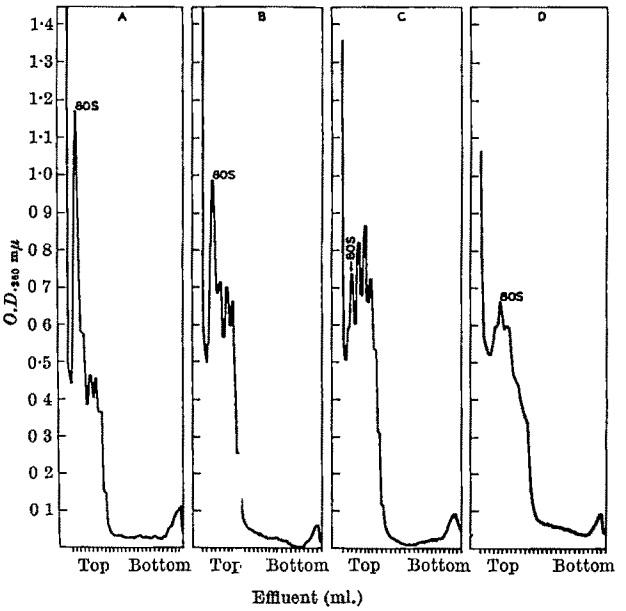

Fig. 5. Influence of different concentrations of DOC on the polysome pattern. (*A*) No DOC (32 μg RNA), (*B*) 0·1 per cent DOC (30 μg RNA), (*C*) 0·3 per cent DOC (33 μg RNA), (*D*) 1·0 per cent DOC (25 μg RNA). Freshly prepared DOC was added in aqueous solution to the postmitochondrial supernatant

polysomes relative to the number of single ribosomes after mitosis, becoming most pronounced 40 min after mitosis (Figs. 6*B* and 7). By 50 min after mitosis a polysome pattern comparable to that found in prophase was re-established (Fig. 6*C*). Similar determinations were made at various stages throughout the rest of interphase and resulted in patterns like those of Fig. 6*C*.

Labelling pattern of polysomes after pulses with lysine-^{3}*H.* Fig. 8 shows the radioactive labelling pattern as observed 1 h before mitosis 3. In Fig. 8*C* radioactive samples were precipitated with 1·5 ml. 0·5 M PCA. One peak can be observed, with its maximum at the position of the trimers. The single ribosome peak contained only slight radioactivity, indicating that there was little or no breakdown of heavy aggregates into single ribosomes. Precipitation of the radioactive samples with 0·6 ml. 100 per cent TCA (giving a final concentration of about 20 per cent) resulted in the curves shown in Figs. 8*A* and 8*B*. Two maxima of incorporation of radioactivity can be seen. The first peak paraleled roughly the optical density pattern and was similar to the radioactivity peak observed in Fig. 8*C*. The second peak was located in the area where aggregates of ten and twenty ribosomes would be expected. In contrast to the peak associated with the optical density pattern, this second peak increased with longer pulses of lysine-^{3}H (Fig. 8*A*).

Certain aspects of protein synthesis in the mitotic cycle of the plasmodium of *P. polycephalum* were investigated by measurement of isotope incorporation and by an investigation of polysome patterns. Such an investigation during different physiological states of a cell should reveal the presence of *m*RNA, which is at least potentially functional in protein synthesis.

The profiles of optical density show that the majority of polysomes obtained from *P. polycephalum* consist of aggregates of two to five ribosomes. Under specified experimental conditions, the patterns are very reproducible, but a slight change in the procedure may lead to complete breakdown of the polysomes. The most critical parameter appeared to be the temperature; it was necessary to carry out the extraction slightly below 0° C. A low concentration of deoxycholate was also essential. Although part of the action of deoxycholate was the release of polysomes from other cell structures (endoplasmic reticulum), it also helped to prevent the breakdown of polysomes, as did the

low temperature. Thus the polysomes of *P. polycephalum* are very labile to the action of nuclease; they appear to be intermediate in lability between those of bacteria[9] and those from rat liver[6–8]. Whether the optimal patterns obtained from *P. polycephalum* are the result of a partial breakdown of still larger polysomes cannot be decided with certainty[10].

Lysine incorporation into acid-insoluble material took place at two positions in the gradients. One coincided with the peak of the optical density pattern (fractions containing clusters of three to five ribosomes), the other at a position where polysomes of ten to twenty subunits should be found. If the latter peak also represents ribosomal clusters with nascent radioactive protein attached, it would appear that nascent protein protects polysomes from breakdown and that the optical density patterns found were caused by a partial breakdown of larger

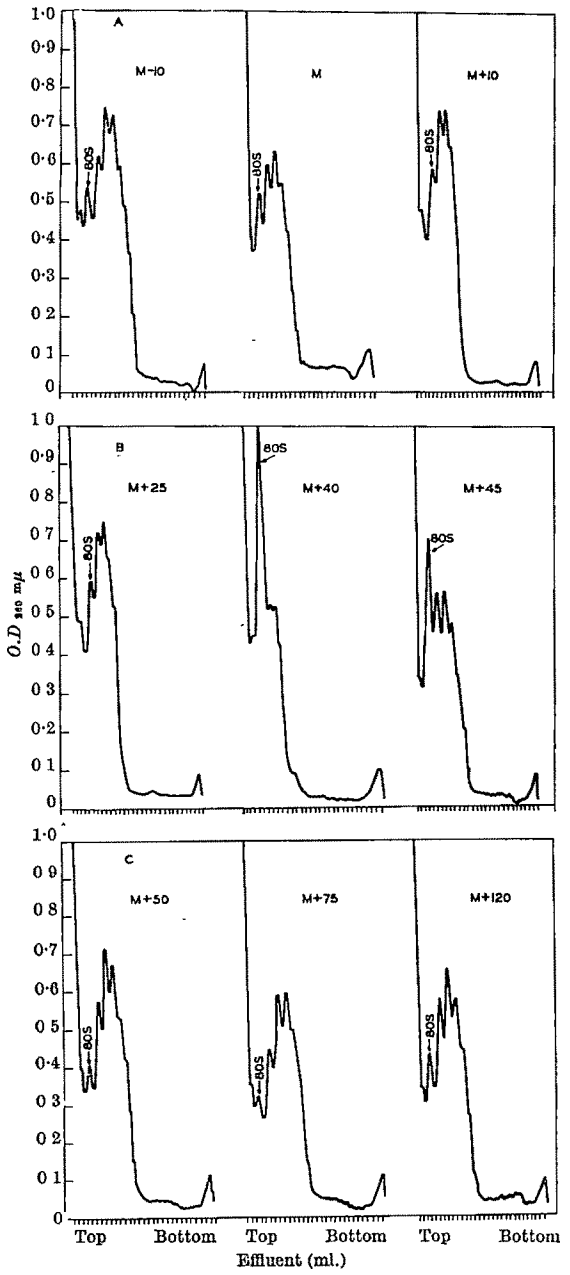

Fig. 6. Polysome patterns found at different stages of the mitotic cycle. (*A*) M − 10, 10 min before mitosis 3 (38 μg RNA load), M, Mitosis 3 (29 μg RNA load); M + 10, 10 min (33 μg RNA load); (*B*) M + 25, 25 min (29 μg RNA load); M + 40, 40 min (24 μg RNA load), M + 45, 45 min (32 μg RNA load), (*C*) M + 50, 50 min (35 μg RNA load), M + 75, 75 min (32 μg RNA load); M + 120, 120 min (33 μg RNA load), after mitosis 3

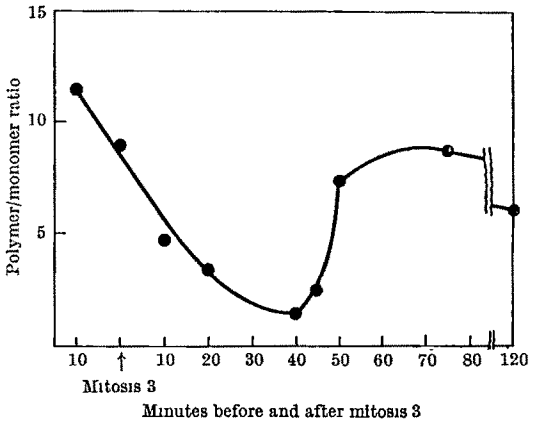

Fig 7 Ratio of polysomes to single ribosomes during the mitotic cycle. The areas occupied by the single ribosome peak and by the polysome peaks were taken from Fig. 6, and the ratio polysomes to single ribosomes (polymer/monomer) was calculated and plotted against the time

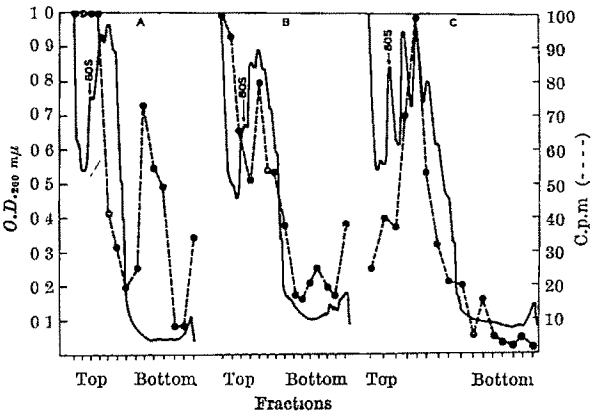

Fig. 8. Polysome pattern 1 h before mitosis 3. In *B* and *C* a 10-min pulse, in *A* a 20-min pulse with lysine-^{3}H was used. In *A* and *B* the samples were precipitated with 20 per cent TCA, in *C* with 0 25 M PCA. The radioactivity of the acid-precipitable material was measured on 'Millipore' membranes

polysomes. Even if this were the case, the optical density patterns obtained during the mitotic cycle show clearly whether or not the ribosomes are present singly or in clusters.

At all times of the mitotic cycle investigated, including mitosis, the majority of ribosomes were present in the form of polysomes. The structural revolution of mitosis in the nuclei therefore does not entail a radical and immediate reorganization of the cytoplasmic protein-synthesizing machinery: functional messenger RNA appears to be carried over from one mitotic cycle to the next. However, there was a partial shift from polysomes to single ribosomes during a period of 40 min immediately after mitosis, rapidly followed by the usual interphase pattern. This temporary shift from polysomes to single ribosomes may reflect the reduced synthesis of *m*RNA. The *m*RNA holding the polysomes together is constantly being degraded and may not be replenished as long as the chromosomes are condensed.

Lysine incorporation investigations show that protein synthesis takes place throughout the mitotic cycle, including mitosis, and corroborate the conclusion from the polysomes experiments. The extent of incorporation varies in the cycle. It is greatest 2 h after mitosis, drops off, and then increases again 2 h before the next mitosis. The pattern is thus reminiscent of that of uridine incorporation into RNA. Low lysine incorporation was observed shortly after mitosis, when the ratio of polysomes to single ribosomes was low.

The polysome pattern during the growth cycle of *P. polycephalum* differs somewhat from that observed with

HeLa cells, in which it is reported that a complete polyribosome disaggregation occurs during metaphase[11]. In *P. polycephalum* the disaggregation of the polyribosomes is less complete and occurs about 40 min after metaphase. Two factors may account for these differences: first, the period of metaphase–anaphase in HeLa cells lasts from 20 to 30 min, compared with a 5-min metaphase–anaphase in *P. polycephalum*; thus, the time of polysome breakdown in HeLa cells may include the comparable period in *P. polycephalum*, where the metaphase period is so much shorter. Secondly, the degree of polysome disaggregation may be correlated with the extent of cellular reorganization during cell division. One would expect such disaggregation to be more pronounced in uninucleate cells, such as HeLa cells, in which cytoplasmic division is concomitant with mitosis, as compared with the changes in a multinucleate plasmodium in which the nuclear wall remains intact during mitosis and cellular fission does not accompany nuclear division.

This investigation was supported in part by U.S. Public Health Service research grants from the National Cancer Institute, National Institutes of Health, and by the Alexander and Margaret Stewart Trust. We thank Mrs. Judith Blomquist for technical assistance.

GOITROGENIC ACTIVITY OF CASSAVA (A STAPLE NIGERIAN FOOD)

By O. L. EKPECHI*, A. DIMITRIADOU† and PROF. RUSSELL FRASER
Department of Medicine, Postgraduate Medical School, London

A RECENT goitre survey[1,2] in the Nsukka Division of Eastern Nigeria revealed a widespread incidence of visible goitre which varied considerably from town to town (1·4–41 per cent). Several of the water supplies of these towns were tested[2], and all were found to be deficient in iodine (under 1·5 μg/l.) but the lowest levels were not found in the most goitrous towns. A search was therefore made for differences in dietary habits, and it emerged that those towns and villages with the highest incidence of goitre were those feeding mostly on dry unfermented cassava‡. Thus, dry unfermented cassava might contain goitrogens, the effect of which only emerges when the associated dietary components are also iodine-deficient.

Experiments were therefore planned to assess this hypothesis. Measurements of thyroid function were made on various groups of rats after they had been fed on either a standard diet, an iodine-deficient diet or on cassava as well as on a group which had received the cassava plus iodide supplements. The effects of the carefully standardized iodine-deficient diets differed from some previous findings and have been published elsewhere[3], while the cassava-feeding experiments, which are reported in this article, indicated that cassava contains a goitrogen with an action similar to those of the thionamide group of goitrogens (? thiaurelene).

Female albino rats weighing 170–198 g were investigated in groups of three, each after a different dietary for seven days, the dietaries having been chosen to allow the assessment of a possibly goitrogenic effect from cassava. Unfortunately, the feeding could only be continued for short periods and to small groups of rats, as only limited amounts of cassava had been brought to London from Nigeria for these experiments. However, some sufficiently definite effects emerged. At the end of the 7-day dietary and 24 h before killing, each rat was injected intraperitoneally with 20 μc. carrier-free iodine-131. Immediately after killing with ether, blood was withdrawn by cardiopuncture and the thyroid carefully dissected. The following measurements were made to assess thyroid function: (*a*) thyroid weight, finally expressed as mg/100 g body weight; (*b*) 24-h thyroid iodine-131 uptake (as percentage of dose); (*c*) 24-h serum protein-bound iodine-131 (as percentage dose/ml.); (*d*) from digests of thyroid tissue prepared as described elsewhere[4,5]: (i) total iodine concentration (μg iodine-127/mg tissue) from one aliquot, and (ii) from the second aliquot, after resin purification and chromatography, the distribution of iodo-amino-acids, measured by scanning the paper chromatograms for iodine-131; the parameters found most relevant being the monoiodotyrosine/diodotyrosine (MIT/DIT) ratio and the iodothyronines (thyroxine or triiodothyroxine) as a percentage of the total gland iodine-131.

The diets so assessed for their effect on thyroid function included: (1) the standard laboratory diet (41_B) detailed by Bruce and Parkes[6] for a control group; (2) an iodine-deficient but otherwise normal diet containing 100 μg iodine-127/kg (as detailed elsewhere[3]); (3) 100 per cent cassava; (4) 50 per cent cassava with 50 per cent standard 41_B laboratory diet; (5) 100 per cent cassava with added iodine in the drinking water (50 μg iodine-127/100 ml. which should provide 10 μg/rat/day).

Measured aliquots of each diet were offered daily (10 g/rat). The tap water of all the cassava-fed groups was supplemented with 'Compound Vitamin Drops' (1 ml./l. water, Paines and Byrne, Ltd.). The iodine-deficient group and the iodide-supplemented cassava group were included because the cassava diet proved to be iodine deficient; a portion being found to contain 90 μg iodine-127/kg, so that each rat on the 100 per cent cassava received less than 2 μg iodine-127/day. Conveniently, this diet approximated very closely in iodine content to the iodine-deficient diet; the former containing 90 μg iodine-127/kg and the latter 100 μg iodine-127/kg. The cassava meals were prepared fresh each day by the methods traditionally used in Nigeria.

As summarized in Table 1, after cassava, the radioiodine uptake by the thyroid is increased, probably because of the associated iodine deficiency of this diet; indeed the avidity of the thyroid for iodine after cassava was similar to that seen after the iodine-deficient diet, while the cassava diet with iodine supplements led to a normal thyroid avidity for iodine. However, the 24-h serum plasma-bound iodine-131 and the thyroid weight, while little increased after the iodine-deficient diet, were both increased after all 100 per cent cassava feeding—suggesting some additional effect from cassava other than iodine deficiency.

The thyroid digest findings corroborate these suggestions of some antithyroid factor in the cassava diet as well as

Differences from controls on standard diet: * Probably significant ($P < 0·05$). † Significant ($P < 0·02$). ‡ Clearly significant ($P < 0·001$). § Data from experiments reported more fully by Dimitriadou *et al.* (ref. 3) (iodine content of diet being 100 μg/kg compared with that of cassava 90 μg/kg). (1), Mostly thyroxine; (2), high proportion of triiodothyronine.

iodine deficiency. After cassava feeding the digest findings showed: (*a*) severe depletion of the gland's precursor and hormone iodine stores, that is, the total thyroid gland iodine was 0·14 μg iodine-127, or much less than the slight depletion seen after an equivalent duration of the equivalently iodine-deficient diet (0·68 μg/mg); (*b*) an impaired iodine-131 transfer from MIT to DIT, that is, a high MIT/DIT ratio (1·3–1·44), again contrasting with the low or normal ratio after the iodine-deficient diet (0·34); (*c*) high transfer of iodine-131 to iodothyronines, a feature also seen in iodine deficiency, but not eliminated when the cassava feeding is combined with adequate iodine supplements.

The diet of 100 per cent dry unfermented Nigerian cassava used for these experiments is deficient in iodine, approximately equivalent to the iodine-deficient diet with which we have compared it, as noted earlier. To this feature is attributable the increased thyroid uptake of iodine-131 seen after the feeding of cassava—for the thyroid uptake was equivalently increased after the iodine-deficient diet, while it was normal with the iodide-supplemented cassava diet. However, the cassava feeding led to several other changes not seen after iodine-deficient diets; the cassava diet is rapidly goitrogenic, it depletes the iodine stores of the gland more rapidly than does iodine deficiency, and it also impairs the transfer of iodine from MIT to DIT (high MIT/DIT ratio) in the gland. Furthermore, giving iodide supplements with the cassava does not remove these last two abnormalities, and merely lessens the first. Thus, many of the effects seen to follow cassava feeding suggest that it contains a weak goitrogen, acting like the thionamide group of antithyroid drugs, since its effects are not reversed by iodide supplements.

Low concentrations of thiouracil have been reported to cause increased thyroid weight with a variable or even high iodine-131 uptake, severely depleted thyroid iodine stores and a high MIT/DIT ratio[7,8], findings rather similar to these reported here after cassava feeding, which clearly might have a similar basis. The high proportion of thyroid iodine-131 found as iodothyronine along with the high serum plasma-bound iodine-131 are most probably due to the low hormone stores in the gland causing a rapid iodine turnover through the gland, once the block at the MIT/DIT transfer has been passed. Possibly another factor might be a diminished peripheral deiodination similar to that reported to occur with thiouracil[9,10].

We have no evidence about the nature of the goitrogen in the cassava. Cassava has long been known to contain a cyanogenetic glucoside[11,12] which the traditional method of fermentation hydrolyses. Recent workers[13,14], however, doubt whether fermentation and boiling before eating remove all this cyanogenetic glucoside. Thus, eating cassava, especially in the unfermented form, may tend to bring about continual ingestion of this cyanogenetic glucoside which could decompose in the body to a goitrogen. Furthermore, whatever the goitrogen in cassava may be, the higher incidence of goitre in iodine-deficient Nigerian villages, which also feed on much cassava, could be explained by the goitrogenic activity of cassava.

TAXONOMIC IMPLICATIONS OF 'MYXOVIRUS'

By PROF. A. P. WATERSON and JUNE D. ALMEIDA

Department of Medical Microbiology, St. Thomas's Hospital Medical School, London

THE bases on which viruses can be grouped have changed fundamentally in the past twenty years or so[1]. Whereas it was once possible to evaluate a virus only from its effect on the host organism[2], and somewhat later on the susceptible cell, it is now possible to view viruses in a much more definitive way. In the light of this recent knowledge about viruses, many previously held concepts now appear inadequate. Groupings which had previously seemed meaningful have now been shown to have only superficial validity and, conversely, unsuspected relationships have come to light. This article sets out to consider the changed relationships that have emerged in the case of one particular group of viruses contained within the overall grouping of the compound (that is, enveloped) helical RNA viruses and, until now, termed myxoviruses.

Luria[3], in discussing the taxonomy of viruses, referred to this group when he observed that a "natural group may be that of the influenza-mumps-Newcastle disease viruses which have similar particles and common enzymic activity on some surface component of red blood cells and on other substrates". Two years later, Andrewes,

Bang and Burnet[4] formally suggested the very acceptable name of 'myxovirus' for this same group of viruses, which then comprised influenza *A*, *B* and *C*, fowl plague, mumps and Newcastle disease virus (NDV). The prefix 'myxo' means mucus and is derived from the Greek μυξα (nasal secretion). This name was chosen because all these viruses have two distinct interactions with mucoproteins, whether these are an integral part of a cell, as on an erythrocyte, or are free, as in serum. First there is attachment of virus to mucoprotein, and then elution occurs from it by means of the enzyme neuraminidase. This two-fold action is the truly distinctive property of the myxovirus group as originally designated. The effect on red cells had considerable practical importance, as adsorption of virus to them gives rise to the phenomenon of haemagglutination, while elution offered a means of obtaining relatively pure virus. In the light of the knowledge available at the time the segregation of these six viruses into a group was both natural and instructive. In addition to this effect on mucus, the members of the group had other properties in common, such as sensitivity to ether, adaptability to growth in the hen's egg, and maturation at the surface of the cell. However, it is the unique interaction with mucoproteins, which might be termed 'myxophily', that both unites them as a group and segregates them from other viruses.

As has already been stated, the decade since 1955 has seen the emergence of much more definitive information on viruses in general and on myxoviruses in particular. The members of the group have been shown to have similarities other than those originally demonstrated. For example, it is now known that they all have RNA as their nucleic acid and that this RNA is in the form of a ribonucleoprotein helix contained in a lipoprotein envelope partially derived from the host and partially from viral material. On the other hand, it has now become evident that some important inconsistencies arise when the term myxovirus is used at the present time.

The group now appears to be less homogeneous than was originally supposed. It no longer maintains its early unity, but has been shown to consist of two distinct sub-groups which can each be named after one of their well-characterized members. These sub-groups are the NDV sub-group of myxoviruses and the influenza sub-group of myxoviruses[5,6]. Although members of both sub-groups are compound helical RNA viruses they are of two distinct types and can readily be identified by the negative staining process in the electron microscope, and also by their reproductive cycle in the cell. The situation is further complicated because the refined techniques of investigating viruses, which have come into widespread use since 1955, have produced many new candidates for inclusion in the myxovirus group. These new candidates began to appear when the negative staining technique revealed the morphology of the myxoviruses in considerable detail, and showed that certain other viruses, of which the first was measles, had a virion indistinguishable from the classical NDV type of myxovirus. Subsequently a whole range of viruses morphologically identical with NDV have been described. These may be divided into (*a*) those which have the same effect on mucoproteins as the classical myxoviruses, and therefore are myxoviruses, (*b*) those which attach to mucoproteins, but do not elute from them because they lack neuraminidase (such as some bovine parainfluenza 3's), and (*c*) those which have no effect on mucoproteins, for example, the measles group.

It is this third group which has caused particular confusion, because their morphological similarity to NDV had led some to label them myxovirus[7] without realizing the implications of the word. The argument runs as follows: "NDV is a myxovirus, and its virion has a characteristic structure. Measles virus has an identical structure, and therefore it is a myxovirus." The fallacy here is that it is the property of myxophily, and not the accompanying morphology, which establishes NDV as a myxovirus. Measles does not share this property of myxophily in spite of its identity of form, and therefore has no valid claim to be in the myxovirus group. The case of the two related viruses, rinderpest and distemper, is the same as that of measles. Indeed, if the word myxovirus is used in the original sense, even those bovine parainfluenza 3's which lack neuraminidase have only a partial claim to be called myxoviruses.

In addition to these viruses which exhibit identical morphology to one sub-group of myxoviruses but are not myxophilous, there has emerged a second assemblage of viruses which have been reported to possess a certain morphological similarity to the myxoviruses (that is, they have a ribonucleoprotein helix enclosed in an envelope) but are not morphologically identical with either sub-group. Such viruses are avian erythromyeloblastosis virus[8] which has been reported to have an internal component of about 40 Å diameter, and rabies[7,9], which has a helix of about 90 Å but is quite different in appearance from the corresponding structure in the influenza group. Yet a third example is the group typified by vesicular stomatitis virus[10]. In spite of the fact that all these viruses possess compound helical structures, there are clearly marked differences both from the two sub-groups of myxoviruses and from each other. To sum up, we find that the term myxovirus, instead of being applied to a homogeneous population of viruses which exhibit myxophily, is actually being applied with varying degrees of inaccuracy to each of the following four groups:

(1) True myxoviruses, all of which have a distinct two-fold interaction with mucoprotein, and fall into one of two distinct sub-groups—the NDV sub-group or influenza sub-group.

(2) Viruses having a structure identical with the NDV group, but distinguishable in that the relation with mucoprotein is limited to attachment, that is, they do not elute, as they do not possess neuraminidase. These are some of the bovine parainfluenza 3's.

(3) The measles-rinderpest-distemper group, the members of which are also morphologically identical with the NDV sub-group, but have no interaction at all with mucoprotein.

(4) A number of viruses, which are compound helical RNA viruses, but are neither myxophilous nor structurally identical with either sub-group of myxovirus. Examples are rabies, vesicular stomatitis, and avian erythromyeloblastosis virus.

Table 1

	Compound helical RNA	Form like NDV	Neuraminidase-sensitive receptors on erythrocytes	Neuraminidase
Newcastle disease	+	+	+	+
Some bovine parainfluenza 3's	+	+	+	−
Measles	+	+	−	−
Vesicular stomatitis	+	−	−	−

Part of this information is summarized in Table 1, and it can be seen that instead of the aforementioned viruses falling into a number of distinct groups, they actually form a series without clearly demarcated boundaries. Since this is so, and if the term myxovirus is to be retained, it becomes necessary to decide to which viruses it is still applicable. If the word is used in its strictly limited sense, that is, for those viruses which are myxophilous, only the NDV and influenza sub-groups, which have the double interaction with mucoprotein, merit the term. However, this would mean that a large group of viruses all having identical morphology would be separated into different terminological categories—those which are myxophilous, such as NDV and mumps, and those which are not, that is, measles, rinderpest and distemper. In our opinion, this division would be artificial and we would like to put forward the following proposals (see Table 2):

Table 2. COMPOUND (ENVELOPED) RNA VIRUSES WITH HELICAL SYMMETRY

	Myxoviruses and pseudomyxoviruses	
	True myxoviruses	Pseudomyxoviruses
NDV sub-group	NDV Mumps Parainfluenza 1,2,3,4	Measles Rinderpest Distemper Some bovine parainfluenza 3's
Influenza sub-group	Influenza *A* (including human and animal influenza *A*'s) Influenza B Influenza C	? Bittner (ref. 11)
Other compound helical RNA viruses		
	Rabies Vesicular stomatitis Cocal Haemorrhagic disease of trout (ref. 12) Avian erythromyeloblastosis	

(1) All viruses having ribonucleoprotein in the form of a helix, and this helix enclosed in a partially cell-derived membrane (envelope), shall be included within the broad heading of the compound helical RNA group.

(2) This overall group would then be divided into two major categories. These would be (*a*) the myxoviruses and any virus having morphological identity with either of the two myxovirus sub-groups, and (*b*) the remainder of those included in (1).

(3) The first of the divisions propounded in (2), that is, the true myxoviruses and those morphologically identical with them, would be further sub-divided into those exhibiting, and those not exhibiting, myxophily. For the latter group we suggest the name pseudomyxovirus. There are, therefore, four categories:

(*a*) The influenza sub-group of myxoviruses.

(*b*) Pseudomyxoviruses, which have influenza morphology.

(*c*) The NDV sub-group of myxoviruses.

(*d*) Pseudomyxoviruses, which have NDV morphology.

The viruses contained within the division (2) (*b*) should, we suggest, be given merely the broad title of compound helical RNA viruses until further information becomes available.

We do not expect that the terminology we have suggested here will be generally adopted, but if workers in this field are more aware of the true implications of the word myxovirus and of the inter-relationships that exist between the myxoviruses and the broader compound helical RNA group, then this paper will have subtracted from, rather than contributed to, the present confusion about myxoviruses.

One of us (A. P. W.) is in receipt of a grant from the Medical Research Council.

A NEW MOLLUSCICIDE, *N*-TRITYLMORPHOLINE

By C. B. C. BOYCE and N. O. CROSSLAND
"Shell" Research, Ltd., Woodstock Agricultural Research Centre, Sittingbourne, Kent
AND
C. J. SHIFF
The Bilharziasis Research Laboratory, Salisbury, Rhodesia

BILHARZIASIS probably affects about 200 million people in the tropical and sub-tropical countries of the world, and in some areas is a very considerable public health problem. As a result of the introduction of new irrigation schemes the incidence of the disease is increasing.

The World Health Organization, in collaboration with the governments of the worst-affected countries, is now directing a major effort to break the transmission cycle of the parasite between man and the aquatic snails which act as intermediate hosts. If this is to meet with success comparable with that already achieved in the control of malaria, simple and effective means of breaking the transmission cycle must be developed. It has been shown[1,2] that it is possible to reduce the incidence of bilharziasis by controlling the intermediate host snails and it is generally considered that this method offers the greatest chance of immediate success.

This article reports the results of extensive field and laboratory trials with a new molluscicide, *N*-tritylmorpholine, which is not only highly effective against aquatic snails but also lends itself to simple methods of application.

(I)

N-tritylmorpholine (I) is a colourless, crystalline solid, m.p. 174°–6° C, which is stable to heat, sunlight and alkalis, but is hydrolysed under mildly acidic conditions to triphenylcarbinol which is not molluscicidal. It is almost insoluble in water (< 0·1 p.p.m.) but soluble in many organic solvents. It is conveniently formulated in tetrachloroethylene as an emulsifiable concentrate which gives satisfactory physical and molluscicidal performance and which is easy to handle in the field.

The concentration-mortality data which are given in Table 1 illustrate the activity of *N*-tritylmorpholine against some of the intermediate host snails of *Schistosoma mansoni* and *Schistosoma haematobium*, as well as of *Fasciola gigantica*. The median lethal concentrations (LC_{50}) for 1 h exposure periods are in the range of 0·1–0·5 p.p.m. ($3–15 \times 10^{-7}$ molar) while for 24-h exposures they are in the range 0·01–0·05 p.p.m. ($3–15 \times 10^{-8}$ molar). Similar molluscicidal activity has been observed in a number of field trials in several countries. For example, in Egypt no surviving *Bulinus truncatus* was found in a canal after the water had been treated continuously for 6 h to give a concentration of 0·25 p.p.m. of molluscicide. In Tanzania, *Biomphalaria pfeifferi* was killed in canals which had been treated for 6 h to give 0·1 p.p.m. of molluscicide, or for 15 min at a rate of 4 p.p.m. In Venezuela, *Australorbis glabratus* was killed in a canal after the water had been treated for 6 h to give a concentration of 0·25 p.p.m. of molluscicide.

However, despite the complete kill of snails in these trials, repopulation was relatively rapid because *N*-tritylmorpholine is not ovicidal and snail eggs were unaffected by the treatments. To control the whole of the snail population with this chemical we have developed a

Table 1. CONCENTRATIONS OF *N*-TRITYLMORPHOLINE, FOR VARIOUS PERIODS OF EXPOSURE, REQUIRED FOR 50 PER CENT AND 90 PER CENT KILLS OF SEVERAL SPECIES OF SNAIL (TEMPERATURE 21°–22° C AND A RECOVERY PERIOD OF 48 H IN FRESH WATER)

Snail species	Size and origin	Concentration of molluscicide (p.p.m.) 1 h LC_{50}	1 h LC_{90}	4 h LC_{50}	4 h LC_{90}	5 h LC_{50}	5 h LC_{90}	24 h LC_{50}	24 h LC_{90}
Australorbis glabatrus	12 mm diam. Laboratory strain	0·20	0·34	0·10	0·17			0·025	0·042
Bulinus truncatus	5 mm long Laboratory strain	0·45	1·0	0·11	0·25			0·053	0 10
Bulinus globosus	7·0–12·5 mm long. Wild	0 22	0·60			0·11	0·28	0·050	0 085
Biomphalaria pfeifferi	5·0–12·0 mm diam. Wild	0·13	0·25			0·034	0·062	0·014	0·023
Lymnaea natalensis	9·0–14·0 mm long. Wild					0 033	0 070		

simple method of treatment which shows great promise for use in irrigation systems. A simple, automatic device is used to apply the molluscicide continuously for several weeks to the intake of an irrigation system.

In initial small-scale trials at the Tanganyika Planting Co., Sugar Estate, near Moshi, Tanzania, no surviving *Biomphalaria pfeifferi* was found after canals had been continuously treated for 16 days to give a concentration of 0·02 p.p.m. of molluscicide in the water. In a later large-scale trial at the same estate, the treatment covered an area of 2,500 hectares which included five reservoirs, varying in capacity from 30,000 to 114,000 m^3, and an extensive system (about 200 km) of canals. The molluscicide was applied for 30 days at the main intake only of the irrigation system to give a concentration of 0·025 p.p.m. Chemical analysis of water samples taken throughout the system indicated that the molluscicide had penetrated most parts of the area within 5 days without a significant reduction in concentration. Snail mortality was assessed by sampling the natural population as well as by using caged snails. During the week before treatment 3,173 *Biomphalaria pfeifferi* were found in 426 samples. During the first week of treatment sixty-five snails were found in a similar series of samples, all in one of the reservoirs. In the following week only two snails were found, and in subsequent sampling none was found in the whole area. The method was thus efficient and eliminated many problems of water management. Furthermore, there was no interference with the irrigation of crops, and the labour force, which for conventional treatments with molluscicide would have involved about eighty people, including skilled staff, working full time for a week, was reduced to two unskilled people.

In another trial of the same technique in Rhodesia, the molluscicide was continuously introduced into a single concrete-lined irrigation canal, 22·5 km long, for 21 days to give a concentration of 0·02 p.p.m. Chemical analysis of water samples indicated that the molluscicide travelled the complete length of the canal without a significant reduction in concentration. Prior to the treatment the canal was populated by *Biomphalaria pfeifferi*, *Lymnaea natalensis* and large numbers of *Bulinus tropicus*. No living snails were found when the canal was re-examined 30 days after treatment, with the exception of a few *Bulinus tropicus*. In subsequent trials in Rhodesia and also in Egypt 0·04 p.p.m. of *N*-tritylmorpholine has proved to be fully effective against *Bulinus* spp.

An entirely different applicational problem is involved in the treatment of static water systems. *N*-tritylmorpholine, applied to give a concentration of 0·2–0·3 p.p.m., has been successfully used in six storage dams. These ranged in capacity from 500–10,000 m^3 and were typical of those which comprise a large proportion of the snail habitat in Rhodesia. In each case the snail population was eliminated or drastically reduced. A recent examination, 12 months after the initial treatment, has shown little evidence of repopulation.

Natural water systems frequently contain many intermittent pools, and drip-feed application in such places is usually impracticable. More effective treatment is generally possible by spraying the molluscicide from the banks. In Rhodesia a small branched water course, approximately 20 km long, was sprayed to achieve a final concentration of 0·5 p.p.m. of molluscicide in the water. The treatment was made during a period of limited breeding, and although a few surviving snails were found after 10 days none could be found one month after treatment.

A valuable feature of *N*-tritylmorpholine is its relatively high degree of selectivity. No effects on plants have been observed during any of the trials or in glasshouse tests. In one of the dams in Rhodesia, samples of the microfauna and microflora were taken before and after treatment with molluscicide. The results which are shown in Table 2 indicate that they were not significantly affected. The effect on fish populations in the trials described has been variable. Although *Barbus* and *Tilapia* spp. were killed in canals treated for 6 h to give 0·1 p.p.m. of molluscicide they survived continuous low-dosage treatments, for example, 0·025 p.p.m. for 30 days, which were fully effective against snails. It is therefore probable that an exploitable degree of selectivity between snails and fish exists and a field evaluation of this is in progress.

Table 2. ANALYSIS OF FAUNA SAMPLES

Fauna	Before treatment	After treatment
Turbellaria	10	6
Nematoda	43	19
Rotifera	3	78
Oligochaeta	7	6
Cladocera	145	103
Ostracoda	12	3
Copepoda	2,251	1,367
Ephemeroptera	302	206
Chironomidae	54	27
Acari	22	3

Nine composite samples each of three sweeps with a 12 cm diam. net were taken immediately before, and 1 week after, treatment with 0·2 p.p.m. of *N*-tritylmorpholine.

The acute oral toxicity of the technical material is partly dependent on the formulation. Concentrates in chlorinated solvents have an LD_{50} value in the range of 100–200 mg of active material per kg. However, when the compound is administered as a wettable powder or as a solution in dimethylsulphoxide the LD_{50} value is in the range of 1,200–2,000 mg/kg. The percutaneous LD_{50} to rats is greater than 1,000 mg/kg for all types of formulations tested. Rats were found to survive exposure for 90 days to 10,000 p.p.m. of *N*-tritylmorpholine in their diet. Histological changes such as bile duct proliferation were evident in the livers of rats receiving 3,000 p.p.m. or more, but no histopathological lesions have been seen in rats receiving 1,000 p.p.m. or less over a 90-day period[3]. It is therefore considered that the compound is safe for those using it and for those who may be exposed to water treated with it.

In view of these promising results, further trials are now being carried out on a larger scale to assess the value of this chemical as a weapon against bilharziasis.

ENGINEERING

Wind Forces and the Proximity of Cooling Towers to Each Other

RECENTLY a study has been completed in this Department of the effect of the geometry and spacing of particles on the forces experienced by them when fluid passes through the array. The results provide an interesting commentary on the recent destruction of three cooling towers at the Central Electricity Generating Board's Ferrybridge Power Station. The towers were destroyed in a severe gale on November 1, 1965.

In the experiments, spherical particles were supported in planes normal to the principal axis of flow, as shown in Fig. 1.

The spheres, 0·25 in. in diameter, were drilled centrally, threaded on to 0·01 in. diameter nylon line and fixed in position. The line was secured at either end to identical sheets of 'precision-perforated' plate, with the perforations aligned to give correct positioning of the spheres. The array of spheres, twenty planes deep with 225 spheres in each plane, was then mounted in a square, close-fitting 'Perspex' flow channel, liquid was passed through the array, and the drag forces on the spheres were obtained from measurements of pressure drop across the array.

The Reynolds number of flow was varied to span the range $0{\cdot}1–2 \times 10^3$. The spacing between centres of spheres in the plane normal to the main axis of flow, shown as x in Fig. 1, was varied from one to three diameters, and y, the spacing between planes, was varied from one to four diameters.

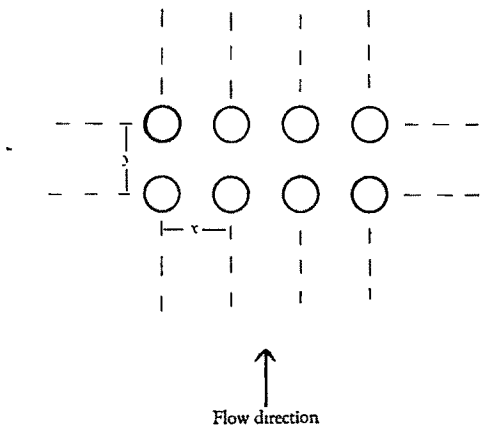

Fig. 1. Experimental layout

It was found that the drag forces on the individual spheres increased when y was increased, and decreased when x was increased. The forces measured were as much as 100 times as great as the forces on an isolated particle at the same Reynolds number of flow.

Fig. 2 shows the effect of a change in x at a constant interplanar separation of one diameter. The results are presented as the dependence of the drag coefficient (the ratio of force on unit projected area to twice the kinetic energy of the fluid) on Reynolds number. The relationship for x = one diameter is shown as line 1, and the coefficients for x = one and a half diameters, x = two diameters and the isolated single particle are shown as lines 2, 3 and 4. For Reynolds numbers greater than 100, the effect of bringing isolated particles into close proximity is to increase drag-forces by a factor of the order of 100.

The drag forces are less sensitive to variation in the interplanar distance y. The results for changing y when x remains constant at one diameter are shown in Fig. 3; for y = one diameter, the relationship is line 1, y = one and a half diameters—line 2, y = two diameters—line 3, y = four diameters—line 5, and the isolated particle—line 4. The individual drag coefficients are increased several-fold when the interplanar separation is increased.

Fig. 4 was published in *The Yorkshire Evening Post* on November 1, 1965 (reprinted by kind permission). The cooling towers were destroyed by winds of 75–90 m.p.h., the winds passing between the towers still standing and destroying the second row. Fig. 4 clearly shows that the tower separation between centres was slightly greater than one diameter—a position that suggests drag forces much higher than those experienced by an isolated tower at similar wind velocities.

The Reynolds number characterizing the interaction between the towers and winds of such high velocities would be in excess of 10^7, and as information on flow through groups of solids at these Reynolds numbers is very sparse indeed, we cannot be sure that the interaction between fluid and bodies will be similar to that observed at lower Reynolds numbers. However, the general reasons for the increase of drag coefficient due to proximity of

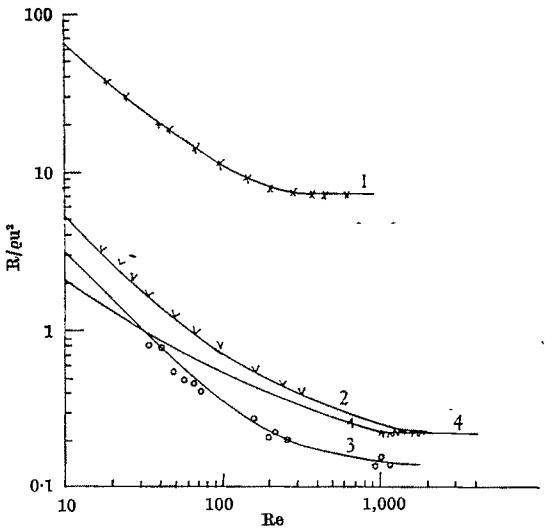

Fig. 2. (1) x = 0 25 in., y = 0·25 in.; (2) x = 0 375 in., y = 0·25 in.; (3) x = 0·5 in., y = 0·25 in.; (4) single sphere

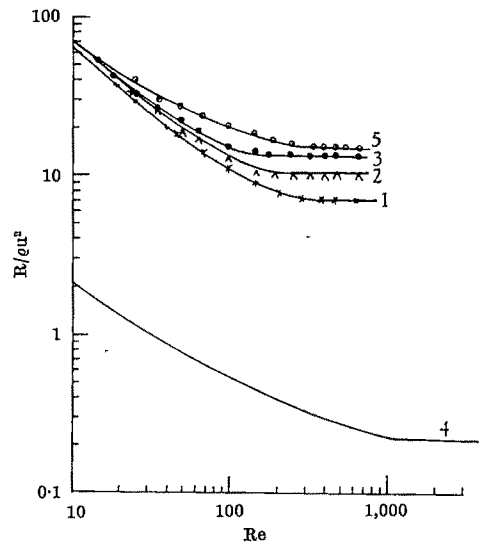

Fig 3. (1) x = 0·25 in., y = 0·25 in.; (2) x = 0·25 in., y = 0 375 in; (3) x = 0 25 in., y = 0 5 in.; (4) single sphere; (5) x = 0 25 in., y = 1 in.

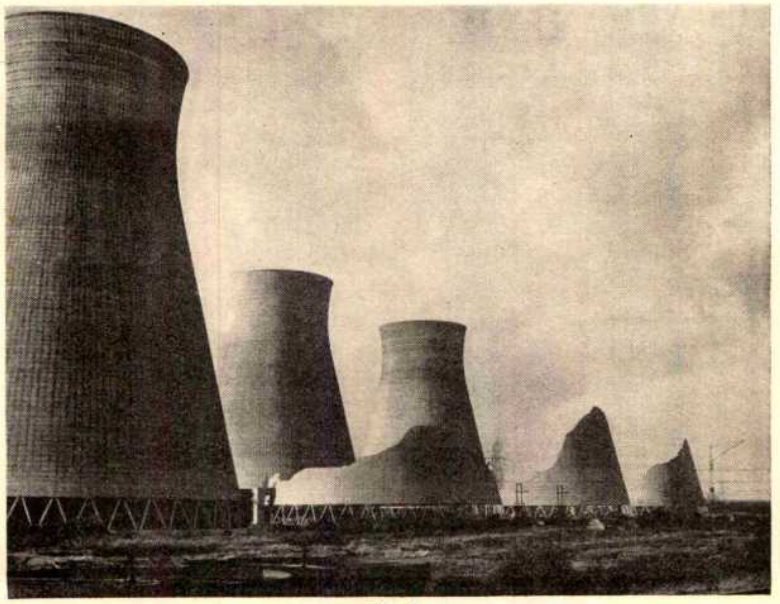

Fig. 4

bodies will be the same even at higher Reynolds numbers. The findings summarized here suggest that in view of uncertainty in wind direction, if the proximity of the cooling towers to neighbours is smaller than 2–2·5 diameters between centres, special provisions for the greater forces due to wind interaction should be made. The particular influence of geometry on drag forces for cooling towers will be somewhat different because of the shape, and because of the higher level of Reynolds numbers, but it is probable that the general nature of the pattern of interaction will be similar.

We thank the Science Research Council for financial support in these investigations.

PHYSICS

Debris Particles from the Second Chinese Nuclear Bomb Test

ON May 14, 1965, the Chinese exploded their second nuclear bomb (*Hsinhua News Agency*, May 14, 1965). Debris first appeared over Sweden in an upper-air sample on May 24, 1965, which was also the strongest sample we collected from this test. Soon after, debris particles were also found in ground air (some of them stronger and larger than the strongest upper-air-borne ones).

The debris was examined in normal routine investigations in which autoradiographs were prepared of the air filters. Investigations were also undertaken of β-disintegration and γ-spectrography, using bulk samples as well as individual particles and particles grouped according to their class of radioactivity (in order to investigate fractionation phenomena)[1]. Finally, particles of all the classes of radioactivity available were prepared and treated according to reversal-autoradiographic methods in order that they could be individually measured and investigated microscopically[2–5].

Unlike the first Chinese test[2], the colour of the particles was remarkably uniform. They varied over a comparably narrow range from colourless to yellow to reddish yellow; sometimes they had a greyish, 'dirty' appearance, but they were always transparent. No optical activity was observed. The particles were for the main spherical (although seldom perfectly so); however, elongated ones were frequently observed, and these were sometimes more elongated than had been observed in earlier (mainly U.S.S.R.) tests (see refs. 2, 5 and 6).

The activity versus particle size of many samples at various ages between 70 and 110 days was investigated, and then recalculated to 100 days age with the aid of measured β-disintegration of some particles[1].

As can be seen in Fig. 1, the activity is strongly related to particle size. It should be noticed that, for the smaller particles, the activity increases faster than the volume. This phenomenon was observed earlier in a sample attributed to one of the first shots in the test series at Novaya Zemlya in the autumn of 1961 (ref. 5). (Even then the colour range of the particles was remarkably narrow, although all particles were red or reddish.) For purposes of comparison, the U.S.S.R. sample has been inserted schematically into Fig. 1. As can be seen, however, the specific activity of the Chinese particles is lower by a factor ~2. The average specific activity of the particles from the second Chinese test can be compared with similar investigations from other tests.

Specific activities of the U.S.S.R. tests from 1958 and 1961 range from about the same value as the second Chinese test, up to more than ten times greater[5]. A value obtained from a test carried out by the United States at Christmas Island in 1961 is about ten times higher[5], so also are those from the U.S.S.R. tests carried out in autumn 1962 (ref. 7). It is probable that these latter tests were air explosions[8].

The first Chinese test, which without doubt was a near-ground shot with considerable incorporation of ground material in the fire-ball, had specific activities almost a hundred times lower[2]. This value indicates an incorporation of ground material in the fire-ball in the order of magnitude of 1,000 tons which is in agreement with the statement that the test was a 20-kton explosion about 30–50 m above ground-level[8].

The high values from samples resulting from tests carried out by the U.S.S.R. and the United States, on the

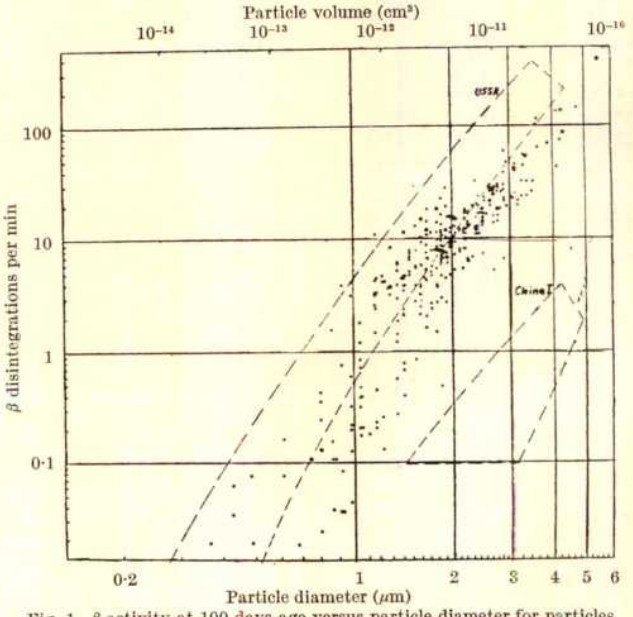

Fig. 1. β-activity at 100 days age versus particle diameter for particles from the second Chinese nuclear-weapon test. For purposes of comparison β-activities versus size for an U.S.S.R. sample (see text) and the first Chinese nuclear-weapon test (ref. 2) are shown schematically. The larger circles indicate particles which were measured in a β-counter. The others were indirectly measured with the help of the spot sizes on the autoradiograms (refs. 4 and 5)

other hand, seem to be remarkably low if it is supposed that only a minimum quantity of non-active material accompanied the fissile material in these explosions[9].

The values from the second Chinese test, however, indicate an intermediate inactive component of 10–100 tons. This finding would support the suggestion[8] that the bomb was a 20-kton device, exploded on a 100-m tower.

Dielectric Properties of Freshly Cleaved Muscovite Mica

THE unique property of mica to split easily into thin lamina has long been exploited in the manufacture of mica condensers. Quantitative investigations of the electrification of mica crystal and the force necessary to split the material were undertaken by Metsik[1]. Ruthberg *et al.*[2] investigated the a.c. properties of the adsorbed film on the surface of mica cleaved in moist air. This communication reports the findings of some investigations of the dielectric properties of freshly cleaved muscovite mica.

Dissipation factors were determined by means of a Boonton *Q*-meter with the aid of a specially designed parallel plate sample-holder consisting of a micrometer (driven earthed) and a 'Teflon' insulated plate.

In the interblock layer of muscovite crystals molecules of partly bound water are present through which contact between individual blocks is established at a number of points[3]. On splitting the crystals along their cleavage planes, separation of heterogeneous particles occurs and the surfaces become electrified. Due to the symmetrical structure of mica crystal with respect to the interblock layer and the non-uniform distribution of water molecules in that layer, electrification of the splitting surfaces is in the form of mosaic with charges of alternating sign.

The freshly split mica specimen may thus be regarded as a composite dielectric consisting of the mica specimen and a charged layer of partly bound water molecules. The dielectric properties of such a split mica crystal would be expected to depend on the properties not only of the mica but also of the surface layer. Assuming that the thickness of the surface layer is the same as in the various cleavage layers of mica crystals, the dissipation factor of the freshly split mica seems to depend on the thickness of the mica. Because the surface layer is a layer of charged water molecules, both its conductivity and dielectric constant are much higher than those of mica. An increase in the dissipation factor with decrease of mica thickness (Fig. 1) is thus to be expected, because the total a.c. resistance of the specimen also decreases. The dipolar nature of the charged layer of water molecules on the surface of the freshly split mica would be expected to be responsible for the nature of the frequency dissipation factor curve (Fig. 2).

In Figs. 1 and 2 it can be seen that the charged layer on the surface of the freshly split mica has a greater effect on the dissipation factor for green than for ruby muscovite. It appears that the green muscovite mica contains more partly bound water between any two lamina.

Of all the possible mechanisms for the dispersal of the charge, leakage along the surface seems to be the most probable. Heating above 100° C evaporates the surface film of moisture, leaving the surface free from any layer.

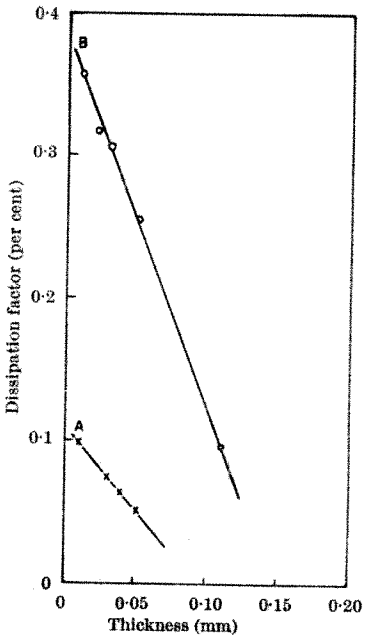

Fig. 1. Effect of thickness of mica on the dissipation factor of freshly split muscovite mica. *A*, Ruby muscovite; *B*, green muscovite

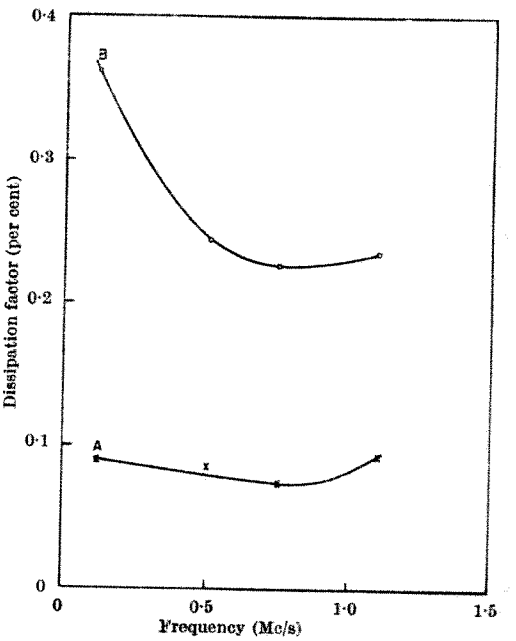

Fig. 2. Effect of frequency on the dissipation factor of freshly split muscovite mica. *A*, Ruby muscovite; *B*, green muscovite

Our findings concerning the improvement of dissipation factor with time and heating corroborated those of Ruthberg and Frenkel[2] and of Mahanti and Mandal[4] (Table 1).

To examine the effect of the charge on the properties of the freshly split mica, one specimen of mica was split

Table 1

(*a*) EFFECT OF TIME ON DISSIPATION FACTOR OF FRESHLY SPLIT MICA AT 500 KC/S

into two pieces, and the dissipation factor of each piece was determined. Thereafter the two pieces were recombined with the fresh surfaces facing each other and the dissipation factor was redetermined. It is observed from Table 2 that after recombination the dissipation factor of ruby muscovite changed from the initial value of the unsplit sample, but higher than the value of one of the split specimens, whereas the green muscovite almost regained the original value of the unsplit specimen. On recombination, it would be expected that the charges on the two faces would neutralize each other and that the properties exhibited could be those of an unsplit mica. (Consideration would have to be taken of the fact that during the process of recombining some air bubbles might stick between the layers, thereby increasing the dissipation factor[5]. Furthermore, leakage of charge as well as evaporation of surface moisture during the process of recombining might also affect the result.)

A few samples were split in alcohol to a thickness of about 0·025 mm. The dissipation factor at 500 kc/s was found to be much higher (0·270 per cent) than for samples split in atmosphere (0·073 per cent). During splitting in alcohol it is possible that some of the OH ions adhere to the charged layer of the freshly split mica, thereby increasing the dissipation factor.

GEOLOGY

Age and Polarity of the Turkana Lavas, North-west Kenya

THE extension of the Trap Series of Ethiopia into north-west Kenya has previously been suggested on stratigraphical and petrological grounds[1]. This area has recently been mapped on the basis of a reconnaissance[2], and the following succession suggested:

Rhyolites and andesites	*Tvr, Tvd*
Olivine basalts	Tvb_3
Phonolites and nephelinites	*Tvp*
Augite and analcime basalts	Tvb_1
Turkana grits	*Tm*

The age of the lavas has hitherto been based on a sparse mammalian fauna found in grits intercalated in basalts (Tvb_1 ?) at Lothidok, 25 km north-east of Lodwar. Initially thought Burdigalian[3], recent work[4] has suggested that it is younger (Up. Miocene) in age. Some fossil wood found in the rhyolites 60 km north of Lokitaung (*Dryoxylon* sp.) hints at a Mio-Pliocene age.

Four lavas have been dated (R. L. G.) at the University of Cambridge; Table 1 gives the results obtained on whole rock samples.

Field mapping showed that the basalts and rhyolites interdigitated in two localities, but neither were observed to overlie phonolites or nephelinites. The *Tvp* group is thus younger than both basalts (but could be older than the rhyolites), and comparable in age with the Lothidok grits and the Kapitian phonolites. The basalts (Tvb_1 ?) at

Table 1

Sites	K_2O (per cent)	Vol. of $^{40}Ar/g$ (mm^3)	Atmos. contam. (per cent)	Age (m. yr.)	Polarity
260/1 (Tvb_1)	1 31	$1\,406 \times 10^{-3}$ $1{\cdot}375 \times 10^{-3}$	38·9 36·7	$32{\cdot}2 \pm 0\,5$ $31{\cdot}5 \pm 0{\cdot}7$	*R*
264/5 (Tvb_1)	0 61	$4\,21\square \times 10^{-4}$ $4\,683 \times 10^{-4}$	48·2 46·4	$20{\cdot}7 \pm 0{\cdot}4$ $23{\cdot}0 \pm 0{\cdot}7$	*R*
293/4 (Tvb_2)	0·90	$7{\cdot}04 \times 10^{-4}$ $6\,99 \times 10^{-4}$	78 0 51 7	$23{\cdot}5 \pm 1{\cdot}1$ $23\,3 \pm 0\,2$	*R*
243/50 (*Tvp*)	3·84	$1\,90 \times 10^{-3}$ $1{\cdot}56 \times 10^{-3}$	54·3 66 5	$14{\cdot}9 \pm 0{\cdot}5$ $12{\cdot}5 \pm 0\,3$	*N*

Lothidok are unconformably overlain by basalts which are considered, on petrological grounds, to be equivalent to the Tvb_2 basalts in the north. However, palaeontological evidence indicates that the Lothidok basalts are much younger, and this discrepancy remains to be resolved.

The disagreement between samples 260/61 and the apparently underlying sample 264/65 might be due to loss of argon in sample 264/65, which shows a high chlorite content, or to local repetition of the succession by faulting: a similar wide scatter has been observed in five dates[6] (30–69 m. yr.) for the Abbai basalts of Ethiopia. The age and character of the Turkana basalts are comparable with those of the (Upper) Magdala Group of the Ethiopian trap series (25 and 33 m.yr.).

The lava succession is best seen in the Lokitaung gorge, where 5,000 ft. of lavas, pyroclastics and sediments are exposed. The complex faulting in the vicinity of Lokitaung has also complicated the sequence of magnetic polarities previously described in the Lokitaung section[6]. The samples of the dated lavas appear to be magnetically stable. The results of thermal and alternating-field cleaning were found to agree closely (Fig. 1), and the shapes of the alternating-field demagnetization curves of the saturation remanence and of the natural remanence were similar (Fig. 2). High-field heating showed only single curie points—a value of 450°–500° C for the basalts, and 150°–300° C for the phonolites and nephelinites (*Tvp*). The last-mentioned, on heating, developed a new, strongly magnetic component with a curie point of about 500°–550° C. Preliminary examinations of the opaque minerals showed a low state of oxidation, with some maghemitization.

The polarities of the sites radiometrically dated are given in Table 1. A further site, 262/3, probably in the same flow as 260/1, had a polarity which became reversed after cleaning by either thermal or alternating-field demagnetization.

The existence of both polarities above the Lokitaung fault has been confirmed by 150 block measurements made in the field (1965) using an astatic magnetometer. No reversed polarities were observed below the fault. The

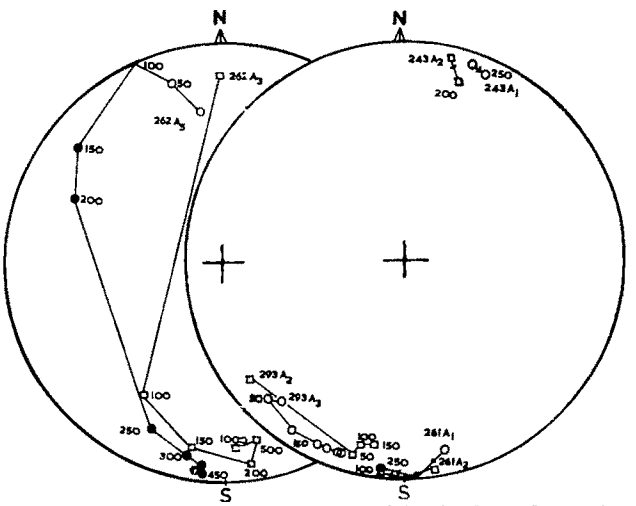

Fig. 1. Polar projection of typical changes of direction during demagnetization. ●, Dips down; ○, dips up: thermal demagnetization—numbers indicate temperatures in °C. ■, Dips down; □, dips up: alternating field demagnetization—numbers indicate peak field in oersteds

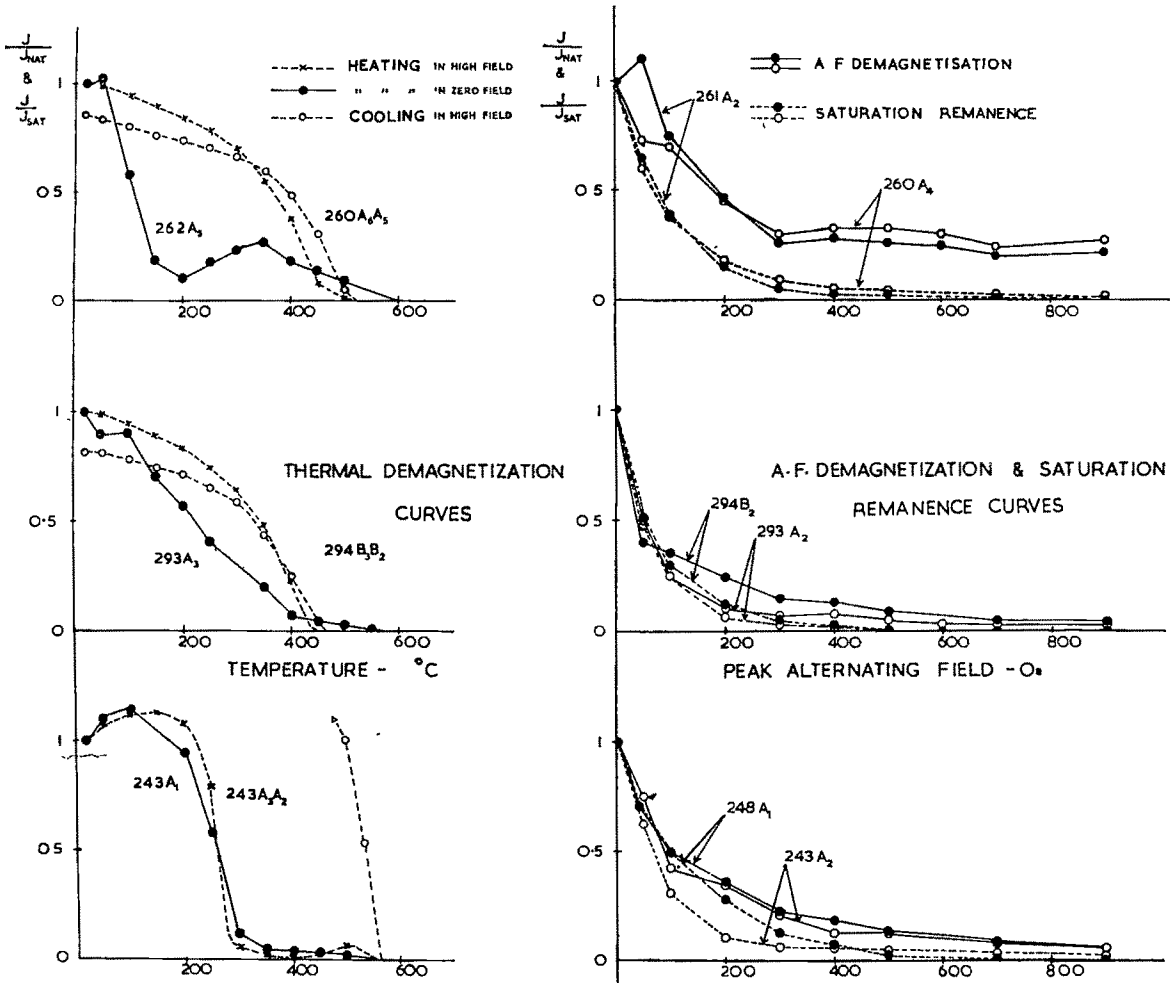

Fig. 2 Behaviour typical of dated sites during thermal and alternating-field demagnetization of natural remanent magnetism, alternating-field demagnetization of saturation remanence and high-field heating and cooling curves

reversed polarities occur in many rock types, an agglomerate horizon having a consistently reversed polarity, whereas highly mineralized fault breccias are magnetized normally.

Self-reversal and tectonic repetition are probably both present, but the foregoing observations support the previous suggestion of a field reversal in the Upper Oligocene preceded by a period of normal polarity.

We thank Prof. A. N. Hunter and Prof. P. M. S. Blackett for initiating the work, which has been carried out under a grant from the Rockefeller Foundation.

Jebel Marra Volcano, Sudan

HAMMERTON'S suggestion[1] that the volcano of Jebel Marra is dormant rather than extinct is not only of considerable vulcanological interest, but also of considerable practical importance to the future development of the area at present being investigated by the United Nations.

These investigations, started for the Sudan government by Hunting Technical Services, Limited, in the winter of 1957–58, and subsequently participated in by an ecologist and pedologists from the company for the United Nations Special Fund Jebel Marra Project, have disclosed new information regarding the formation of the volcano.

The 1957–58 geological investigations led to the recognition of three phases of volcanic activity at Jebel Marra. The first phase resulted in the accumulation of a great thickness of basalt and trachyte lavas and tuffs which form the main mass of the volcano. A period of relative quiescence ensued during which the newly formed mountain was subjected to intense sub-aerial erosion resulting in the formation of extensive piedmont alluvial and colluvial deposits. Relatively small quantities of basaltic lavas, intercalated in, or overlying, the alluvial deposits, represent the second volcanic phase. The third and final phase was entirely explosive and resulted in the formation of extensive deposits of tuff.

No new evidence regarding the age of volcanic activity was obtained in 1957–58. Since then White[2] has made observations which suggest that the ash eruptions may have continued into recent, possibly early historical, times.

Leaf impressions were also discovered in an exposure in the piedmont during the course of the second phase studies and are still being examined. Sandford[3] suggested previously that the crater was of recent formation.

Clearly the volcano proper has been inactive for many centuries, and hot springs and fumaroles could be regarded, therefore, as the final manifestations of the earlier activity. The interesting point is, however, that fumaroles have not been reported previously from Jebel Marra although the mountain has been traversed a number of times by different observers[4,5]. During the traverse made by the Hunting team in 1957–58, warm springs were recorded at Jebel Idwa, a subsidiary cone 2 km north of the main crater[6]. Water temperatures were not recorded, but the description 'warm' suggests that they were considerably lower than the values recorded by Hammerton. No fumaroles were observed.

Lynes has commented on the bad 'sulphurous' smells within the crater. These can be interpreted as arising from the decay of organic matter in the saline lake. No odours were noticed during the 1957–58 studies and one of us (G.E.W.) also recorded the lack of sulphurous smells during a visit in February 1964. However, by mid-1964, other team members were reporting strong odours of sulphur dioxide.

Thus the possibility that the fumaroles reported by Hammerton have formed during the last few years, and that there has been a rise in the geoisotherms below Jebel Marra, presaging a renewal of volcanic activity, cannot be entirely discounted. Workers in the area should be on the watch for any further signs of increasing activity.

GEOCHEMISTRY

Behaviour of Nickel during Magmatic Crystallization

THE enrichment of nickel in minerals such as olivine which appear at any early stage during fractional crystallization of magmas is well established[1,2]. This behaviour of nickel is contrary to all commonly accepted "rules" governing the distribution of minor elements during magmatic crystallization[3–6]. The behaviour is also anomalous when considered in relation to the binary system Mg_2SiO_4–Ni_2SiO_4 in which, on account of the higher melting-point of magnesium orthosilicate, early crystals are impoverished and late liquids enriched in nickel olivine[5]. Ringwood attributed the observed nickel enrichment in natural olivines to the preferential replacement of ferrous iron in the olivine structure, but this explanation is thermodynamically improbable. It was suggested recently by Ahrens[7] that the nickel–oxygen bond in olivine is stabilized by crystal-field effects, but no mechanism for the early uptake was given. An earlier interpretation[8] was apparently overlooked.

In order to account for the enrichment it is necessary to postulate that solid–liquid distribution coefficients may be inverted in systems of different chemical composition. Thus, in the binary system Mg_2SiO_4–Ni_2SiO_4 we have:

$$\left(\frac{Ni}{Mg}\right)_{olivine} < \left(\frac{Ni}{Mg}\right)_{liquid}$$

while in a basaltic system we find

$$\left(\frac{Ni}{Mg}\right)_{olivine} > \left(\frac{Ni}{Mg}\right)_{liquid}$$

A significant difference between these two systems is that, in the simple binary system, liquids are dominated by octahedral cation sites while both octahedral and tetrahedral sites are present in a basaltic liquid[8]. The crystal-field stabilization energy of divalent nickel ions in octahedral co-ordination in oxide structures (29·2 kcal) is larger than in tetrahedral co-ordination (8·6 kcal) and the resultant site preference energy (20·6 kcal) is the largest known for M^{2+} transition-metal ions[9,10]. The divalent nickel ion will occupy preferentially octahedral sites in a liquid and will enter tetrahedral sites only if thermal energy is comparable with site-preference energy or if the stability of the anionic framework of the liquid forces such entry. Magnesium may also favour octahedral sites through a comparable lattice energy effect, but the additional electronic stabilization to a transition-metal ion from crystal-field effects cannot be acquired by magnesium. These considerations applied to a 6 : 4 liquid will result in:

$$\Delta H_{fusion,\ Ni} > \Delta H_{fusion,\ Mg}$$

and

$$\Delta S_{fusion,\ Mg} > \Delta S_{fusion,\ Ni}$$

Both terms will lead to a higher melting-point or lower solubility for the nickel relative to the magnesium compound.

Table 1

	MgO	NiO	FeO
Melting-point (°C)	2,802	1,957	1,368
Heat of fusion (kcal/mole)	18·5	12·1	7·5
Entropy of fusion (cal/deg/mole)	5·8	5·4	4·6
Lattice energy (kcal/mole)	939	974	938

Previous attempts to explain the behaviour of nickel during magmatic crystallization illustrate the confusion that has developed in the geological literature over the use of melting-points as criteria of bond strengths[4–7,11]. Melting-point is related to the difference in bond energies and entropies of solid and liquid phases and not to the properties of either phase alone. At the melting-point (T), solid and liquid phases are in equilibrium. Therefore, $\Delta G_{fus} = 0$, and $\Delta H_{fus} = T\Delta S_{fus}$ or $(H_{liq} - H_{sol}) = T\ (S_{liq} - S_{sol})$, where H_{liq} H_{sol} and S_{liq} S_{sol} are the enthalpies and entropies of liquid and solid phases, respectively. Melting-points are determined by the relative values of heat of fusion, and entropy of fusion, high melting-points being favoured by a large ΔH_{fus} and small ΔS_{fus}. Generally, heats of fusion of binary compounds are one or two orders of magnitude smaller than lattice energies, which indicates that bond energies are comparable in the solid and liquid phases. Consider, for example, the oxides magnesium oxide, nickel monoxide and ferrous oxide, thermodynamic data for which are summarized in Table 1[12,13]. The lattice energies indicate that the nickel–oxygen bond energy is larger than magnesium–oxygen and iron–oxygen in the solid phase. There is a correlation between melting-point and heat of fusion; magnesium oxide has the largest heat of fusion and highest melting-point.

Similar correlations exist for most pairs of diadochic elements. Generally, compounds of B-sub-group elements or transition-metals have lower melting-points, smaller heats of fusion, and comparable or higher lattice energies than the A-sub-group compounds with which they are

matched[14]. These data indicate that melting-points cannot be used as criteria of bond energy in the solid state.

MINERALOGY

A Green Variety of Yoderite

THE spectacular purple magnesium–iron–aluminosilicate, yoderite[1,2], was described from Mautia Hill, Kongwa, Tanganyika (now Tanzania), by McKie in 1959. Since that date, no other occurrence of the mineral has been recorded and unpublished analyses of yoderite from variant associations at Mautia Hill have been found to be not significantly divergent.

During the field season of 1961 a party of geologists engaged on training traverses across Mautia Hill sent a parcel of specimens, including a small specimen of a quartz talc schist containing an emerald-green mineral, to the laboratories of the Geological Survey of Tanganyika, where it was discovered that the optical properties (α, 1·691; β, 1·693; γ, 1·712 (all $\pm 0{\cdot}003$); $2V_y$, 30°; with pleochroic scheme α, green; β, pale yellow; γ, yellow) and X-ray-powder diffraction pattern of the green mineral were closely similar to those of yoderite. The locality on Mautia Hill from which the specimen came was not recorded at the time of finding and subsequent visits to the hill have failed to rediscover it. In due course, single crystal X-ray studies served to confirm the identification of the green mineral as yoderite.

The green mineral has the same space group, its unit-cell dimensions are identical (within the limits of accuracy quoted by McKie[1]), and its diffraction pattern exhibits the same distinctive array of subsidiary (non-Bragg) reflexions as yoderite. The chemical composition of the green yoderite has been determined by Mr. J. H. Scoon as: SiO_2, 36·05; TiO_2, 0·10; Al_2O_3, 43·46; Fe_2O_3, 3·85; FeO, 1·72; MnO, $<0{\cdot}01$; MgO, 12·25; CaO, $<0{\cdot}01$; H_2O+ 3·13 (Σ100·56) corresponding to an average unit-cell content of $(Fe^{II}_{0\cdot16}Ti_{0\cdot01}Mg_{1\cdot99}Fe^{III}_{0\cdot32}Al_{3\cdot51})^{[5,6]}Al^{[5]}_{2\cdot00}(Al_{0\cdot07}Si_{3\cdot93})^{[4]}O_{17\cdot72}(OH)_{2\cdot28}$.

The estimation of Fe^{II} in purple yoderite[1] was never regarded as completely satisfactory, and its titanium and calcium contents have been shown by electron-probe analysis, kindly performed by Dr. J. V. P. Long, to have been significantly over-estimated; a new analysis (shortly to be published elsewhere) leads to an average unit-cell content of $(Ca_{<0\cdot01}Mn^{II}_{0\cdot03}Ti_{0\cdot01}Mg_{1\cdot98}Mn^{III}_{0\cdot06}Fe^{II}_{0\cdot41}Al_{3\cdot55})^{[5,6]}Al^{[5]}_{2\cdot00}(Al_{0\cdot08}Si_{3\cdot92})^{[4]}O_{18\cdot06}(OH)_{1\cdot94}$. Fe^{II} in green yoderite and excess oxygen in purple yoderite have been determined by the method of Ingamells[3] and both values are now thought to be reliable. The new analysis suggests that the colour of purple yoderite is to be attributed to the presence of the chromophore group Mn^{3+}—O—Mn^{2+} rather than Fe^{3+}—O—Fe^{2+} as was suggested earlier[1]; the green colour of manganese-deficient yoderite bears out this conclusion in that in the absence of the manganese chromophore the mineral exhibits much the same colour as a wide range of aluminosilicates of similar ferrous and ferric iron content.

CRYSTALLOGRAPHY

Crystallographic Data on New Rare Earth–Germanium and Silicon Compounds

DURING an investigation of samarium–germanium compounds of composition near Sm_5Ge_3, X-ray powder diffraction photographs indicated additional lines which could not be indexed on the basis of the hexagonal unit cell established for Sm_5Ge_3 by Gladyshevskii[1]. Investigations of single crystals showed the phase to be orthorhombic and of a new structure-type. An analysis of the crystal structure[2] showed the stoichiometry to be Sm_5Ge_4.

Five other lanthanide metals in combination with both germanium and silicon have now been examined for the occurrence of this phase. The preparations were made by arc-melting the component metals in an argon atmosphere. Lattice constants were derived from oscillation and Weissenberg photographs with an estimated accuracy of about 0·2–0·3 per cent.

The results are as follows: when germanium was used as the combining element, all the rare earths studied exhibited the orthorhombic 5 : 4 phase. The lattice constants, summarized in Table 1, follow a uniform lanthanide contraction so that the axial ratio, $a : b : c$, remains rather constant. It seems likely that most, if not all, of the rare-earth elements will form a germanide of this type.

Table 1. CRYSTALLOGRAPHIC DATA. SPACE GROUP. $Pn2_1a$ (FROM STRUCTURE DETERMINATION ON Sm_5Ge_4). UNIT CELL CONTAINS FOUR FORMULA UNITS

Compound	a (Å)	b (Å)	c (Å)	Volume (Å^3)
Nd_5Ge_4	7·86	15·06	7·93	939
Sm_5Ge_4	7·75	14·94	7·84	908
Gd_5Ge_4	7 69	14·75	7 76	880
Tb_5Ge_4	7·62	14·66	7 72	862
Er_5Ge_4	7·51	14·41	7·59	821
Y_5Ge_4	7·63	14·68	7 68	860
Tb_5Si_4	7·41	14·58	7 69	831
Er_5Si_4	7·27	14·32	7·58	789
Y_5Si_4	7·39	14 52	7·64	819

For the analogous silicon compounds, the situation is more complex. Three of the lanthanide elements, terbium, erbium and yttrium, formed Sm_5Ge_4-type compounds. It is probable that gadolinium also forms a similar compound. However, this preparation did not yield sufficiently large crystals for investigations to be carried out on individual ones. X-ray powder diffraction patterns, using chromium $K\alpha$ radiation and a 57·3-mm radius camera, indicated that gadolinium monosilicide[3] (FeB-type) was the major phase. The remaining lines fit a pattern expected for the orthorhombic 5 : 4 phase. Additional work is necessary to establish the occurrence of Gd_5Si_4 with absolute certainty. The results indicate that the orthorhombic R_5Si_4 compounds will occur most readily for the heavier lanthanides, that is those having smaller atomic radii.

In support of this, the silicide preparation using neodymium yielded crystals with a primitive tetragonal cell in which $a=7{\cdot}87$ Å and $c=14{\cdot}79$ Å. The unit cell volume corresponds with the orthorhombic 5 : 4 series;

however, substantial differences in the reflexion intensities indicate that this material has a different structure.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

Three Different Isomers in the Same Crystal

WE wish to report the discovery of a crystal in which three different isomers occur in the proportion 1 : 1 : 1.

In connexion with the problem of the identity of two different forms of diborinotetramethylbiphosphine[1], $BH_3(CH_3)_2P\text{-}P(CH_3)_2BH_3$, we have examined by X-ray diffraction the lump form having the lower vapour pressure. The crystals were found to be monoclinic, with $a = 6{\cdot}78$ Å, $b = 11{\cdot}64$ Å, $c = 20{\cdot}41$ Å, and $\beta = 95°$. The space group is $P2_1/c$, with six molecules per unit cell, a result which indicates that at least two of the six molecules must have centres of symmetry. It therefore follows that these two molecules are in the *trans* conformation. (This situation is reminiscent of the case of biphenylene, where Waser and Lu[2] found that crystals of the presumed biphenylene synthesized by Lothrop[3] were in space group $P2_1/c$ with six molecules per unit cell, a result which eliminated the non-centrosymmetric structures for the molecule of $C_{12}H_8$ favoured by Baker[4] and Coulson[5], and confirmed that Lothrop had, in fact, synthesized biphenylene.)

The structure was solved by means of a Patterson function calculated with three-dimensional Weissenberg data. The identification of the carbon and boron atoms was then carried out by three different and independent approaches.

(1) Least-squares refinement of the three positional and one thermal parameter per atom was carried out in which the form factor curve for carbon was used for all nine of the crystallographically distinct terminal ligands to phosphorus. The resulting values of the thermal parameters, B, are: (i) on $P(1)$: 6·2, 4·9 and 8·6; (ii) on $P(2)$: 5·3, 5 6 and 9·7; (iii) on $P(3)$ (in the crystallographically centric molecule): 4·1, 6·4 and 8·8. The higher B values for the last member of each of the three groups represent an attempt by the least-squares procedure to lower the form factor, and indicate that these three atoms are boron rather than carbon.

(2) Least-squares refinement was then continued, with the boron form factor curve used for the three atoms identified as such above. The following bond lengths to phosphorus were obtained: (i) to $P(1)$: 1·84, 1·85 and 1·93 Å; (ii) to $P(2)$: 1·87, 1·83 and 1·96 Å; (iii) to $P(3)$: 1·81, 1·82 and 1·97 Å. The shorter bond lengths correspond to *P–C*, the longer to *P–B*, and the three longer bonds involve the same three atoms already identified as boron. (The nine thermal parameters now range from 6·1–6·8 (boron) and 4·9–6·4 (carbon).)

(3) A three-dimensional electron density function, phased with the results of the least-squares calculation, gave the following relative peak heights, in electrons per Å^3: (i) $P(1)$, 23·1, ligands to $P(1)$, 4·62, 4·82 and 3·88; (ii) $P(2)$, 22·2, ligands to $P(2)$, 5·35, 5·65 and 3·66; (iii) $P(3)$, 24·0, ligands to $P(3)$, 5·63, 5·05 and 4·25. The three lowest peak heights correspond to the same three atoms previously identified as boron.

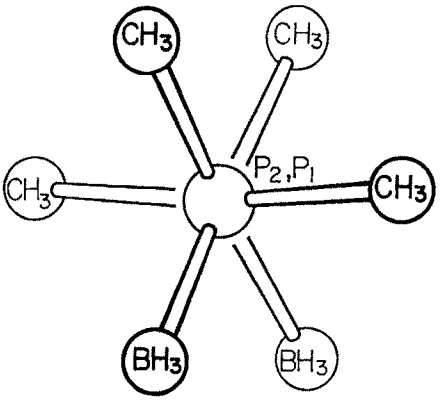

Fig. 1. View of the molecule as projected along the $P(1)$–$P(2)$ bond

There is thus little doubt concerning the identification of the boron and carbon atoms.

The molecule containing $P(3)$ and its centric counterpart is, of course, *trans*, as already pointed out. The molecule in the four-fold general position which contains $P(1)$ and $P(2)$ is not *trans*, but *gauche*, as may be seen in Fig. 1, which shows a projection of that molecule down the $P(1)$–$P(2)$ bond. The operations of the space group require that two of these asymmetric molecules in the unit cell have chirality opposite to the other two. The unit cell thus contains two *trans* molecules, two D-*gauche* molecules, and two L-*gauche* molecules.

The refinement of this structure is being continued. Meanwhile, we feel that the discovery of a crystal which consists of three different isomers is of more general interest.

This work was supported by the National Science Foundation. Fig. 1 was kindly prepared by Mrs. Maryellin Reinecke. We thank Prof. A. B. Burg for providing us with crystals suitable for X-ray analysis.

CHEMISTRY

A Non-seeded Electrically Augmented Flame System

THE augmentation of flames by the addition of electrical energy has recently received considerable attention. Most of the systems reported use a.c. augmenting power in one form or another and require the electrical conductivity of the flame to be enhanced by the addition of easily ionized seed material. By using d.c. augmentation, we have found it possible to operate a suitable augmented flame with no seed addition once the discharge has been established.

Briefly, the addition of distributed electrical energy to a turbulent flame increases the enthalpy of the flame gases by a form of ohmic heating. Karlovitz[1–3] has proposed that the dispersion of such a discharge depends on a high level of turbulence, such that the turbulence exchange time is less than the time for a discharge to break down into an arc filament. It is also necessary to increase the electrical conductivity of the flame by adding an easily ionized seed

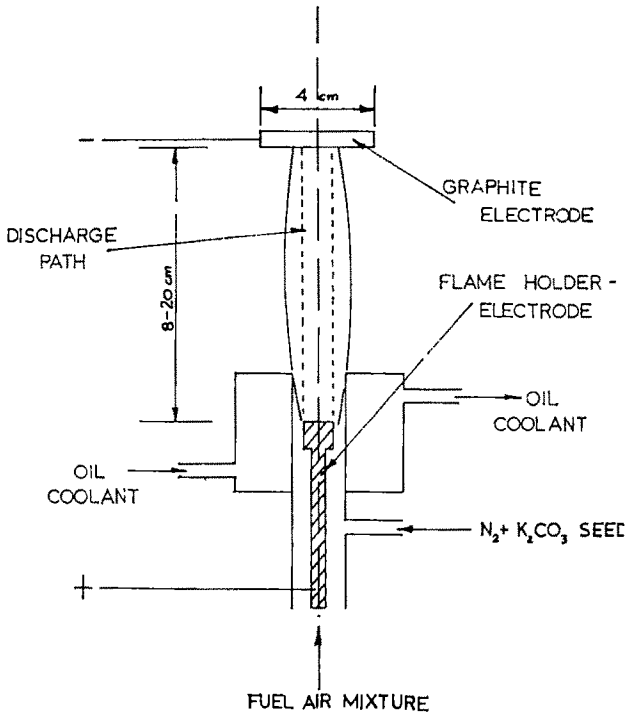

Fig. 1. Burner arrangement

material. Using a.c. augmenting power, Karlovitz found that once the discharge had been initiated, it was possible to reduce the concentration of potassium chloride seed material in the flame gases, but in order to maintain a steady discharge it was essential to continue seeding the flame.

The necessity for continuous seeding is a drawback. Seed materials, usually potassium salts, are expensive and, worse, corrosive. One of the aims of our work has been to reduce the seeding to a minimum and, if possible, to eliminate it altogether.

By using the configuration shown in Fig. 1, and a d.c. rather than an a.c. discharge, steady operation of the augmented flame has been found possible over a wide range of operating conditions, without any seed material being added, except when initiating the discharge. Once it has been established, the seed supply can be cut off.

Table 1. OPERATING CONDITIONS OF UNSEEDED D.C.-AUGMENTED HYDROCARBON GAS-AIR FLAMES

Burner	
Burner nozzle diameter, 1·875 cm	
Diameter of central electrode (flame holder), 1·25 cm

Non-enzymatic Formation of Nitrogen Gas

SINCE comprehensive treatment of the biochemical reduction of nitrate of Gayon and Dupetit[1] it has been generally assumed in denitrification studies that nitric oxide, and particularly nitrogen gas, evolved either from cell preparations or soil systems under moderate conditions of acidity (*p*H 5·0–7·0) and temperature (28°–30° C), are dissimilatory products of 'nitrate or nitrite respiration'[2–4]. Recent evidence has shown, however, that nitric oxide can also be formed from nitrite in sterile, moderately acid systems when certain transition-like metals are present[5]. Subsequent experiments to be presented in this communication further indicate that nitrogen gas can be formed as a result of reacting potassium nitrite and ferrous sulphate.

All experiments were carried out in electrolytic respirometer flasks with gas analyses being made with a Beckman '*GC*-2' gas chromatograph[6]. *p*H determinations were made using a Beckman 'model *G*' *p*H meter. The following reagents were used: aqueous potassium nitrite equivalent to 10,000 p.p.m. nitrogen; aqueous ferrous sulphate mixtures equivalent to 5,000 p.p.m. of iron, and brought to the appropriate *p*H values with the addition of potassium hydroxide; sulphuric acid adjusted to *p*H 3·0. Where potassium hydroxide was added, *p*H determinations were recorded only after equilibria were established.

Flask preparations were obtained by pipetting 20 ml. of the ferrous sulphate or sulphuric acid directly into the open flasks and then inserting an appropriate vial into which 20 ml. of the potassium nitrite was pipetted. After sealing the flasks in the usual manner[6], and flushing with purified helium for 30 min, the vials were tipped, allowing the observed reactions to proceed. All experiments were conducted at 29° ± 1° C. Values given are averages of duplicate determinations.

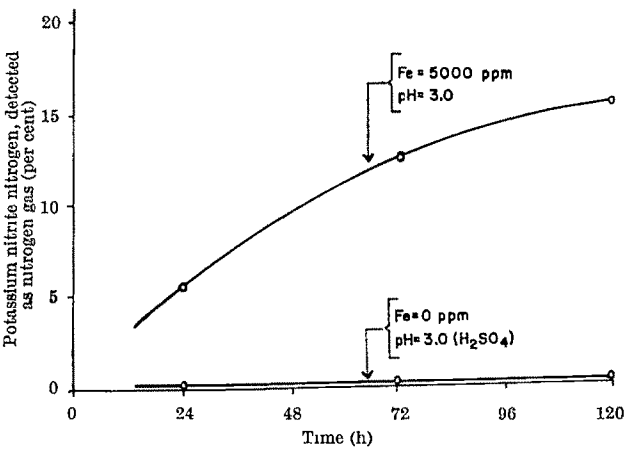

Fig. 1. Formation of nitrogen from potassium nitrite and ferrous sulphate

The formation of nitrogen by reacting nitrite ions with iron or other closely related metals is not well defined. (We were unable to locate specific experimental evidence attesting to the observed reactions.) However, it is apparent from Fig. 1 that nitrogen was evolved in the presence of the iron reagent. It is noteworthy that no nitrogen was detected at 0 p.p.m. iron when we attempted to react the nitrite ions with sulphuric acid. Clearly the observed reaction was iron-dependent. But it is not clear whether the reaction involved any intermediates, such as nitrogen oxides and/or metal complexes[7]. It will be remembered that nitric oxide is formed under similar conditions and was, indeed, detected in these experiments except where iron was omitted. At no time was nitrous oxide detected.

In order to determine what effect *p*H might have, NO_2^- was reacted with ferrous sulphate adjusted to *p*H 6·4. The results are shown in Table 1.

Table 1

Time	Fe p.p.m.	pH	Percentage nitrogen in KNO_2 recovered as nitrogen gas
72 h	5,000	3·0	13·0
72 h	5,000	6·4	15·0

Little or no effect was observed, that is to say, with decreased acidity there was little change in the quantity of nitrogen detected. Nevertheless the possibility existed that nitrogen formation might relate to *p*H, as it has been established that acidic conditions generally favour the reduced state of transition-like metals which is more active than the oxidized form with respect to nitric oxide formation[8]. The effect of *p*H, however, on oxidation-reduction processes is exceedingly complex and may vary with different ranges of *p*H. And, as emphasized by Hewitt[9], even though the effect is complicated it is not necessarily great.

The implications of the data presented here are far-reaching and may be related to denitrifying systems since intermediate fermentation products formed under anaerobic conditions may participate directly or indirectly in the reduction of such metals as iron[10]. Thus the very conditions which favour classical denitrification may be expected to promote metal-nitrite reactions. This possibility places in question the status of nitrogen as a strictly biochemical product. It appears that the key intermediate between the gaseous and non-gaseous states is the nitrite ion whether it arises via denitrification, nitrification, nitrate reduction, direct addition or by some anomalous route. The speculative scheme given in Fig. 2 seems appropriate at this time. As indicated, the formation of nitrogen may be a direct effect or may occur through one or more intermediates. The nitrite ion and nitric oxide are reactive with metal solutions and commonly form complexes with them such as $(FeNO(H_2O)_5)^{2+}$ formed from nitric oxide and aqueous ferrous sulphate[11]. These complexes may be stable or reactive depending on the conditions of the total system. It is conceivable, therefore, that the complexes could play an important part irrespective of whether they are products of nitrite or nitric oxide reactivity. Another possibility is that the metals may react directly with nitrite or nitric oxide without forming easily recognizable intermediate or complexes. Whatever the actual mechanism(s) in operation, it is reasonable to theorize that both nitrite and nitric oxide may be reduced to nitrogen by active metals. Of course a more thorough understanding of metal-nitrite reactions is needed to test the validity of the pathways proposed.

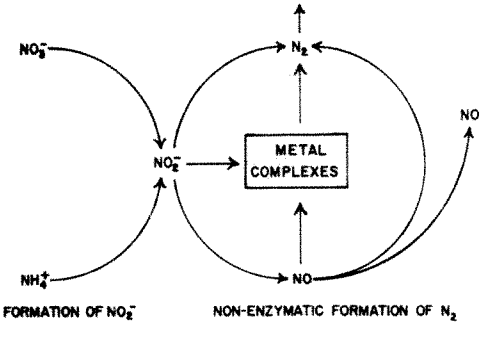

Fig. 2. Schematic diagram of hypothetical non-enzymatic pathways of metal-nitrite reactions leading to nitrogen production

Non-enzymatic formation of nitrogen mediated by transition-like metals may help to clarify heretofore inexplicable losses of mineral nitrogen from both soil and cell preparations. In addition these findings may partially explain certain data which have been interpreted as 'aerobic denitrification'[12]. Additional parameters which may affect the reaction reported here are being investigated.

Reaction of 2,2′-Diphenyl-1-picrylhydrazyl with Hydroperoxides

It has been reported that the stable free-radical 2,2′-diphenyl-1-picrylhydrazyl (DPPH) is entirely unsatisfactory for most rate measurements of free-radical production[1,2]. These findings have been confirmed and extended during our investigations on the use of DPPH for the quantitative determination of hydroperoxides of unsaturated fatty acids[3]. We have found that the rate of the reaction of DPPH with different hydroperoxides depends on the concentration of both reactants. Furthermore, we have discovered that while the rate of the heat-induced decomposition of, for example, methyl oleate hydroperoxides is 0·01 per cent/h, at 70° C, the rate increases a thousandfold in the presence of DPPH[4]. It was, therefore, concluded that the function of DPPH is not that of a reliable ·OH counting device, which may reflect the primary O-O bond cleavage of long-chain, unsaturated fatty hydroperoxides. For the same reasons, it was thought that the actual chemical reaction between DPPH and hydroperoxides should be different from that previously reported[5–8].

This communication reports an investigation of the reaction between DPPH and hydroperoxides, as well as the identity of the predominant reaction products.

250 ml. of chromatographically purified *n*-heptane containing 1×10^{-4} M concentrations of DPPH and pure methyl oleate or linoleate or linolenate hydroperoxides were heated under purified nitrogen at 70° C until all measurable absorbance at 517 mμ had disappeared. Similar blank experiments showed a negligible change in the absorbance of DPPH.

The solvent was removed in a rotating evaporator heated at 30° C in a water bath, under a vacuum of 15 mm of mercury. The powders thus recovered were dissolved in a small amount of chloroform and the solutions were spotted on thin-layer plates prepared from 'Silicagel-*G*', 0·3 mm thick. Chromatographically purified benzene was used as mobile phase.

Several spots became visible when the plates were sprayed with molybdophosphoric acid, while the powder from the blank gave one spot only (DPPH). Similar chromatograms did not give any colour reaction with potassium iodide or 2,4-dinitrophenylhydrazine.

After developing fresh plates by the aforementioned method, all spots were scraped off, eluted with chloroform or benzene, combined and filtered. Most of the solutions were respotted and the plates were developed with a

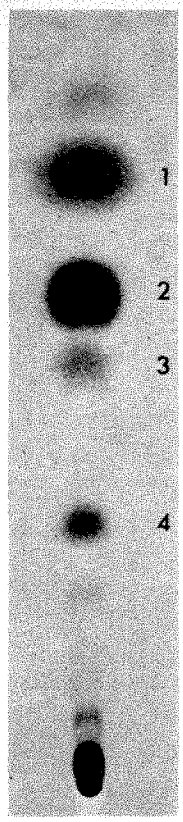

Fig. 1. Thin-layer chromatography of DPPH-hydroperoxides reaction mixture, developed by spraying with molybdophosphoric acid

variety of solvents to ascertain the purity of the eluted compounds.

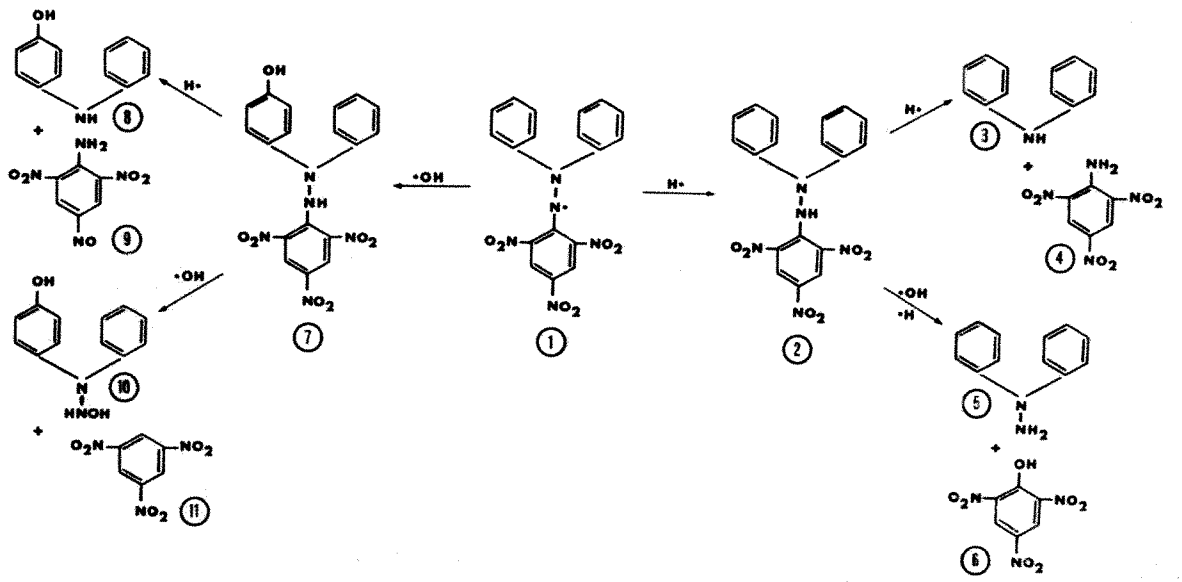
The above experiments were carried out both under diffused daylight and in the dark.

The ultra-violet, visible, and mass spectra of all fractions, as well as of model compounds, were recorded, using a 'Unicam' *SP* 800 or 200 recording spectrophotometer or an *MS* 2 *H* and *MS* 9 'Vickers' mass spectrometer.

The decomposition of DPPH after reaction with hydroperoxides is illustrated in Fig. 1, while the compounds identified as corresponding to the numbered spots and representing approximately 85 per cent of the total are shown in Table 1. Under the conditions of the experiments and the solvents used, all decomposition products of the hydroperoxides have moved together with the solvent front.

Table 1. COMPARISON OF ABSORPTION MAXIMA AND MASS OF VARIOUS SPOTS ISOLATED BY THIN-LAYER CHROMATOGRAPHY AND THOSE OF MODEL COMPOUNDS

Spot*	% of total	Compound	Absorption maxima (mμ) Known	Found	Mass Known	Found
1	30–35	Diphenylamine	286	285	169·2	169
		Hydroxyphenyl-phenylamine†			185·2	185
		Diphenylhydrazine†			184·2	183
		2-hydroxyphenyl-2′-phenyl-1-hydroxyhydrazine†			216·2	216
2	30–35	2,2′-diphenyl-1-picrylhydrazine	250, 315	250, 315	395·3	395
		2-hydroxyphenyl-2′-phenyl-1-picrylhydrazine	294, 375	294, 375	411·3	412
3	5	2,2′-diphenyl-1-picrylhydrazyl	332, 517	332, 517	394·3	394
4	15	Picramide	312, 396	310, 395	227·1	227
		Trinitrobenzene	303, 370	301, 369	213·1	214
		Picric acid	352	352	229·1	229



* As in Fig. 1.

† The absorption maxima are not known.

The formation of all products identified cannot be explained as taking place only by a direct and/or secondary ·OH attack on the DPPH molecule. Only compounds 7, 10 and 11 may be predicted as resulting from destruction of DPPH by the trapping of ·OH radicals, yet it was found that compounds 7, 10 and 11 actually consist of less than 15 per cent of the total amount of identified products. Since identical results were obtained when the reaction of DPPH with hydroperoxides was carried out in diffused daylight or in the dark, there is no question of photoreduction of DPPH[9], nor of photo-oxidation of the solvent. No effect on the DPPH has been observed when blank experiments were carried out. In addition, the absence of water from the reaction mixture has been strictly assured, thus excluding the possibility of hydrolysis.

It is, therefore, reasonable to assume that most of the decomposition products of DPPH are formed by a combined ·OH and ·H attack. The latter may be visualized as being abstracted from any of the known labile sites of the long-chain unsaturated fatty hydroperoxides.

The results also give evidence that the addition of the hydroperoxide decomposition products to the intact DPPH takes place on the phenyl group and not at the —N free-radical site, as formerly suggested[5–8]. Further-

more, since only (DPPH)OH and (DPPH)H addition products have been identified, and not even one product isolated in measurable amounts gave mass higher than 412 in the mass spectrum, any reaction between RO· or ROO· and DPPH may be considered as negligible.

Reliability of the Thiobarbituric Acid Test in the Presence of Inorganic Iron

IN recent years, the validity of the 2-thiobarbituric acid (TBA) test for the determination of oxidative deterioration in animal and plant tissues, or their food products, has been challenged. However, since most authors prefer to use their own modification of a TBA test, comparison of results obtained at different laboratories is virtually impossible. Considerable confusion is therefore created by these claims, rather than clarification of the subject.

It has been demonstrated time and again that the TBA test is one of the most reliable tests for measuring the extent of oxidative deterioration in substrates containing unsaturated fatty acids. Only in the case of measurements involving either the initial or the very late stages of oxidation is the TBA test not very valid.

The TBA test measures the amount of malonaldehyde which is formed during the oxidation of the unsaturated fatty acids[1]. Malonaldehyde is primarily produced from the oxidative cleavage of 2-enals and 2,4-di-enals[2], which in turn are products of the breakdown of hydroperoxides[3]. Therefore no malonaldehyde is expected to be found at the early stages of oxidation, during which the rate of decomposition of hydroperoxides is negligible.

On the other hand, it has been shown conclusively that malonaldehyde does not accumulate as a stable end product during the oxidation of unsaturated fatty acids, but that it is destroyed at the very late stages of oxidation[4]. It is not, therefore, surprising that malonaldehyde cannot be found after an 18 h oxidation of methyl linolenate under ultra-violet radiation at 45° C (ref. 5).

It has been reported recently that inorganic iron present in the medium during the performance of the TBA test gives much higher results, in comparison with tests during which no iron is present[6]. Because of the extremely high concentration of free iron used in this investigation (10,000–100,000 p.p.m.), which is scarcely to be expected in any animal or plant, we have re-investigated the effects of iron on the TBA test.

The TBA methods used for assay were those described in previous publications[7,8].

100–5,000 p.p.m. of ferric ions were added before or after distillation to 0·1–1 g of methyl linolenate, rape seed, soyabean or groundnut oil, which were oxidized to a peroxide value (P.V.) from 1 to 40 mmoles/kg[9]. After the TBA test was carried out on a portion of the distillate[7,8] and under a variety of conditions, including heating at 20° C or 100° C, in water or 90 per cent acetic acid solution, the absorbance of all samples was measured at 530 mμ in a 'Unicam' *SP* 800 recording spectrophotometer. In no case was any significant difference in absorbance observed between the samples containing iron and the appropriate blanks. However, when 10,000–100,000 p.p.m. of ferric ions were added to the same oils and the experiments were repeated, significant increase in absorbance was observed in the samples containing iron before distillation, for example, the absorbance was increased from 0·9 to 2·8 by the presence of ferric ions. This increase was directly proportional to the P.V. of the substrate before the test, and it was much lower when the test was performed in water at 20° C than in acid at 100° C.

The effects of iron on TBA and the TBA-malonaldehyde complex[10] were investigated because of suggestions that the increased absorbance may be due to formation of metal chelates.

Ferric ions were added to 1×10^{-2} M TBA or 5×10^{-5} M TBA-malonaldehyde solutions in water or acetic acid, which were then heated to 20° C or 100° C for 15 h or 40 min respectively. In all cases, even when the concentration of iron was as high as 300,000 p.p.m., no difference in absorbance at 530 mμ was observed from that of the blanks. It is, therefore, concluded that inorganic iron does not form complexes with the above compounds, or if it does, the change in absorbance at 530 mμ is negligible and it does not alter the results of the TBA test.

The effects of iron on malonaldehyde have been investigated previously[11]. It has been shown that although malonaldehyde chelates iron, the recovery by distillation is not affected by iron chelation even with 10 : 1 ratios of iron to malonaldehyde.

The results of the experiments show that ferric ions present in a medium up to a concentration of 5,000 p.p.m. do not alter the results of the TBA test. Higher concentrations of iron induce changes which may be attributed to an acceleration of the decomposition of malonaldehyde precursors by the iron[12] rather than to formation of iron chelates. Since the changes induced by iron take place almost exclusively when the test is performed in acid medium and at high temperatures, the use of milder conditions during the performance of the TBA test[8] is recommended.

Exchange Reactions in the Radiolysis of Adsorbed Hydrocarbons

THE radiolysis of hydrocarbons adsorbed on silica gel was first investigated by Caffrey and Allen[1] and later by Sutherland and Allen[2], who found that the hydrogen yield was several times larger than that expected from the amount of energy absorbed directly by the hydrocarbon itself. In an attempt to investigate more thoroughly the role of the silica gel, we have studied the radiolysis of *cyclo*hexane-d_{12} adsorbed at low coverages on silica gel.

Silica gel (50–60 mesh) was obtained from Analabs, Inc., Hamden, Connecticut, and had a surface area of

710 ± 60 m²/g, as calculated by the Brunauer–Emmett–Teller (B.E.T.) method using nitrogen as the adsorbate. The gel was dried by heating at 500° C in air for 72 h or more, and was then evacuated at 400° C to 10^{-6} mm mercury for 18 h. This procedure should give a silica gel surface about one-half covered with hydroxyl groups[3]. The *cyclo*hexane-d_{12} (Merck, Sharp and Dohme of Canada, Ltd.) was shaken with concentrated sulphuric acid and distilled. Samples were irradiated at room temperature with a cobalt-60 γ-ray source at a dose rate of about 9×10^{17} eV/g min to doses of between 3 and 90×10^{18} eV/g. All experiments reported here were carried out at a surface coverage of *cyclo*hexane of 0·51 per cent of a monolayer, taking the area of the *cyclo*hexane molecule[4] to be 39 Å².

The yields of hydrogen as a function of dose are shown in Fig. 1, the G values being the number of molecules of hydrogen produced for every 100 eV absorbed in the entire sample. The yields of hydrogen and deuterium hydride are much larger than that of deuterium, showing that chemical reactions involving the hydrogen atoms of the gel are at least as important as the decomposition of the hydrocarbon itself. No hydrogen whatsoever was obtained by irradiation of the gel alone.

At low doses, the primary liquid products are those observed in liquid-phase radiolysis[5], that is, bi*cyclo*hexyl and *cyclo*hexene; these can be recovered in amounts equivalent to the hydrogen yield (Fig. 2). The yields of these two products are extremely dose-dependent.

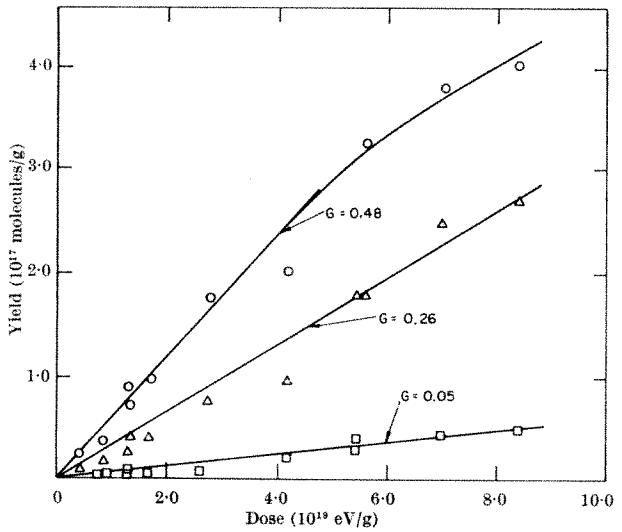

Fig. 1. Hydrogen yields for the irradiation of *cyclo*hexane-d_{12} adsorbed on silica gel. ○, Hydrogen; △, deuterium hydride; □, deuterium

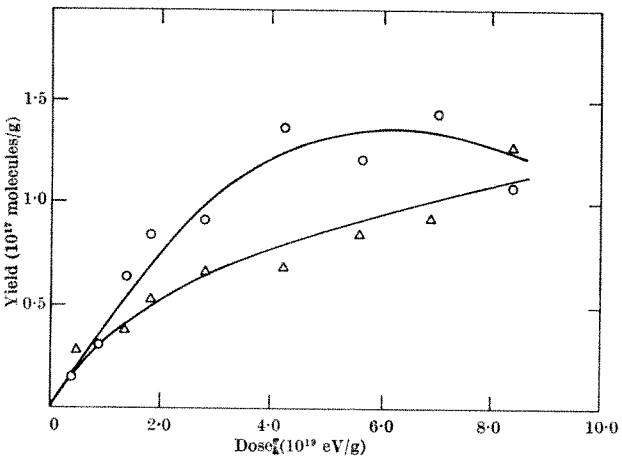

Fig. 2. Yields of the major liquid products of the radiolysis of *cyclo*hexane-d_{12} adsorbed on silica gel. ○, Bi*cyclo*hexyl; △, *cyclo*hexene

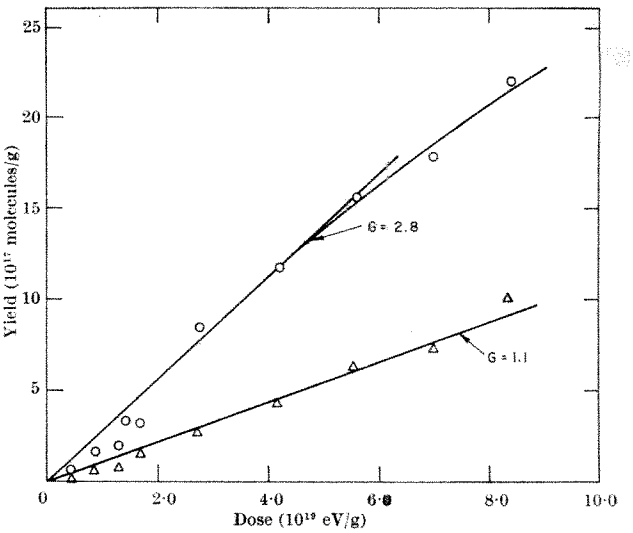

Fig. 3. Radiation-induced exchange of *cyclo*hexane-d_{12} adsorbed on silica gel. ○, $C_6D_{11}H$; △, $C_6D_{10}H_2$

This dose-dependence explains the very different products obtained by Zhabrova *et al.*[6], who irradiated *cyclo*hexane on silica gel to the much higher dose of $5{\cdot}4 \times 10^{21}$ eV/g.

Our most important observation is that the bi*cyclo*hexyl was highly exchanged. Mass spectral analysis of this product showed parent-ion peaks with masses covering the range 188 ($C_{12}D_{22}$) to 182 ($C_{12}D_{16}H_6$); masses 188 and 187 were about equal, with smaller amounts of the more highly exchanged bi*cyclo*hexyls.

The recovered *cyclo*hexane was examined for exchange and the yields of $C_6D_{11}H$ and $C_6D_{10}H_2$ are shown in Fig. 3. G(H), the total number of hydrogen atoms found in the *cyclo*hexane-d_{12} per 100 eV absorbed in the system, was 8 ± 2, which shows the existence of chemical processes which would not be detected by simple measurements of decomposition products. Although a radiation-induced exchange between light methane and deuterated silica gel has been observed by Kohn[7], this is the first comparison of exchange rate and decomposition rate in a system in which the hydrocarbon is strongly adsorbed.

In the present system (*cyclo*hexane on silica gel) radiolysis in the adsorbed state involves much more than an energy transfer from the solid to the adsorbate. Many efficient exchange reactions occur with even greater yield than the decomposition.

We thank Dr. J. A. Stone for many helpful discussions, and especially for advice on gas chromatographic techniques.

Pulse Radiolysis of Aqueous Eosin

WE have been investigating the radiolysis of aqueous eosin induced by 1 μsec pulses of 33-MeV electrons from a Linac accelerator at approximately 1,200 rads per pulse. The flash spectra were taken on a Hilger *E*498 quartz prism spectrograph by synchronizing a 15 μsec (overall) flash from an E.G. and G. type *FX*-33 flash-tube to give

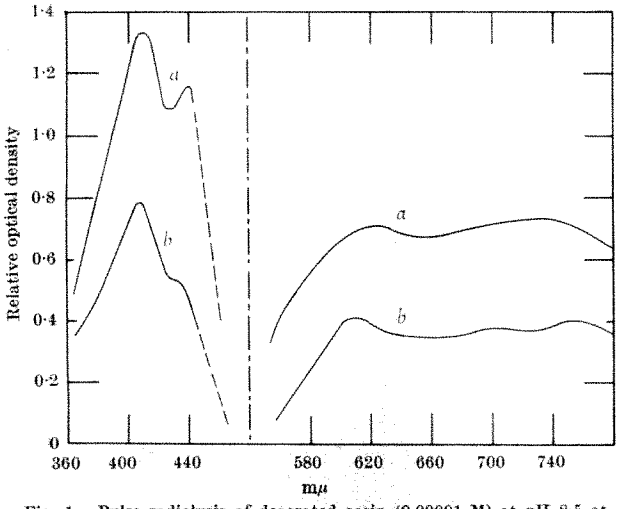

Fig. 1. Pulse radiolysis of deaerated eosin (0·00001 M) at *p*H 8·5 at 5 μsec (*a*) and 500 μsec (*b*) time delay. The spectra were taken on a Kodak '*I–N*' spectroscopic plate and are not corrected for emulsion sensitivity

a minimum 5 μsec peak-to-peak time delay. The rate data were obtained by measuring the transmission transients in narrow wave-length bands by means of photoelectric detection and oscilloscope display, with an Osram *XBO*-450 xenon arc as the monitoring lamp. The irradiations were performed in a 5-cm long fused-silica cell, located in a two-pass optical system, which could be evacuated to 2×10^{-6} mm mercury. The solutions were prepared with chromatographically purified eosin–sodium in triply distilled water and C.P. grade chemicals.

Fig. 1 shows flash spectra taken of 1×10^{-5} M eosin in 0·001 M sodium tetraborate buffer (*p*H 8·5). The transient at 5 μsec delay consists of a strong band at 405 mμ, a band to longer wave-lengths superimposed on the transmission increase due to dye bleaching, and a diffuse absorption in the red region. The 405 mμ band was identified in flash photolysis studies as semi-reduced eosin di-anion (*R*) (refs. 1 and 2). The band shifted to 369 mμ when eosin was radiolysed at *p*H 5·5, which corresponds to the absorption of the mono-anion[2]. The superimposed band is attributed to semi-oxidized eosin (*X*) (λ_{max} = 462 mμ; ref. 3), where the true maximum is shifted by the "negative absorption" caused by eosin bleaching (λ_{max} = 516 mμ). Kinetic measurements at 700 mμ showed that the red absorption has a fast component (~ 2 μsec) due to the hydrated electron (e^-_{aq}) and a slow component (~ 2 msec) attributed to triplet eosin (*T*). The e^-_{aq} life-time agrees with measurements in deaerated water at high dose rate[4] and is independent of eosin concentration up to 1×10^{-5} M, which sets an upper limit of ~ 4×10^{10} M^{-1} sec^{-1} on the reaction of e^-_{aq} with eosin. The e^-_{aq} absorption was obscured by the triplet above 2×10^{-5} M eosin. The slow decay at 700 mμ is of second order ($k/\varepsilon = 1{\cdot}1 \times 10^5$ cm sec^{-1}) and independent of eosin concentration from 2×10^{-5} M to 1×10^{-3} M. Taking $\varepsilon \sim 1 \times 10^4$ M^{-1} cm^{-1} (ref. 2) gives $k \sim 1 \times 10^9$ M^{-1} sec^{-1}, which is in agreement with the flash photolysis value of $1{\cdot}1 \times 10^9$ M^{-1} sec^{-1} for bimolecular triplet decay[3]. The disappearance of semi-reduced eosin is of second order, where the rate constant decreases with increasing eosin concentration (Table 1).

Table 1. Rate Constants for the Disappearance of Semi-reduced Eosin

Eosin concentration (M)	Rate constant* (M^{-1} sec^{-1})
0·00006	$0{\cdot}62 \times 10^8$
0·00004	$0{\cdot}75 \times 10^8$
0·00003	$2{\cdot}4 \times 10^8$
0·00002	$3{\cdot}2 \times 10^8$
0·00001	$3{\cdot}9 \times 10^8$

* ε (*R*) at 405 mμ, $3{\cdot}8 \times 10^4$ M^{-1} cm^{-1} from ref. 2.

Although it has been found that radiolysis produces aromatic triplets from a number of molecules in organic solvents[5,6], this would seem to be the first case reported of substantial triplet formation in aqueous solution. Water is not known to have a low-lying triplet state available for energy transfer and electron exchange is postulated as the mechanism of triplet production[5]:

$$S(\uparrow\downarrow) + e^-(\uparrow) \rightarrow T(\uparrow\uparrow) + e^-(\downarrow) \qquad (1)$$

Eosin reduction cannot be explained by the triplet electron-transfer reactions[3]: $T + T \rightarrow R + X$ and $T + S \rightarrow R + X$, because the rate constants of ~ 1×10^8 M^{-1} sec^{-1} are too slow to account for the "prompt" semi-reduced dye. The oxidation of impurities by OH which might later reduce eosin can be discounted also, because *R* was not suppressed by the addition of formate to scavenge OH. The remaining possibility is the capture of hydrated electrons:

$$S + e^-_{aq} \rightarrow R \qquad (2)$$

A comparison of Fig. 1 with the e^-_{aq} yield in deaerated water gives $G(R) \sim 1{\cdot}6$ and requires $k_2 \geqslant 1 \times 10^{10}$ M^{-1} sec^{-1}, which is not inconsistent with the upper limit deduced from the scavenging observations. The origin of *X* is explained by a fast reaction of OH with eosin:

$$S + OH \rightarrow X + OH^- \qquad (3)$$

The rate was estimated by measuring the competition with carbonate ion in the reaction:

$$OH + CO_3^{2-} \rightarrow CO_3^{-}\cdot + OH^- \qquad (4)$$

Taking $k_4 = 2 \times 10^8$ M^{-1} sec^{-1} (ref. 7) leads to $k_3 \sim 1 \times 10^{10}$ M^{-1} sec^{-1}. Thus, at low dye concentrations the decay of *R* is predominantly:

$$R + OH \rightarrow S + OH^- \qquad (5)$$

while at high dye concentrations hydroxyl is scavenged by way of reaction (3) and *R* disappears by the presumed slower dismutation:

$$R + R \rightarrow S + L \qquad (6)$$

where *L* is leuco-eosin (see Table 1).

The formation of triplet eosin raises the question as to whether dye-sensitized radiolysis can occur. Preliminary results with *p*-cresol indicate that this may be the case. Pulse radiolysis of deaerated *p*-cresol (0·005 M, *p*H 11) gives a spectrum at 5 μsec delay showing the e^-_{aq} absorption, the narrow bands of *p*-methylphenoxyl at 405, 385 and 369 mμ (ref. 8), and a broad absorption below 340 mμ. The addition of 0·1 M sodium formate suppresses all but e^-_{aq}, indicating that hydroxyl is the predominant oxidizing species:

$$OH + CH_3C_6H_4OH \begin{cases} \nearrow CH_3C_6H_4O\cdot \\ \searrow CH_3C_6H_4(OH)_2\cdot \end{cases} \qquad (7)$$

where the short wave-length band is attributed to the addition product. Fig. 2 shows the results obtained with the eosin/formate/*p*-cresol system. The shoulders on the *R* absorption located at the maxima of the *p*-methylphenoxyl bands (the arrows) prove that the latter species is present even though OH was scavenged by formate. (The absence of the semi-oxidized eosin band confirms that OH was not available to react with eosin and *p*-cresol.) The result is explained by the triplet reaction:

$$T + CH_3C_6H_4OH \rightarrow R + CH_3C_6H_4O\cdot \qquad (8)$$

which has been studied in detail with flash photolysis[2]. Although our preliminary work does not make a full comparison possible, it is interesting to note that eosin parallels methylene blue (MeB) by its high reactivity with hydroxyl and hydrated electrons, but differs markedly in its high triplet yield by radiolysis: $k(e^-_{aq}$ + MeB) = $2{\cdot}5 \times 10^{10}$ M^{-1} sec^{-1} and *G* (triplet MeB) $\leqslant$ 0·1 (ref. 9).

We thank Dr. J. Ovadia for his advice and for his contributions during the initial stages of this work, which

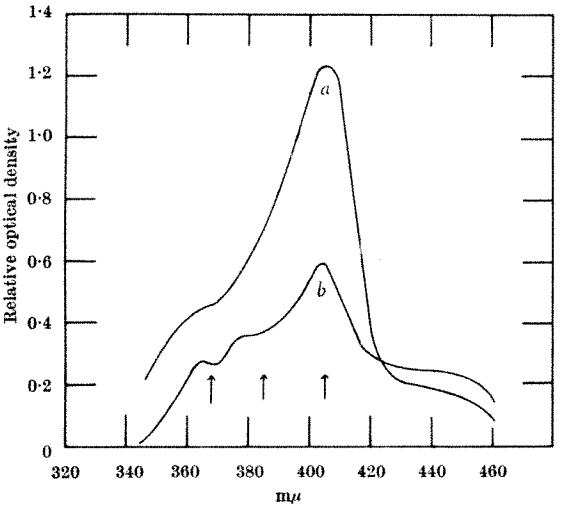

Fig. 2. Pulse radiolysis of deaerated eosin (0·00001 M) and *p*-cresol (0·005 M) in the presence of 0·1 M formate (*p*H 8·7) at 5 μsec (*a*) and 50 μsec (*b*) time delay. The arrows indicate the absorption maxima of *p*-methylphenoxyl (ref. 8). The spectra were taken on a Kodak '103–0' spectroscopic plate and are not corrected for emulsion sensitivity

BIOCHEMISTRY

Structural Aspects of Polyribosomes and Endoplasmic Reticulum Fragments isolated from Rat Liver

THE isolation of polyribosomes from rat liver has been described in previous communications[1–4]. In addition to the polyribosomes found in the 75,000*g* pellet, three coloured layers localized in the interface between 1·5 M and 2 M sucrose can be isolated. The lower layer consists mainly of rough endoplasmic reticulum (membranes with attached ribosomes)[2]. In the upper layers the membranes are almost devoid of ribosomes. In both these layers polyribosomes are frequently encountered which are connected to the membrane surface only by way of one single terminal monomer (compare Fig. 1*E*).

In the negative stained preparations the attachment of these monomers to the membranes seems to be either a tight junction or a short stem (Fig. 1*D*). Furthermore, it appears that the membranes are built up by small globular sub-units with a diameter of about 40 Å. This substructure can be detected as well in the smooth membranes as in the rough ones.

Since membrane-attached polyribosomes are observed in the upper layers, the question arises whether part of the unattached polyribosomes in the pellet may have been detached during homogenization and centrifugation. However, when the layers are re-submitted to the whole isolation procedure, no second pellet is found. This evidence favours the assumption of a substantial number of attached ribosomes.

Webb *et al.*[5] arrived at the conclusion (based on a comparison of the pellet obtained from untreated and deoxycholate-treated 15,000*g* supernatant) that at least 50 per cent of the polyribosomes in normal rat liver are tightly bound to membranes.

Our results confirm these observations in that the amount of RNA recovered from the three coloured layers is approximately the same as that recovered from the pellet and the 2 M sucrose layer. Moreover, after treatment of the combined coloured layers with 1 per cent deoxycholate after centrifugation at 100,000*g* for 30 min, a pellet is obtained which contains about the same amount of RNA as the pellet obtained from deoxycholate-treated 2 M sucrose layer combined with the polysomal pellet. One might expect that a tight binding would originate from attachment of polyribosomes to membranes by way of a great number of monomers, but the electron microscopic evidence suggests that the link

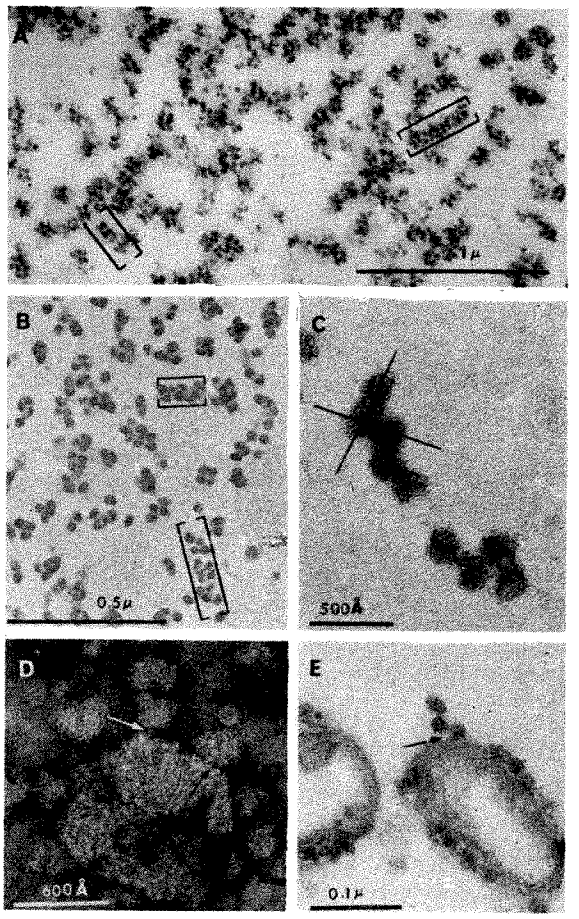

Fig. 1. (*A*) Pellet of polyribosomes, thin section stained with 1 per cent uranyl acetate. Some ribosomal aggregates show a helical configuration. (*B*) Pellet of polyribosomes, spread preparation shadowed with carbon–platinum while rotating. Polyribosomes formed by rows of paired units. (*C*) Pellet of polyribosomes, spread preparation positive staining with 1 per cent uranyl acetate. These ribosomal aggregates show clearly a helical configuration, with an angle of approximately 78°. (*D*) Lower layer, spread preparation negatively stained with 1 per cent uranyl acetate. The white arrow points to a stem-like attachment, the black arrow to a tight junction. Note also the globular structure of the membraneous sheet. (*E*) Lower layer, thin section stained with uranyl acetate. The arrow points to a small chain of ribosomes. The connexion with the membrane element is made by a monomer

between the membranes and the chain of polyribosomes often consists only of a single ribosome.

Further observations on the fine structure of the polyribosomes localized in the pellet after centrifugation of the postmitochondrial supernatant reveal that many ribosomal aggregates appear as helices with angles which vary in the range 50°–80° C (Fig. 1*A*, *B* and *C*). This finding is in agreement with a recent report by Pfuderer *et al.*[6]. The results of their physico-chemical investigation of polyribosomes in solution favour a helical model. This configuration may well result from a transition during isolation of clusters of ribosomes which are arranged *in vivo* as spirals or rosettes. The latter configurations have been related to free and membrane-bound ribosomal aggregates[7].

We thank Miss M. R. Gerhards and Miss C. v. d. Voorn for skilled technical assistance.

Separation and Recombination of Ribosomal Ribonuclease from Ribosomes

Ribosomes obtained from *Escherichia coli* contain ribonuclease (RNase) which is latent if the ribosome is intact[1]. It has been reported that this enzyme originates in the cell wall and adds to the particle only during preparation[2]. This finding is in contradiction to earlier work[3,4] and the work of Anraku[5] which suggest that the enzyme is an intrinsic part of the ribosome. The experiments of Neu *et al.*[2] showed addition of RNase to ribosomes but no inactivation had been mentioned. If ribosomes are treated with 0·5 M ammonium chloride solution the RNase is released[6,7] and subsequently separated from the ribosome by 'Sephadex' filtration[8].

It has been found that in intact ribosomes the RNase becomes released and activated at 62° C, whereas sensitivity to the action of this enzyme occurs already at 54° C, in both cases leading to the breakdown of the whole ribosome. Thus, the temperature of thermal decomposition is an indication of the activation of the RNase[9]. Using this technique we have investigated to what extent release and activation of ribosomal RNase by 0·3–0·5 M sodium chloride can be reversed by removing the salt.

Ribosomes have been prepared as described by Matthaei *et al.*[10]. Thermal degradation has been carried out in a silica cell by raising the temperature in 3°–5° C gradients every 15 min. The degradation, resulting in formation of a precipitate, was measured photometrically; since this was carried out at 260 mμ any hypochromicity could also have been noted. A typical degradation pattern resulting from this procedure is shown in Fig. 1*a*. Enzyme activity was tested as described before[9] using poly-*C* (Miles) as the substrate. Ribosomes suspended in 50 per cent caesium chloride still form distinct particles of Svedberg constants 23*s* and 42*s*[11]. After removal of caesium chloride by dialysis, these particles still contain RNase

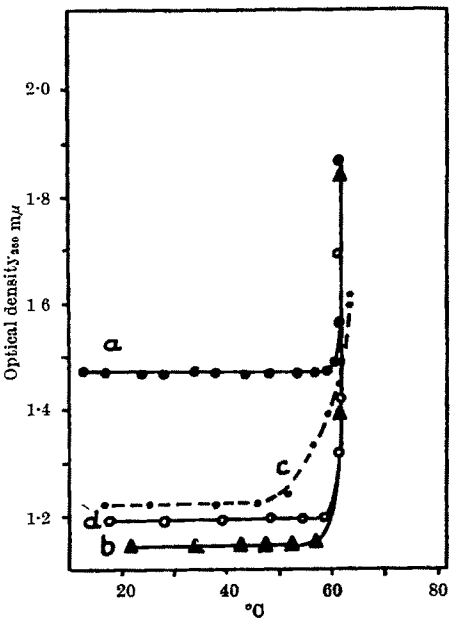

Fig. 1. Light absorption of ribosome solutions at various temperatures: (*a*) ●—●—●—●—● Untreated (*b*) ▲—▲—▲—▲—, Treated with 50 per cent caesium chloride followed by dialysis. (*c*) ● – – ● – – ● –, In 0·3–0·5 M sodium chloride solution. (*d*) ○—○—○—○—, 0·3–0·5 M sodium chloride, treatment followed by dialysis. In the temperature region of the flat parts of *a*, *b*, and *c* increase of light absorption at prolonged heating was negligible

in latent form; this has been shown by comparison with untreated ribosomes in the following two experiments:

(1) Untreated and caesium chloride-treated ribosomes in 0·01 M *tris*-hydrochloric acid (*p*H 7) and 0·01 M magnesium acetate were heated up as described. Degradation of both took place at nearly identical temperatures (62° C) (Fig. 1*a*, *b*). In both cases, addition of 0·5 mg/ml. pancreatic RNase caused this degradation to occur below 54° C.

(2) Untreated and caesium chloride-treated ribosomes in 0·01 M magnesium acetate, 0·01 M *tris*-hydrochloric acid (*p*H 7·4), and 0·005 M β-mercaptoethanol (1 mg/ml.) were heated for 20 min to various temperatures and then cooled down to 4° C. A schlieren sedimentation analysis was performed with each sample. The bands ascribed to the ribosomes and their sub-units (traces) were only slightly changed at temperatures up to 59° C but were absent in samples heated up even higher (65° C). This temperature step was also marked by the appearance of RNase activity.

Ribosomal RNase can be liberated by treatment with 0·3–0·5 M sodium chloride. The effect of this treatment can be seen from Fig. 1. Degradation begins at a lower temperature and occurs over a much wider temperature range (*c*) than the degradation of untreated ribosomes (*a*). When the salt is removed by dialysis the degradation pattern of (*a*) is almost restored (*d*).

We note that centrifugation of such a sodium chloride-containing ribosome solution at 39,000 r.p.m. in an '*SW* 39' Spinco rotor for 3 h is not sufficient to remove the RNase completely from the particle. Those ribosomes have also been found to be a little more labile than untreated particles (Fig. 2*e*). When 0·5 M sodium chloride enzyme supernatant solution and pellet ribosomes are remixed in their original proportions, the degradation pattern (*f*) in Fig. 2 is obtained. Removal of salt from this mixture by dialysis again results in almost complete restoration (Fig. 2*f*). Under those conditions no enzyme activity can be demonstrated in the supernatant when this recombined sample is centrifuged at 39,000 r.p.m. in the Spinco '*SW* 39' rotor.

Ribosomal particles obtained by treatment with 50 per cent caesium chloride and subsequent dialysis do

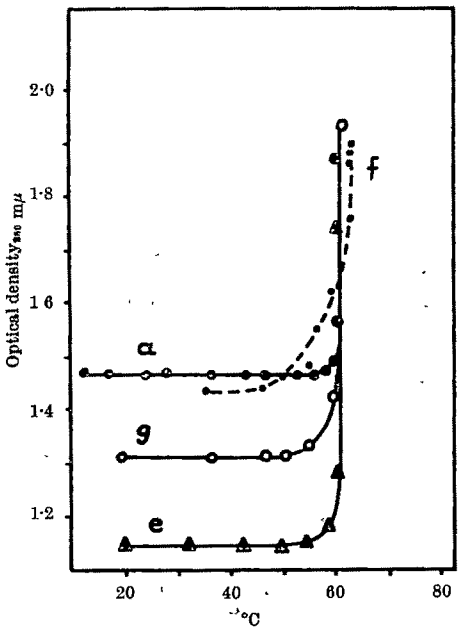

Fig. 2. Light absorption of ribosome solutions at various temperatures. (*a*) ●—●—●—, Untreated, identical to (*a*) in Fig. 1. (*e*) ▲—▲—▲—, Pelleted in buffer containing 0·35–0·5 M sodium chloride and subsequently heated in 0·01 M *tris*-hydrochloric acid, *p*H 7, and 0·01 M magnesium acetate. (*f*) ● – – ● – – ● – –, Pellet and supernatant remixed. (*g*) ○—○—○—, Pellet and supernatant mixture dialysed

not differ in their thermal degradation behaviour from untreated ones. This effect can be explained by recombination of the enzyme with the particle during dialysis. This interpretation is supported by results obtained from ribosome solutions containing 0·5 M sodium chloride. In such solutions the enzyme is released and activated. Removal of the salt, however, restores the original shape of the thermal degradation diagram. Thus, the conditions under which the enzyme is thermally released approximate to those conditions found with ribosomes which were not treated with sodium chloride. Within the limits allowed by the procedure, we conclude, therefore, that the enzyme can recombine with the ribosome, and become latent on gradual removal of the 0·5 M sodium chloride from the solution.

Separation of the enzyme activity from the ribosome itself, by centrifuging 0·5 M sodium chloride ribosome solutions, is not complete. We still found RNase activity using poly-*C* as a substrate. Moreover, this centrifugation procedure renders the ribosome a little more labile. This might interest workers who include washing with such salt concentrations in their ribosome purification.

Isolation of a Pre-viral Deoxyribonucleic Acid

IN 1943, we found that hydroxylamine can induce viral polyhedrosis in silkworms[1]. Pursuing this finding, one of us has established a metabolic cycle producing virogens and mutagens[2]. It has further been demonstrated that the polyhedral pre-viral genome is located in the chromosome of the host cell[3]. We have now succeeded in isolating the pre-viral deoxyribonucleic acid from the larval nucleus and have confirmed that hydroxylamine is able to accelerate its separation from the other nucleic acid portion.

Cellular deoxyribonucleic acid was prepared with sodium dodecylsulphate according to our method[4] from nuclei which had been collected from digestive organ-free tissues of healthy silkworms using the procedure described before[5]. Viral deoxyribonucleic acid was also prepared with the same reagent in a similar way[4] from polyhedra which had been obtained from larvae inoculated with the virus[6].

The results of analysis showed that the cellular and viral deoxyribonucleic acid have almost the same base composition. The data of sedimentation with an analytical ultracentrifuge indicated, however, that the average molecular weight of the former is 46×10^6 and that of the latter 24×10^6. Therefore, we tried to fractionate the cellular nucleic acid, to find a component which has the same molecular weight as the viral nucleic acid. For this, a gradient centrifugation was first applied to the viral deoxyribonucleic acid. The freshly prepared nucleic acid was dissolved in a mixture of 0·2 N sodium chloride plus 0·01 M sodium citrate to a concentration of 40 μg/ml. and the solution obtained was put into a tube containing 5–20 per cent sucrose solution in 0·1 N sodium chloride and 0·05 M potassium phosphate buffer, *p*H 6·7. The tube was centrifuged at 30,000 r.p.m. for 4 h in a 'Spinco *L*' ultracentrifuge at 10° C. The centrifugation pattern showed that the viral deoxyribonucleic acid is represented by the 35 *S* (sedimentation coefficient) component as a linear form. The cellular nucleic acid was then dissolved in the same way in a chloride–citrate mixture. To facilitate the fractionation, the solution was stirred at 2,000 r.p.m. for 30 min in a blender under cooling. Immediately after that, the sucrose gradient centrifugation was applied to the solution as in the case of the viral nucleic acid. The obtained pattern indicated that the cellular deoxyribonucleic acid consists of 62 *S*, 55 *S*, 44 *S*, 35 *S* and 24 *S* components. The amount of 35 *S* was about 4 per cent of the total acid.

It seemed reasonable to assume that the 35 *S* component in the cellular deoxyribonucleic acid was the polyhedral pre-virus. To confirm this, the 35 *S* fraction was collected, dialysed and freeze-dried. The dried component was dissolved in 0·01 M sodium carbonate and 0·02 ml. of the solution was injected into each larva on the first day of fourth instar. At the same time, the injection was also carried out with the carbonate solution of viral and cellular deoxyribonucleic acid. In addition, the cellular nucleic acid was treated with 0·01 M hydroxylamine at 35° C for 2 h at *p*H 7·0, and after dialysing against 0·01 M sodium carbonate the solution was injected into larvae. Some of the results are given in Table 1.

Table 1. VIROGENIC ACTION OF DEOXYRIBONUCLEIC ACID (DNA) PREPARATIONS

Kind of preparation	Viral DNA	Pre-viral DNA	Cellular DNA	Cellular DNA + hydroxylamine
Concentration of preparation	10 μg/ml.	25 μg/ml.	450 μg/ml.	450 μg/ml.
Number of test larvae	15	15	15	15
Number of virozed larvae	5	4	2	6

In the control, it was verified that the injection of 24 *S* (35 μg/ml.) or hydroxylamine (0·01 M) in 0·01 M sodium carbonate causes no polyhedral disease. From these observations, one can conclude that the 35 *S* component in the host cell must be a pre-viral deoxyribonucleic acid. There was also the possibility that the larger components

still involve the pre-viral nucleic acid molecule and the data of hydroxylamine-treatment appeared to suggest that the action of this amine is to break appropriately chromosomal nucleic acid to liberate the pre-virus. The cellular deoxyribonucleic acid was therefore mixed with 0·005 M hydroxylamine and after 2 h at 35° C the mixture was centrifuged with a 'Spinco *L*' ultracentrifuge according to the procedure mentioned above. It was corroborated that the yield of 35 *S* amounts to 6 per cent of the cellular nucleic acid employed. The centrifugation of the intact cellular deoxyribonucleic acid which had not been treated with a blender or hydroxylamine gave only about 2 per cent 35 *S* component. It can thus be confirmed that the pre-virus is pre-existent in the larval cell and that its separation is promoted by suitable means.

Recently, Northrop[7] demonstrated that a new phage can be produced by a long treatment of *Escherichia coli* with triethylene melamine. Ikuta and Zimmerman[8] also proved that a new virus is produced in the precancerous state of mice implanted with carcinogenic hydrocarbons. These results may be explained by the appropriate cleavage of cellular nucleic acids by chemicals. It is further assumed that duplicants proposed by Butenandt[9], Druckrey[10] and Euler[11] for precursors of cancers may correspond to pre-viral nucleic acids.

Pyridoxal and Pyridoxamine Phosphate Breakdown by an Acid Phosphatase Preparation

DURING investigations of the controlled inactivation of pyridoxal phosphate-dependent enzymes, an acid phosphatase preparation has been used to effect co-enzyme destruction. Alkaline phosphatases of mammalian origin are known to hydrolyse both pyridoxal and pyridoxamine phosphates[1,2] and an alkaline phosphatase preparation from *E. coli* has been used for the resolution of tryptophanase[3]. A preliminary report on the inactivation of L-α-alanine : phenylglyoxal transaminase by treatment with alkaline phosphatase has also appeared[4]. The breakdown of vitamin B_6 phosphates by acid phosphatases does not appear to have previously been reported.

In the present work a commercial preparation of wheat germ acid phosphatase (B.D.H., Ltd.) was used. Activities with a variety of substrates were measured by the colorimetric assay of orthophosphate production according to the method of Gomori[5], readings being made at 715 mμ. Reaction mixtures contained buffer (0·2 M), 1·0 ml.; enzyme preparation in water 0·4 ml., substrate (7·0 mM), 0·5 ml.; and additions up to 3·5 ml. Incubations were carried out at 37° C and terminated by the addition of 0·5 ml. trichloroacetic acid (50 per cent).

With pyridoxal phosphate as substrate, preliminary experiments showed that optimum activity occurred at *p*H 5·5. Acetate buffers were used in this region, maleate and veronal buffers being used to cover a wider range of *p*H. Pyridoxal phosphatase activity rapidly declined between *p*H 5·5 and 7·0, and no evidence of a second peak at the alkaline side of neutrality was obtained, even at high enzyme concentrations. Pyridoxamine phosphate was hydrolysed optimally at the same *p*H but at a much lower rate. The respective specific activities were 88·0 and 10·8 mU. per mg protein, compared with 340·0 mU. per mg for disodium phenylphosphate used as a reference substrate.

Magnesium ions, as magnesium sulphate, had no effect on pyridoxal phosphatase activity at a concentration of 1 mM, and EDTA had no inhibitory effect at concentrations below 0·1 mM although 30 per cent inhibition was observed at 1 mM. Sodium fluoride caused marked inhibition at concentrations as low as 10·0 μM (10 per cent) and inhibited 70 per cent at 1 mM. Iodoacetate, β-mercaptoethanol, or cysteine had no effect on phosphatase activity when tested over the same concentration range, after 30 min preincubation with enzyme. Preincubation of pyridoxal phosphate in buffer with cysteine or histidine, which are known to form respectively thiozolidine and imidazo-tetrahydro-pyridine derivatives with the coenzyme[6], had no detectable effect on the rate of enzymatic hydrolysis.

The effect of substrate concentration on the initial rates of enzyme activity, using either pyridoxal or pyridoxamine phosphates, was investigated. Michaelis constants for these substrates were determined from double-reciprocal plots by the method of Lineweaver and Burk[7], and found to be 0·52 and 1·30 mM, respectively, when measured at *p*H 5·5.

The foregoing results show that wheat germ acid phosphatase readily hydrolysed pyridoxal phosphate. Pyridoxamine phosphatase activity was lower, however, and less favoured by the Michaelis constant. This result is in contrast to the results obtained using mammalian preparations[1,2]. It is interesting to note that an alkaline phosphatase from human brain hydrolysed pyridoxal phosphate more rapidly than all other substrates tested[2], and that whereas a bacterial acid phosphatase preparation had no activity with vitamin B_6 phosphates[3], a preparation of prostatic acid phosphatase was also more effective with pyridoxal phosphate than any other substrate[8]. The possible role of phosphatases in the regulation of pyridoxal phosphate requiring enzymes has been discussed elsewhere[9,10].

Loss of Adenine during the Hydrazine Degradation of Deoxyribonucleic Acid

THE treatment of deoxyribonucleic acid (DNA) with anhydrous hydrazine causes the degradation and removal of the pyrimidine bases but leaves the rest of the polynucleotide chain more or less intact[1,2]. This degradation of the pyrimidine ring occurs irrespective of whether the pyrimidines occur as part of a nucleic acid or as free base, nucleoside or nucleotide[1–5]. This reaction has recently been considered in detail by Temperli *et al.*[5]. The pyrimidine-free DNA (apyrimidinic acid) can be hydrolysed by potassium hydroxide[4] to tracts of oligopurine nucleotides having the general formula, $(\text{purine nucleoside})_n$ $(\text{phosphate})_{n+1}$, where *n* has been observed to vary from 1 to 13

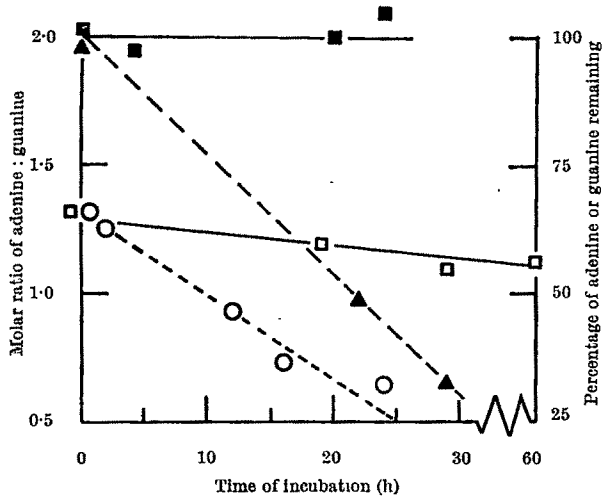

Fig. 1. Effect of anhydrous hydrazine on the loss of purines from calf thymus DNA and from deoxymononucleotides. Dried calf thymus DNA was incubated with anhydrous hydrazine (Fluka, water-free) at 37° C □—□ and 60° C ○ - - - ○. At the end of the incubation, the hydrazine was removed by co-evaporation with ethanol using a rotary evaporator. The product was heated in 0·3 M potassium hydroxide at 100° C for 1 h, desalted by adsorption on and elution from DEAE-cellulose (bicarbonate) and hydrolysed with 72 per cent perchloric acid at 100° C for 1 h. 5′-*d*AMP ▲ - - - ▲ and 5′-*d*GMP ■——■ were incubated with anhydrous hydrazine at 60° C, dried and hydrolysed with perchloric acid. In all cases, the bases were separated and estimated by quantitative paper chromatography. Data in duplicate experiments agreed with the results shown

(refs. 4, 6, 7). For any one value of n, these tracts are known as isostichs[8].

It has been claimed[1,2,6] that the treatment of DNA with anhydrous hydrazine at 60° C causes a rapid and complete degradation of the pyrimidine bases while leaving the purine residues unaffected. Although we have confirmed that the pyrimidines are rapidly removed from DNA under these conditions, we have found that there is also a loss of adenine as indicated by the decreasing molar ratio of adenine to guanine with time of incubation at 60° C (Fig. 1). This ratio fell almost linearly with time and had decreased to 90 per cent of its original value (1·32) after 4 h incubation, 85 per cent after 6 h and 51 per cent after 20 h. As expected, the rate of loss of adenine was much lower with an incubation temperature of 37° C; at this temperature there was a negligible loss after 4 h and a 7 per cent loss after 20 h incubation. In agreement with the results of other workers[1–6], the degradation of pyrimidines is rapid and results obtained for the loss of cytosine and thymine from DNA at 37° and 60° C are given in Table 1.

Table 1. DEGRADATION OF PYRIMIDINES ON INCUBATION OF CALF THYMUS DNA WITH ANHYDROUS HYDRAZINE*

Time of incubation (h)	Cytosine remaining (per cent) 37° C	60° C	Thymine remaining (per cent) 37° C	60° C
0	100	100	100	100
2	22	0	72	15
4	15	0	35	0
8	2	0	10	0
16	0	0	0	0

* Experimental conditions as for those described in Fig. 1.

This effect of hydrazine on adenine was confirmed by following the breakdown of 5′-*d*AMP in anhydrous hydrazine at 60° C (Fig. 1). It was found that the rate of loss of adenine was very similar to that observed with DNA with a 50 per cent loss after 20 h (Fig. 1). On the other hand, under similar conditions, there was no loss of guanine from 5′*d*GMP (Fig. 1).

It is difficult to explain the discrepancy between the claims that anhydrous hydrazine at 60° C causes negligible loss of purines[1,2,4–6] and the results reported here. Where an incubation time of 4 h has been used[2,4–6] a 10 per cent loss of adenine, as found here, could well go undetected. However, Sedat and Sinsheimer[7], using an incubation time of 18–20 h at 60° C, reported that there was little loss of adenine compared with the nearly 50 per cent found under our conditions. Whatever may be the explanation for these discordant results, it appears that prolonged incubation of DNA with anhydrous hydrazine at 60° C can cause extensive loss of adenine. The results in Fig. 1 and Table 1 indicate that incubation of DNA and anhydrous hydrazine at 37° C for 16 h or at 60° C for 4 h are the optimum conditions of incubation, ensuring maximum degradation of pyrimidines commensurate with minimum degradation of adenine.

Inactivation of Rennin by Dansyl

RENNIN (*EC* 3.4.4.3) is a proteolytic enzyme[1] that is of considerable industrial importance because of its ability to clot milk. Evidence has been presented that its clotting action on milk depends on the splitting of an ester bond[2]. If this is so, the active centre of rennin could be expected to be similar to those of other enzymes with esterase activity such as chymotrypsin (*EC* 3.4.4.5) in which catalytic activity is associated with reactive serine[3] and histidine[4] side-chains. We have shown that rennin may be inactivated by photo-oxidation with methylene blue and that the loss of activity is probably due to destruction of histidine as there is no loss of activity when photo-oxidizable side-chains other than histidine are modified[5].

Cheeseman has reported[6] that rennin is not inactivated by di-isopropylfluorophosphate (DFP), which may inactivate esterases by reacting with a single serine side-chain[7]. We have confirmed this, and have found in addition that rennin does not react with toluenesulphonyl chloride. Like DFP, this reagent has been shown to react with active-centre serine[8] and the failure of both these reagents to inactivate rennin suggests that this enzyme may not possess a catalytic serine residue.

In a search for a means of labelling the active centre we have used dimethylamino-naphthalene sulphonyl chloride (dansyl), a fluorescent reagent recently introduced for determining the end groups of proteins[9]. We have found that, at *p*H 8 and 3° C, rennin is inactivated by adding to the solution sufficient dansyl to react with 1·5–2 residues of the rennin. In a typical experiment, 50 μl. of a solution of dansyl in acetone (6 mg/ml.) was added to 12 ml. of rennin solution (2 mg/ml.) at *p*H 8 and 3° C in phosphate buffer (I = 0·2), and the solution stirred continuously. 50 μl. of acetone was added to a control solution kept in the same conditions. At intervals of about 30 min, 0·1 ml. of the solution was pipetted into 10 ml. of phosphate buffer at *p*H 6·5, and used for activity tests with skimmed milk reconstituted in 0·01 M calcium chloride[10]. After 30 min the activity of the dansylated rennin had fallen to about 50 per cent, and after 1 h to about 40 per cent, of that of the control, which was almost unaffected. Addition of a further 20 μl. of dansyl was required at this stage and in these experiments caused a drop in activity to a minimum of 15 per cent of that

of the control. The rennin was then separated from free and hydrolysed dansyl by gel filtration on 'Sephadex G25'. The amount of dansyl bound to the protein was estimated from ultra-violet difference spectra, assuming that the absorption of bound dansyl was the same as that of dansyl in isopropanol. At maximum (85 per cent) inactivation, the bound dansyl was estimated at 1·4 moles dansyl per mole rennin, and at lower levels of inactivation (such as 70 per cent) less dansyl (0·7 residues) was bound. When the dansyl was added at *p*H 6·5 instead of at *p*H 8, there was no inactivation.

Our results suggest rather strongly that the rennin is inactivated by reaction of the dansyl with a single residue. Work aimed at identifying the site of the reaction is in progress and will be reported later. However, the present results encourage the hope that this reagent may be useful for labelling the active centre of rennin and suggest its use in similar investigations of other enzymes.

Mechanistic Interpretation of Empirical Enzyme Rate Equations

THE kinetic behaviour of most enzymes is more complicated than that described by Michaelis and Menten[1] for the relatively simple mechanism: $E+S = ES \rightarrow E+P$. Many enzymes have more than one substrate or product; others are inhibited by product and/or substrate, and their rate equations are correspondingly complex. For such enzymes, Michaelis–Menten kinetics are sometimes applicable at limiting conditions (such as velocities measured in the absence of product—that is, in zero time—using a large excess of all but one substrate), but this normally precludes any rigorous interpretation of the results. Oversimplifications of this kind have resulted in conflicting interpretations of the same data, leading to unnecessary controversy.

Recently, Cleland[2] has discussed rate equations derived from hypothetical mechanisms for enzymes having two or more substrates or products. Such techniques are extremely useful. Proposed mechanisms can be excluded if they do not predict the observed kinetic behaviour of the enzyme. Some enzymes, however, have very complicated mechanisms, consisting of perhaps ten steps. Many possibilities must then be considered, each resulting in a rate equation which may contain many hundreds of terms. Often the experimental evidence required to select between the possibilities is unobtainable by the available techniques. It then becomes necessary to reason directly from the experimental kinetic results, and to decide what generalizations about the mechanism can be inferred from these. It is intended here to suggest what deductions can be made about mechanisms from experimental rate equations. For the sake of simplicity, only non-random mechanisms will be considered.

A convenient technique for deriving steady state rate equations from proposed mechanisms is the schematic method of King and Altman[3]. This method gives rate as a quotient. The numerator consists of a positive and a negative term, containing respectively the product of the concentrations of all the substrates consumed, and the product of the concentrations of all the products formed. The denominator is a sum of terms containing most possible combinations of the concentrations of the various substrates and products. If an experimental rate equation is arranged in this form, an interpretation of the terms can be made from the significance of analogous terms in theoretically derived rate equations.

Numerator terms are related to the overall rate of production of substrates from product. The positive term is proportional to the overall rate of the combined forward reactions, and the negative term to that of the reverse reactions. Their ratio is the equilibrium constant for the reaction catalysed, and can be used to calculate the free energy change. If the numerator contains more than the two terms mentioned above, it follows that there is more than one way of producing products from substrates, that is to say, the reaction is non-ordered, and the treatment discussed here does not apply. If the numerator does not contain additional terms, it can be concluded that the rate of alternative pathways is negligible within experimental error. If the numerator contains only a positive term, the reaction can be considered to be irreversible, at least until more accurate measurements reveal the existence of a small negative term.

The denominator as a whole is proportional to the total enzyme concentration. It consists of combinations of terms relating to the concentrations of the various (free and combined) forms of the enzyme. The coefficient of any term is proportional to the fraction of the total concentration of the enzyme which consists of forms which can arise from sequences containing all the reactants in that term. In a reaction of n steps, then, any coefficient is the sum of a number of products of rate constants: one product for each possible combination of $n-1$ reactions which (*a*) is directional—that is, does not contain a cyclic process or both directions of a reversible reaction; and (*b*) consumes all and only the reactants governed by the coefficient.

Although many of the denominator terms are mechanistically unintelligible, two generalizations may usefully be made. First, terms which contain the concentration of a single reactant as the only variable represent the total binding power of the enzyme system (in the steady state) toward that reactant. The binding power of the enzyme system toward the various substrates and products can therefore be compared if there are terms containing these as the only variable. Second, it is sometimes informative to consider the denominator to be two sets of terms, one related to the relative concentration of free enzyme, and the other to that of bound enzyme, that is, the magnitude of one of the sets of terms represents the tendency of the enzyme to become free, the magnitude of the other its tendency to become bound. The two sets can be distinguished as follows. If the reaction is (as assumed) non-random, only one of the substrates and only one of the products will be found to react with free enzyme in the absence of all the others. Terms related to the tendency of the enzyme to become bound must contain the concentration of one or the other of these reactants, since a molecule of one of them must be consumed in any reaction in which free enzyme becomes bound. Terms related to the tendency of the enzyme to become free can contain neither of them, since a process involving either must result in the net consumption of free enzyme.

The mechanism by which factors such as temperature, *p*H, ionic strength, inhibitors or activators alter the coefficients of experimental rate equations can in this way be interpreted rigorously in terms of increased or decreased affinity of enzyme for substrate or product, increased or decreased tendency of the enzyme to become bound, or

an increased or decreased rate of the forward or reverse reactions.

Lipoperoxidation of Rat Liver Microsomal Lipids induced by Carbon Tetrachloride

IT has been known for 17 years[1] that *d*-α-tocopherol can protect rats from the lethal effects of carbon tetrachloride. Anti-oxidant protection implies that the reaction of the liver to the toxin involves destructive lipoperoxidation. Under certain circumstances, lipoperoxidation can be detected by following the evolution of malonaldehyde by means of the thiobarbituric acid (TBA) reaction. We have monitored malonaldehyde evolution in *in vitro* experiments utilizing the microsome-supernatant fraction of rat liver, and have found that carbon tetrachloride can act as a pro-oxidant in this system. Diethyl ether and heptane were inert. These *in vitro* findings support the hypothesis that the hepatotoxic chloroalkanes have as one of their vectors of toxicity the initiation of destructive lipoperoxidation. If carbon tetrachloride acts similarly *in vivo*, it should be possible to find supportive evidence. We have found that malonaldehyde is readily metabolized by rat liver mitochondria, hence the TBA reaction cannot be used as a tool in the search for evidence of lipoperoxidation *in vivo*. However, the appearance of malonaldehyde is only one index of destructive lipoperoxidation. It has been known for 20 years, from the work of Bolland and Koch[2], that during the course of autoxidation of ethyl linoleate there occurs a rearrangement of double bonds into diene conjugation. The spectra of normal conjugated dienes, that is, molecules such as butadiene, are characterized by a very intense absorption, the so-called *K*-band[3], at 215 to 250 mμ (ref. 4). The spectra of peroxidized lipids are characterized by an intense *K*-band at 233 mμ, with a shoulder, due to ketone dienes, in the region from 260 to 280 mμ (ref. 2). The appearance of diene conjugation in peroxidized, unsaturated fatty acids, or their derivatives, is due to resonance following free radical attack on methylene bridges separating the double bonds in these compounds[5]. It should be borne in mind that microsomal lipid is largely phospholipid.

It appeared to us not unreasonable to imagine that if there were a free-radical attack on the methylene bridges of unsaturated fatty acid side-chains of microsomal lipids, resonance could occur, at least in a certain number of instances, with displacement of the organic free-radical electron toward the methyl end of the fatty acid. Subsequent formation of an organic peroxide, and cleavage of the carbon chain would result in degenerate complex lipids with diene conjugation in the fatty acid residues still tied to the glycerol moiety by way of an ester bond. Accordingly, lipids extracted from peroxidized rat liver microsomes should exhibit typical diene conjugation absorption, whereas lipids extracted from control, non-peroxidized rat liver microsomes should not. The expectation was realized. The left panel of Fig. 1, taken from Bolland and Koch[2], shows the typical diene conjugation absorption of a peroxidized unsaturated fatty acid (upper trace). The non-peroxidized lipid (lower trace) shows only simple end-absorption. The right panel of Fig. 1, upper trace, shows the absorption spectrum of the lipid extracted from rat liver microsomes peroxidized *in vitro* at 38° C, in air, in the presence of ascorbic acid, at *p*H 5·6. Typical diene conjugation absorption is present. The lower trace of the right panel of Fig. 1 shows only simple end-absorption for lipids extracted from an equivalent amount of microsomes which were also incubated in air at 38° C in presence of ascorbic acid, but with peroxidation prevented by addition of ethylenediamine tetraacetic acid (EDTA). The middle trace is the difference spectrum. There can be no doubt that peroxidation *in vitro* is accompanied by the appearance of typical diene conjugation absorption in the lipids extractable from the peroxidized microsomes. If the microsomes are protected from peroxidation by EDTA, the extracted microsomal lipid is completely devoid of diene conjugation absorption. If carbon tetrachloride acts *in vivo* by initiating autocatalytic, destructive, lipoperoxidation, it should be possible to extract from the liver microsomes degenerate complex lipids exhibiting the characteristic 233 mμ absorption of diene conjugation. Six rats were fasted overnight, following which three were given 250 μl. of carbon tetrachloride, in mineral oil, intragastrically, per 100 g body-weight. The remaining three rats received mineral oil alone. After 6 h the rats were killed and the liver microsomes recovered. Microsomal lipid was extracted in chloroform–methanol (2 : 1). The chloroform–methanol extract was forced into a two-phase system by addition of water. The recovered chloroform phase was dried down under oxygen-free nitrogen. The recovered lipids were redissolved in methanol and examined in the ultra-violet spectrophotometer. The mean difference spectrum, carbon tetrachloride-poisoned minus controls, is shown in Fig. 2. There is no doubt that the expected diene conjugation absorption is there. A similar experiment was carried out in which the rats were killed 90 min after carbon tetrachloride poisoning Typical diene conjugation absorption was also found in this experiment.

It has been suggested by Butler[6] and by Wirtschafter and Cronyn[7] that carbon tetrachloride is cleaved homolytically in the liver to yield trichlormethyl free-radical and monatomic chlorine. Rubinstein and Kanics[8] showed that hepatic metabolism of carbon tetrachloride takes place in the microsome fraction, in presence of the supplemented supernatant fraction. The work reported here supports the hypothesis that carbon tetrachloride is cleaved homolytically in or near the lipoidal components of the endoplasmic reticulum of the hepatic parenchymal cells. We envisage that free radicals, arising from carbon tetrachloride cleavage, then attack the methylene bridges

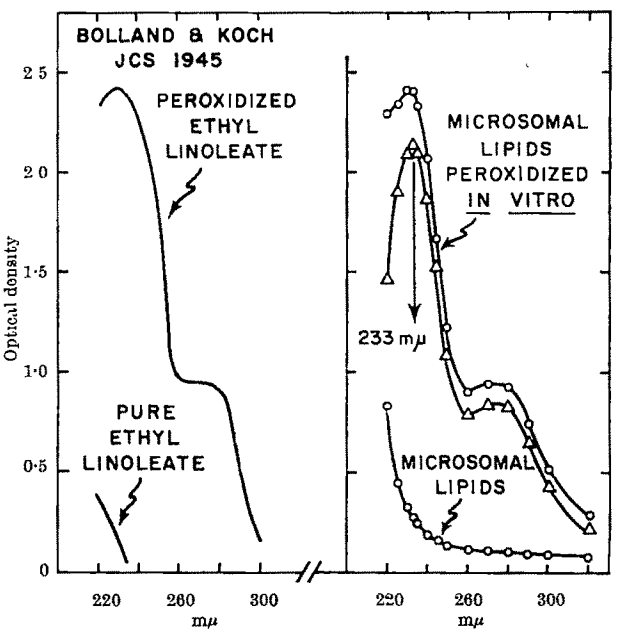

Fig. 1. Diene conjugation in lipids of rat liver microsomes peroxidized *in vitro*

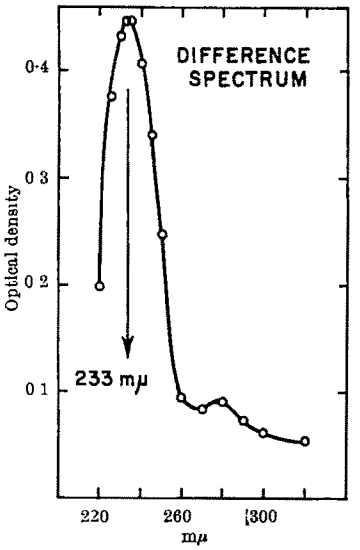

Fig 2. Diene conjugation absorption of rat liver microsomal lipids 6 h after carbon tetrachloride poisoning

of the unsaturated fatty acid side-chains of complex structural lipids of the endoplasmic reticulum, setting off autocatalytic chains of peroxidative lipid decomposition. Loss of physiological and biochemical properties of the endoplasmic reticulum would then follow, leading eventually to the well-known pathological consequences of carbon tetrachloride poisoning.

Alkaloids as Possible Intermediaries in Plant Metabolism

SINCE their discovery 150 years ago, alkaloids have been the subject of innumerable research papers, practically all of which have been concerned with the occurrence, production in the plant and properties of the final molecular species. Even when the plant produces a series of closely related alkaloids, it has normally been considered sufficient to show their order of formation and which was the ultimate molecule. In all this work the tacit assumption has been that alkaloids are the end-products of interesting biosynthetic sequences and that functionally they represent slowly accumulating heaps of metabolic sludge. Only rarely is there any evidence of return to metabolic circulation and the quantities involved are extremely small[1]. However, some workers have shown that nicotine, which itself is derived partly from nicotinic acid[2], may not be an end-product substance but suffers extensive metabolic change, acting as a methyl donor to choline[3] and is also incorporated into insoluble organic substances[4], related alkaloids, amino-acids, sugars and other common metabolites[5]. Another approach has been to study the variation in alkaloidal pattern during plant growth; Hemberg and Flück[6] found some variation in total alkaloids in *Datura* species at 4-h intervals, and Heydenreich and Pfeifer[7] have demonstrated marked variation in the alkaloidal pattern in *Papaver somniferum* fruits at 6-h intervals. These variations suggest a dynamic role for the alkaloids, and our own work on developing fruits of *Conium maculatum* and *Papaver somniferum* has shown that even more marked variations occur at 3-, 2- and 1-h intervals[8–10]. Furthermore, our results indicate that the major alkaloids, conine and morphine, respectively, disappear rapidly soon after formation, again indicating that they are not 'dead-end' substances but may be the precursors of non-alkaloidal substances of metabolic significance. In order to confirm this and gain further information on the problem, we carried out a preliminary experiment by feeding radioactive morphine (the major alkaloid) to poppy plants (*Papaver somniferum* L.) in 1963. Examination of the fruits a few days later showed that the morphine had been converted into non-alkaloidal substances; accordingly, we decided to repeat the experiment more carefully the following year.

Radioactive morphine was prepared by feeding carbon-14 labelled tyrosine hydrochloride (universally labelled) to poppy plants and separating the now active morphine from the latex collected about a week after feeding. The purity of the radioactive morphine was checked by R_F values, melting point and reverse isotope dilution. In the first experiment, 5 mg, as the hydrochloride dissolved in water at *p*H 7·2, was fed to four poppy plants just below the developing capsules by the method already described[10], 18 days after petal fall. Three days after feeding, the capsules were gathered and the seeds separated and extracted with methanol. In the second experiment, 23 mg of another batch of radioactive morphine was fed to four plants and the seeds collected and treated as before, 5 days after feeding. The methanol extracts were examined for radioactivity, and the results recorded in Table 1 show that about 3–6 per cent of the fed activity was present in these extracts. This was in marked contrast to the alkaloidal fractions which were separated from the capsules and other parts of the plant (stem, leaf, root) which showed practically no radioactivity apart from the phenolic alkaloids of the capsule which contained about 0·01 per cent of the fed radioactivity.

Table 1

^{14}C-morphine fed	Seeds collected after feeding (days)	Total radioactivity in methanol extract of the seeds (d.p.s.)	Radioactivity incorporated (per cent)
5 mg containing 680 d.p.s.	3	20	3·0
23 mg containing 2,040 d.p.s.	5	116	5·7

The methanol extracts were examined by paper chromatography using *n*-butanol–water–acetic acid (5 : 2 : 1) as running solvent and spraying with Dragendorff and ninhydrin reagents. Appropriate spots were also cut out and their radioactivity measured in a scintillation counter. As was to be expected, no alkaloids were detectable in the seeds and only very slight radioactivity was present in the position on the chromatogram where morphine would occur. About 90 per cent of the total radioactivity was present in three diffuse ninhydrin spots of low R_F value (distinctly lower than that of morphine in the same system). The radioactivity of these ninhydrin positive substances must be derived from the body of the morphine molecule and not from the labile *N*-methyl group since the latter would be non-radioactive in the morphine we used. It is interesting to note that methanol extracts of seeds from plants fed with carbon-14 labelled tyrosine also showed similar radioactive ninhydrin spots which contained about 75 per cent of the total activity of the extracts. As we had more active material to work with, we examined seeds collected 3, 4 and 5 weeks after feeding and found that the radioactivity in the methanol soluble fraction decreased with age but that in the methanol insoluble fraction increased. It may well be that these ninhydrin substances are themselves gradually built into larger molecules as the seed develops. We are now preparing larger quantities of specifically labelled

morphine for further investigation of these interesting changes.

Our results are obviously of only a preliminary nature and leave unanswered the question of the fate of the 94–97 per cent of the morphine activity not accounted for. Clearly there are many ways in which the newly formed substances could be translocated, such as within the ramifying latex system or by transfer to the phloem and xylem vessels of the vascular bundles. Dispersal by these means to other parts of the plant might account for some of the missing activity. Some of the newly formed substances might be broken down into $^{14}CO_2$, for which, unfortunately, we were not able to test under the conditions of the experiment. In further experiments we intend examining the newly formed compounds as soon as possible after their formation in the latex.

Interest in the seeds stems from our earlier observation that there is no anatomical connexion between the latex vessels and the seeds[11]. Latex vessels occur in all parts of the plant except the stamens, ovules and seeds; alkaloids are also absent from these organs. The presence of derivatives of morphine in the seeds is therefore of some interest.

Significance and Regulation of Methaemoglobinaemia

Beutler and Mathai[1] have rather simplified my thesis[2]. A central theme, that the methaemoglobin–oxyhaemoglobin and oxidized-reduced glutathione (GSSG–GSH) systems are loosely linked in a buffering system against the selective and destructive effects of different types of oxidizing compound, has already been discussed[3]. On the basis of published[4–10] and otherwise unpublished[2] observations, it was also proposed that the pentose phosphate pathway governs the equilibrium between methaemoglobin formation and GSH depletion, and thus generally between the degrees of methaemoglobinaemia and haemolysis in erythrocytes exposed to catalytic oxidants. The suggestion was made that, by providing a source of reductant energy which varies in degree and direction with the oxidant stress, the pentose phosphate pathway might well have played an important part in the evolution of the anuclear mammalian erythrocyte. These concepts, relating to the adaptive role of the pentose phosphate pathway, seemed essentially in accord with previous and concurrent observations concerning the role and control of the pentose phosphate pathway in other mammalian tissues (see refs. 11–22, and refs. 70–74 cited by Jandl *et al.*[23]).

Of more immediate relevance were the differences observed *in vitro*, which appeared sufficiently striking to warrant the following tentative classification of oxidant haemolysins[2]: (1) 'simple' oxidants such as nitrite, which cause methaemoglobin formation, with GSH depletion only if the pentose phosphate pathway is inadequate, and irreversible damage in normal cells only after prolonged exposure; (2) catalytic oxidants such as quinone, *p*-aminophenol and the phenylhydrazines, which cause in succession GSH depletion, methaemoglobin formation, oxidative destruction of haemoglobin, and osmotic hyperfragility, and which are relatively ineffective stimulants of NADPH-dependent methaemoglobin reduction; (3) catalytic oxidants such as naphthoquinones, which catalyse methaemoglobin formation and GSH depletion in normal cells potently and to a similar relative degree, cause irreversible damage only after gross GSH depletion, and are powerful catalysts of NADPH-dependent methaemoglobin reduction; (4) powerful catalysts of NADPH-dependent methaemoglobin reduction, such as methylene blue, which cause gross GSH depletion (and frank haemolysis *in vivo*[24]) only with an inadequate pentose phosphate pathway of GSSG reduction; (5) catalytic oxidants such as 2-naphthol and 'Primaquine', which selectively increase osmotic fragility relative to other changes; (6) aromatic compounds such as phenacetin and acetylsalicylic acid, which presumably oxidize erythrocytes only after conversion *in vivo* to an active derivative; (7) aromatic compounds such as 'Primaquine', which are active *in vitro*, but appear likely to exert an additional effect after degradation *in vivo*[24].

Because acetylphenylhydrazine causes complete loss of GSH before achieving methaemoglobin formation, prior formation of methaemoglobin by nitrite would not be expected to favour GSH depletion by this aromatic compound. The experiments of Beutler and Mathai[1] thus seem in agreement, rather than in disagreement, with my thesis. Clearly, their findings neither confirm nor refute the buffering effect of the oxyhaemoglobin-methaemoglobin system on the GSH–GSSG system in erythrocytes exposed to more potent methaemoglobin-forming catalysts, such as naphthoquinones, or to 'simple' oxidants such as nitrite. However, our observation that methaemoglobin formation usually precedes both haemoglobin destruction and osmotic hyperfragility suggests that the production of methaemoglobin may buffer the cell against irreversible oxidative changes, even by drugs which have first depleted GSH. The very conversion of oxyhaemoglobin to a reconvertible derivative, incapable of catalysing the generation of erythrotoxic hydrogen peroxide by oxidants[25,26], might well be regarded as a cellular adaptive mechanism.

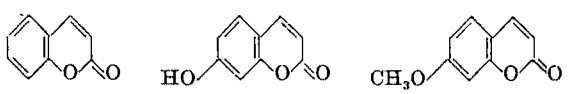
Production of Coumarins by *Phytophthora infestans*

THE causal organism of potato blight, *Phytophthora infestans* (Mont) de Bary, has been subjected to very close investigation since it was first described just over a century ago. It is only in recent years, however, that it has been possible to culture this organism *in vitro* on a chemically defined medium, and very little work has been done on its secondary metabolism. Such investigations are of interest because they may provide some insight into the basis of the host–parasite relationship.

The tissue surrounding blight lesions in potato tubers of several varieties fluoresces strongly in ultra-violet light and at least part of this fluorescence is due to an accumulation of oxygenated coumarins and their glucosides. Scopoletin (I) and scopolin accumulate to the greatest extent[1], but increases in aesculetin (II) and umbelliferone (III) also occur[2] (Fig. 1).



I II III

Fig. 1. Coumarins from blight lesions

Although the potato tuber is capable of producing these compounds[3], and in fact coumarin itself[2], since they are present in uninfected tubers, the possibility exists that *P. infestans* can also produce them. This has now been shown to be the case.

When cultured on an extract of French beans, prepared by blending 250 g of beans in 1 l. of distilled water and filtered through celite, an isolate of race 4 of *P. infestans* grew well, but no coumarins were detected either in the mycelium or in the culture filtrate. However, when grown on a synthetic minimal medium[4], small amounts (about 0·1 mg/l.) of three coumarins were produced. Although *P. infestans* grows well on this synthetic medium, better growth occurs on the French bean extract, and it may be that the formation of these compounds is stimulated by stress conditions as in certain higher plants[5–7]. The coumarins were isolated and shown to be coumarin (IV), umbelliferone (V) and herniarin (VI) by paper and thin-layer chromatography, characteristic fluorescence and reactions with base, R_t values in gas–liquid chromatographic analysis, ultra-violet spectra and, not least, odour (for coumarin and herniarin). The properties of the isolated compounds corresponded with those of authentic samples.

IV V VI

Fig 2 Coumarins produced by *P. infestans*

Recent work with higher plants has clarified the biosynthetic routes from phenylalanine to the coumarins[8]. Accordingly, radio-tracer experiments were carried out with *P. infestans* to determine whether similar or different pathways are operative. They involved the administration of 150 μmole/l. of generally ^{14}C-labelled L-phenylalanine and L-tyrosine and specifically 2-^{14}C-labelled *trans-p*-coumaric acid to one-day-old surface cultures growing on the minimal medium. Ten Roux bottles, each containing 200 ml. of medium, were used for both amino-acid experiments, and six were used for the *p*-coumaric acid experiment. Hyphal fragments, obtained by lightly blending the mycelium of seed cultures in a Waring blender, were used for the inoculum. After eight days growth, the mycelium was extracted with acetone and the culture filtrate with ethyl acetate. The incorporations of activity into coumarin and umbelliferone were measured by inverse dilution analysis[9]. Thus, known weights (about 12 mg) of unlabelled coumarin and umbelliferone were added to each organic extract and completely dissolved. The coumarins were then isolated from the extracts by repeated thin-layer chromatography on Kieselgel *G* using solvents (9 : 1 chloroform-methanol; chloroform) that effected their complete separation. Each was then eluted from the Kieselgel, fractionally sublimed, and crystallized to constant activity from water. The incorporation levels into coumarin and umbelliferone are shown in Tables 1 and 2. The herniarin present was not quantitatively measured, but the pattern of its activity was identical with that of the umbelliferone. It should be recognized that the low incorporation levels are due in part to the very small quantities of coumarins formed in the experiments.

Table 1. INCORPORATIONS INTO COUMARIN

Precursor	C p.m. fed	Percentage incorporation ($\times 10^{-2}$) Mycelium	Broth	Total
L-Phenylalanine	$3\cdot502 \times 10^6$	3 93	5 67	9 60
L-Tyrosine	$3\cdot362 \times 10^6$	0 170	0 316	0 486
p-Coumaric acid	$1\cdot081 \times 10^5$	0·264	0 315	0·579

Table 2. INCORPORATIONS INTO UMBELLIFERONE

Precursor	C p.m. fed	Percentage incorporation ($\times 10^{-2}$) Mycelium	Broth	Total
L-Phenylalanine	$3\cdot502 \times 10^6$	6 16	6 31	12 47
L-Tyrosine	$3\cdot362 \times 10^6$	0·298	0 060	0 358
p-Coumaric acid	$1\cdot081 \times 10^5$	2 30	5 83	8·13

The results show that phenylalanine is a good precursor of coumarin and umbelliferone. They further indicate that *p*-coumaric acid is a good precursor of umbelliferone, but not coumarin, and that tyrosine is not significantly used for either. The pattern of incorporation into herniarin matches that into umbelliferone.

The involvement of *trans-p*-coumaric acid in the biosynthesis of both umbelliferone and herniarin indicates that deamination of an aromatic amino-acid is part of the operating sequence. The negligibly small incorporation of tyrosine is good evidence that the pathway lies from phenylalanine to *trans*-cinnamic acid, which may then give rise to coumarin. The specific *para*-hydroxylation of cinnamic acid will result in *trans-p*-coumaric acid[10], the precursor of umbelliferone and herniarin. Clearly, these compounds may be ultimately derived from shikimic acid, as they are in higher plants[11].

The direct 7-hydroxylation of coumarin to give umbelliferone cannot be excluded, but the good incorporation of *p*-coumaric acid into umbelliferone suggests that the hydroxylation pattern is established at the cinnamic acid stage The methylation of umbelliferone to give herniarin may occur, and this would constitute a variant of the apparent pathway to herniarin in lavender[12]. The steps from the cinnamic acid stage to the lactone ring system may involve hydroxylation *ortho* to the side chain, direct attack by the acid group, or spirolactone rearrangement[8]. These alternatives are under investigation.

These preliminary observations permit a definition of the overall pathways that may give rise to the coumarins in *P. infestans* cultures (Fig. 3), since control experiments have demonstrated that their presence is a result of the metabolic activities of the fungus, rather than a spontaneous cyclization of cinnamic acids[13].

Thus, *P. infestans*, using glucose as its main carbon source, is capable of total syntheses hitherto observed solely in higher plants[14]. Its observed secondary metabolism bears striking resemblances to that of certain higher plants since similar intermediate compounds are involved in similar biosynthetic pathways.

The results suggest that *P. infestans* may contribute to the accumulation of coumarins which occurs in infected potato tubers. The apparent relationships of the synthetic mechanisms used by both host and parasite

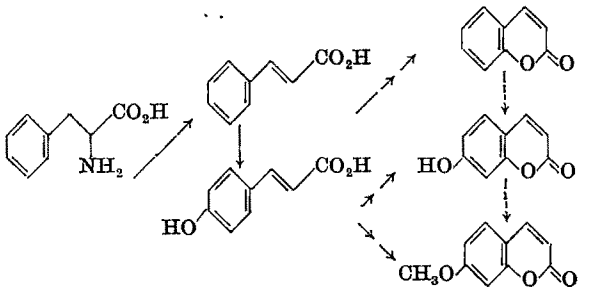


Fig. 3. Possible routes to coumarins in *P. infestans*

offer the possibility of an interaction between the two in which intermediates synthesized by one are further metabolized by the other. Although coumarin and certain of its oxygenated derivatives possess well-documented physiological activity[15,16], there is no evidence as yet to implicate them as primary factors in the control of the development of the host–parasite relationship.

We thank Miss J. Brown and Miss M. McKenzie for their technical assistance, and one of us (D. J. A.) thanks the Department of Scientific and Industrial Research for a research studentship.

BIOLOGY

Phosphorous Metabolism and Auxin Action

SEVERAL workers have proposed that an increase either in utilization or synthesis of adenosine triphosphate (ATP) accompanies growth induced by applied auxin, and they imply that the increased rate of metabolism of ATP is concerned directly in the mechanism of auxin action. Sen Gupta and Sen[1] reported that treating coleoptile sections of *Avena* with indolylacetic acid (IAA) increased the amount of ^{32}P incorporated from orthophosphate into adenosine pyrophosphate and hexose phosphate. Marrè and Forti[2] reported a transitory increase in concentration of ATP 30 min after treating sections of etiolated pea stem with IAA. In the work reported here the effect of IAA on metabolism of phosphorylated compounds in sections of pea stems grown in light was investigated by measuring the amount of ^{32}P incorporated into nucleotides in short 'pulse-chase' experiments.

The stem sections were similar to those used by Galston and Kaur[3]. After cutting, they were suspended in phosphate buffer (10 mM, *p*H 6·1) or buffer plus 0·1 mM IAA (Sigma Chemical Co.) as required. Replicate batches of sections held in small stainless-steel baskets were treated with ^{32}P-orthophosphate by lowering into 4 ml. of the appropriate solution containing 0·15–0·2 mc./ml. After the time required, baskets and sections were removed, drained on paper tissue and washed in unlabelled medium.

Preliminary experiments demonstrated that ^{32}P-orthophosphate was washed from the 'free space' of the tissue in approximately 4 min and that treating with IAA did not alter the rate of uptake of ^{32}P-orthophosphate into the tissue. Treating sections with IAA for 30 min at 25° C induced elongation significantly greater than in controls. To examine the effect of treating sections with IAA on incorporation of ^{32}P into organic phosphate, replicate batches of fifteen sections were treated with ^{32}P-orthophosphate with or without IAA (0·1 mM). After 1 or 2 min, the sections were removed, drained and washed in unlabelled medium for 0·5, 1, 2 or 4 min. Phosphates were extracted and prepared for chromatography by the method of Bieleski and Laties[4]. The extracts were analysed by chromatography in two dimensions on Whatman No. 3 *MM* paper washed in 1 N acetic acid, using *n*-propyl acetate—90 per cent (v/v) formic acid–water (11 : 5 : 3, by volume)[5] followed by *iso*-butyric acid–ammonia (specific gravity 0·91)–water (66 : 1 : 33, by volume)[6]. Organic phosphates were located in preliminary experiments by co-chromatography. Autoradiographs were prepared by leaving in contact with X-ray film (Kodak, 'Blue brand') for 10–12 days. Circles of paper containing radioactive spots were placed in large planchets and radioactivity was measured using a Nuclear Chicago '*D* 47' gas-flow counter. When required, phosphates were eluted from the paper and from appropriate blank areas of equal size by soaking in sulphuric acid (10 mM) and total phosphorus estimated[7]. Specific activities were calculated using a mean value of total phosphorus from all four batches of tissue receiving the same treatment.

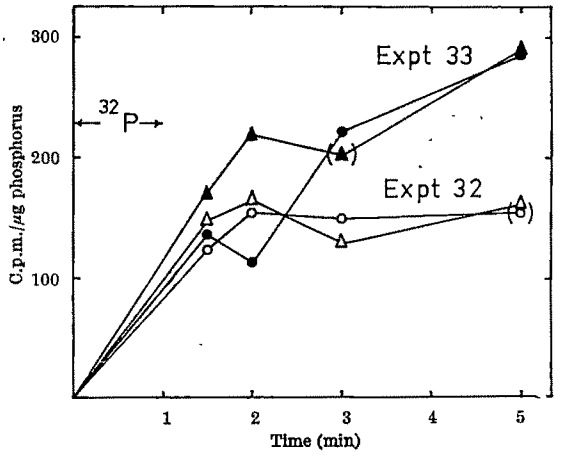

Fig. 1. Change in specific activity of ATP in sections of light-grown pea stem after treating for 1 min with ^{32}P-orthophosphate. Before and after treatment, the sections were washed in ^{32}P-orthophosphate buffer (10 mM, *p*H 6·1) with (△ and ▲) or without (○ and ●) IAA (0·1 mM). Treatment with IAA was not significant ($P = 0·05$) when tested by split-plot analysis. Symbols in brackets are calculated missing values

Fig. 1 shows that the change in specific activity of ATP during the chase in unlabelled medium was not altered by treating with IAA. In treated tissue, the concentration of ATP decreased and the ratio ADP/ATP appeared higher (Table 1) though a reliable estimate of ADP concentration was made only in experiment 33.

Label could not be detected in glucose phosphate on autoradiographs of all experiments. The label recovered in this fraction from tissue washed for 4 min is shown in Table 2.

Table 1. Mean Concentration of Nucleotides and the Ratio ADP/ATP in Tissue Incubated with and without IAA

Expt.	Treatment	Nucleotides: μmoles per 15 sections ADP	ATP	ADP/ATP
32	Control	0·0355*	0·0229	1·55
	IAA	0·0266	0·0150	1·77
33	Control	0·0331	0·0237	1·40
	IAA	0·0349	0·0116	3·00

* Single observation only.

Table 2. Amount of ^{32}P Recovered in Glucose Phosphate from Tissue Washed for 4 min in Unlabelled Medium

Expt.	Duration of pulse of ^{32}P (min)	^{32}P recovered in glucose phosphate (percentage of total ^{32}P esterified) Treatment IAA	Control	IAA/Control
28	2	28·2	17·4	1·62
30	2	9·4	3·8	2·47
31	1	7·1	4·5	1·58
33	1	8·9	2·7	3·30

If we represent the synthesis and utilization of ATP as

$$P_i \xrightarrow{k_1} ATP \xrightarrow{k_2} XP$$

and assume first order kinetics for these reactions,

$$(k_1 + k_2) \cdot t_{\frac{1}{2}} = \log_n 2$$

where $t_{\frac{1}{2}}$ is the half-time of maximum labelling of ATP (ref. 8). As treating with IAA does not alter $t_{\frac{1}{2}}$,

$$k_{1(\text{control})} + k_{2(\text{control})} = k_{1(\text{IAA})} + k_{2(\text{IAA})}$$

If we assume that the concentration of ATP is at a steady state and that the concentration and specific activity of orthophosphate at the phosphorylation sites are equal in both treated and control tissue:

$$\frac{k_{2(\text{control})}}{k_{1(\text{control})}} \cdot AT^{32}P_{(\text{control})} = \frac{k_{2(\text{IAA})}}{k_{1(\text{IAA})}} \cdot AT^{32}P_{(\text{IAA})}$$

As the concentration of $AT^{32}P$ is greater in control than in treated tissue,

$$\frac{k_{2(\text{IAA})}}{k_{1(\text{IAA})}} > \frac{k_{2(\text{control})}}{k_{1(\text{control})}}$$

We cannot tell directly from these results if treating the tissue with IAA increases k_2 or lowers k_1. The greater amount of ^{32}P-glucose monophosphate recovered from treated tissue suggests that IAA increases k_2, although decreasing utilization of glucose monophosphate could account for this effect also. However, glucose 1-phosphate is a precursor of cell-wall components, and increasing the rate of synthesis of glucose monophosphate could be an important part of the mechanism of action of IAA. Increase in label recovered in hexose monophosphate is the only change common both to light-grown (Table 2) and dark-grown[1] tissue treated with IAA, as the increased concentration of ATP (ref. 2) and increased recovery of $AT^{32}P$ (ref. 1) does not occur in the light-grown tissue (Fig. 1 and Table 1). In these experiments we cannot distinguish if label enters glucose monophosphate by way of photosynthesis or by the reactions catalysed by amylose phosphorylase or hexokinase. The investigation is continuing using a starch-free tissue grown in darkness.

Bispecific Cell Aggregation in Sponges

Recently, Curtis[1] has pointed out that cell aggregation in sponges is not species specific as was generally thought[2] but that bispecific aggregates can be obtained by controlling the time of addition of the cell suspension of one species to that of the other.

In the case of a mixture of *Hymeniacidon perleve* and *Suberites* (= *Ficulina*) *ficus*, Curtis also obtained simultaneous intermingling of the cells in the aggregates. Previously, de Laubenfels[3], using two *Pachychalina*, and Sarà[4], with two related species of *Leucosolenia*, have also observed intermingling of cells of two different species.

To test the capacity to intermingle of cells from taxonomically distant sponges, we have used the following species of various orders of the class *Demospongiae: Tethya aurantium* (Pallas), *Polymastia mammillaris* (Bow.), *Hymeniacidon sanguinea* (Grant), *Petrosia ficiformis* (Poiret), *Haliclona elegans* (Bow.), *Ircinia variabilis* (O. Schmidt) and one species of the class *Calcispongiae*, *Clathrina coriacea* (Montagu).

In order to follow the intermingling, one of the pair of species was previously vitally stained over a period of 48 h with neutral red diluted 1 : 50,000 in sea water. By staining with neutral red it is possible to control the behaviour even of single cells adhering to mixed aggregates. Cell suspensions were obtained by squeezing 1 g of sponge through bolting cloth '*n. XXXOO*'. 100 mg of the resulting cellular suspension were diluted with 1 ml. of filtered sea water. Suspensions of $0{\cdot}7–1 \times 10^6$ cells per ml. of each species were obtained. For the experiments on mixed aggregations, 0·5 ml. of this suspension of each of the pair of species was used and the cells were allowed to settle on coverslips in Petri dishes, 5 cm in diameter, containing 5 ml. of filtered sea water.

Bispecific aggregations of the following pairs of *Demospongiae: Tethya aurantium* and *Hymeniacidon sanguinea*; *T. aurantium* and *Haliclona elegans*; *T. aurantium* and *Petrosia ficiformis*; *H. sanguinea* and *Polymastia mammillaris* were observed at different time intervals for 24 h at 18°–20° C. A large number of aggregates were formed with intermingling of cells of the two associated species (Fig. 1 *a*, *b*). Monospecific aggregates were present in smaller numbers.

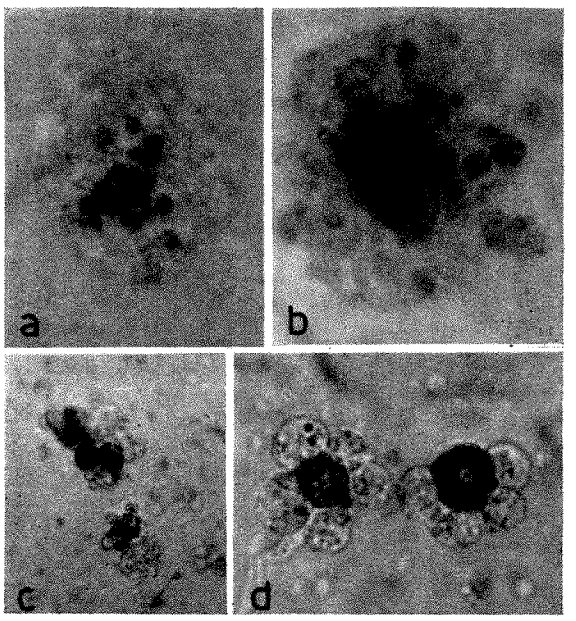

Fig. 1. (*a* and *b*) Bispecific aggregates of *Hymeniacidon sanguinea* (stained) and *Tethya aurantium* (after 3 h, ×850); (*c*) bispecific aggregates of *Clathrina coriacea* (stained) and *Tethya aurantium* (after 3 h, ×240); (*d*) cells of *Haliclona elegans* adhering to a cell of *Clathrina coriacea* (stained) (after 3 h, ×875)

A certain number of aggregates with intermingling of cells was also obtained in aggregations of *Clathrina coriacea* and *Hymeniacidon sanguinea*, *C. coriacea* and *Haliclona elegans* (Fig. 1 *d*), *C. coriacea* and *Tethya aurantium* (Fig. 1 *c*), consisting of mixed cell suspensions of a calcareous and a siliceous sponge. Monospecific aggregates were present in larger number. However, one or more cells of the other species were often incorporated in these monospecific aggregates of *Clathrina* or of the siliceous sponge.

In the aggregation of *Tethya aurantium* and *Ircinia variabilis*, a few small aggregates were formed and sometimes patches of cells of the two species loosely adhered. Only in this type of reaggregation was a significant intermingling of cells not observed.

In conclusion, bispecific aggregates of sponge cells may easily be obtained by mixing simultaneously cell suspensions of two species, even if they belong to different classes, *Calcispongiae* and *Demospongiae*.

Mixed Cell Aggregation between Sponges and the Anthozoan *Anemonia sulcata*

OUR observations[1] show that sponge species of distant taxonomic position, even if they belong to different classes such as *Calcispongiae* and *Demospongiae*, may form bispecific cell aggregates after dissociation.

To test the capacity of sponge cells to form bispecific aggregates with cells of other animal phyla we have carried out experiments on mixed aggregation between the sponges *Clathrina coriacea* (Montagu) (*Calcispongiae*), *Tethya aurantium* (Pallas) Gray, *Haliclona elegans* (Bow.) and the anthozoan *Anemonia sulcata* (Pennant).

Sponges were vitally stained in advance for 48 h with neutral red diluted in sea water 1 : 50,000. With this method a cell marking in living aggregates was obtained that was more satisfactory than the difference in appearance between sponge cells and sea-anemone cells. Marking with fluorochrome-acridine-orange was also utilized.

Cell suspensions were obtained by squeezing the sponge tissue or sea-anemone tentacles through bolting cloth without chemical treatment or after treatment for 2 h with 0·004 ethylenediamine tetraacetate (EDTA) in 0·55 M sodium chloride buffered with 0·004 M hydroxymethylaminomethane (*tris*). Sponge dissociates were diluted with filtered sea water to give suspensions of $0{\cdot}7$–1×10^6 cells per ml. More concentrated sea-anemone suspensions (6–8×10^6 cells $+ 1$–$1{\cdot}5 \times 10^6$ *Zooxanthellae* per ml.) were used.

For the experiments on bispecific aggregation (*Clathrina-Anemonia*; *Tethya-Anemonia* and *Haliclona-Anemonia*) 0·5 ml. of these sponge and sea-anemone suspensions were used. Cells of both species were allowed to settle on coverslips in Petri dishes of 5 cm diameter containing 5 ml. of filtered sea water.

Controls were performed on monospecific aggregates of sponges and *Anemonia*. Cell aggregation after dissociation in Anthozoa is known in the sea feather *Leptogorgia*[2]. In this case aggregates are formed without a further development. In *Anemonia* the aggregation process is very slow and small aggregates can be observed only after some hours, while much of the cell material is not aggregated. *Zooxanthellae* and nematocysts are present in large numbers.

In all bispecific experiments mixed aggregates (Fig. 1) were formed: they are viable at 18°–20° C even 48 h after the beginning of the culture. Moreover, as compared to the monospecific controls, aggregation appears to be stimulated by the coexistence of sponge and sea-anemone cell suspensions.

The appearance of these aggregates is variable, depending in part on the different species of sponge utilized in the experiments. In some cases, adhesion of sponge and cnidarian aggregates leads to the formation of chains of aggregates; in these cases, the single aggregates are totally or nearly totally monospecific, whereas in other cases aggregates show an intimate mixture of sponge and sea-anemone cells.

Aggregates of *Tethya aurantium–Anemonia sulcata* obtained by mixing suspensions respectively of $1{\cdot}5$–2×10^6 cells (*Tethya*) and 6–8×10^6 cells $+ 1$–$1{\cdot}5 \times 10^6$ *Zooxanthellae* (*Anemonia*) per ml. after 24 h in synthetic sea water[3] and attachment on wooden substrates were transferred to natural sea water in aerated aquaria.

At 72 h a mosaic pattern of tissue patches of *Tethya* and *Anemonia* was observed (Fig. 2) after fixation in Bouin's liquid and staining in Carazzi's haemalum-eosin. Due to detachment of aggregates from their substrate we have so far been unable to follow their further development.

In conclusion, viable cell aggregates may be formed from mixtures of cell suspensions of species of two different phyla, Porifera and Cnidaria. A selective organization of tissue of both species takes place.

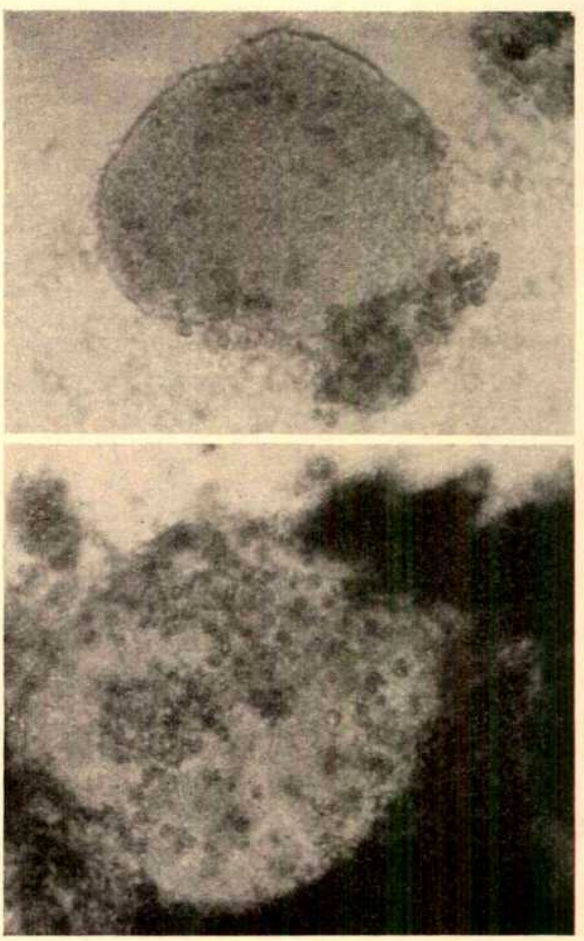

Fig. 1. Interspecific living aggregates of *Haliclona elegans* (dark, vitally stained) and *Anemonia sulcata* (light, unstained). After 11 h. ×225

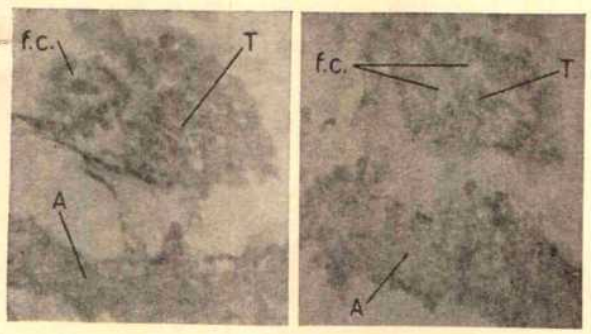

Fig. 2. Mosaic pattern from a *Tethya–Anemonia* aggregate (*T*, *Tethya* tissue, *A*, *Anemonia* tissue, *f.c.*, flagellate chambers). After 72 h. ×650

Our results agree with recent work on mixed cell aggregation[4,5] or heterokaryon formation[6,7] in emphasizing that compatibility may exist between cells from different species.

Temporary Alteration of the Behavioural Repertoire of a Hermit Crab

DURING intraspecific interactions, hermit crabs rarely do physical damage to one another, but communicate by means of displays[1,2]. The aggressive displays executed by a crab during an interaction are determined by a number of factors. Each species has an aggressive repertoire, in which some behaviour patterns occur frequently and others are rare. Every individual has gone through physiological and psychological developmental sequences which affect that crab in any interaction[3]. Characteristics of the environment will also determine, in part, what will happen in an aggressive interaction.

When specimens of *Calcinus tibicen* Herbst, a common intertidal hermit crab of the Caribbean area, interact, several types of aggressive displays may be executed. The two most common displays have been termed the cheliped extension and the ambulatory raise[1]. They involve stereotyped upward-outward movements of the respective appendages. The frequencies of occurrence of these behaviour patterns during aggressive interactions have been determined[4]. Also it has been found that individuals of *C. tibicen* react to the presentation of aggressive models fashioned from conspecific specimens[1]. A series of presentation experiments were carried out to determine how a crab's immediate past experience might affect its behaviour in aggressive interactions.

Two models were fashioned from dried specimens of *Calcinus tibicen* and attached with Duco cement to glass rods, 6 mm in diameter. The ambulatory legs of one model were in a neutral position and its chelipeds in the raised position of a double cheliped extension. The chelipeds of the second model were in a neutral position but the first ambulatory legs in the fully extended position of a double ambulatory raise. Twenty individuals of *C. tibicen* were removed from a maintenance tank and placed in individual culture dishes, 8·5 cm in diameter, which contained a layer of sand. Three hours after placing in the dishes, presentations were started. Ten animals were presented with the cheliped extension model and ten with the ambulatory raise model. Each presentation consisted of slowly moving the model toward the animal, holding it about 5 mm from the animal for 3 sec, and then removing the model. The animal's reaction to the presentation was recorded (execution of a cheliped display, ambulatory display, retreat, ducking back into shell, move toward the model or no observable reaction) and the model presented to the next animal.

Thirty presentations were made to each animal the first day, forty each day for the next four days and ten the last day for a total of 200 presentations to each animal of four groups (Groups 3–6), while two groups (Groups 1 and 2) were given only 100 presentations (10, 40, 40, 10 on four consecutive days). Presentations were made in series of ten and at least 1 h elapsed between the end of one series and the start of the next. Three hours after the final series of presentations, the twenty animals of a group were placed together in an aquarium and the displays executed by each animal during aggressive interactions were recorded for 1–2 h. Each animal had been marked on the back of the gastropod shell it inhabited so that individual recognition was possible. No shell exchanges occurred during the observation periods. The animals to which the cheliped model had been presented will be referred to as 'cheliped-pre' animals and those presented with the ambulatory model the 'amb-pre' animals.

The responses of one group of animals to the presentations of the cheliped model were compared with the responses of the other animals to the ambulatory model by a two-by-two contingency test. The number of cheliped and ambulatory displays executed by the cheliped-pre animals during aggressive interactions was compared with the number of displays executed by the amb-pre animals by a chi-square contingency test. In addition, the frequency of execution of the two types of displays by the members of each class of animals was compared with the frequencies of these two types observed in the general aggressive interactions of untreated groups of *Calcinus tibicen* (ambulatory displays = 0·55 of aggressive displays executed, cheliped displays = 0·45) (ref. 4). Finally, the individuals were ranked within their group according to the number of displays, of the same type as the model, executed in response to the model presentations and according to the number of displays, of the same type as the model, executed during the general interaction period. These two rankings were compared by a Spearman *r* rank order correlation test.

The results for the six groups of animals are presented in Table 1. In all groups, the responses of the animals to the presentations of the two types of models were very

‡ $P < 0.05$.

§ $P < 0.01$.

significantly different ($P < 0.01$). In no group was the rank order correlation significant. The behaviour of the two classes of animals during the second hour of interaction was not significantly different in any group ($P \geqslant 0.05$).

It is clear that the presentation of the different models elicits different responses. Cheliped displays were much more frequently executed at the cheliped extension model and ambulatory raises more frequently executed at the ambulatory raise model. This occurs during natural aggressive interactions between crabs[4] and appears to be an example of social facilitation[5]. Retreat from the models and no observable response to the presentation occurred frequently with both models and no significant difference in the elicitation of these acts by the two models occurred. One hundred presentations was not sufficient to effect a significant change in subsequent behaviour whereas 200 presentations did effect a change. However, the change was very temporary since the behaviour patterns of the two classes of animals during the second hour of interaction were not statistically different by the tests used. Individuals were exposed to both kinds of displays during the first hour of general interaction and this may have counteracted the effects of the model presentations.

In groups 3 to 6, the behaviour of the cheliped-pre animals was very significantly different when compared with that of the amb-pre animals. However, when the frequencies of execution of displays was compared with the frequencies observed in untreated groups of *Calcinus tibicen*, only the cheliped-pre animals appeared to show a statistically significant change in behaviour. These frequencies were obtained for individuals of populations collected and observed in Curaçao, N.A., and it is conceivable that the frequencies of displays are different in the Miami populations of this species. If this were so, the behaviour of both classes of animals could show a change when compared with the behaviour of untreated groups. That is, the behaviour of a crab in any given situation is dependent, in part, on its past experience insofar as the particular display that a crab executes is affected by the kind of displays recently executed towards it.

The data give little information as to the basis of action of these presentations, that is, how they effected a change. The effect of the presentations cannot be explained by simple conditioning. Removal of the aggressive model probably is a re-enforcing stimulus, but that re-enforcement was given whether the animal did nothing, retreated from the model, or executed a display at it. The lack of correlation between an animal's responses to the model presentation and its behaviour when placed with the other members of the group indicates that it was not the repeated execution of a given display by a crab that tended to increase the frequency of execution of that display. It appears that seeing a display temporarily changes the probability of execution of that display.

This work was supported by a U.S. Public Health Service grant from the National Institute of Mental Health. I wish to thank Dr. Arthur A. Myrberg for many helpful discussions.

Movements and Co-ordination of the Latero-frontal Cilia of the Gill Filaments of *Mytilus*

THE observations described here were made on very young mussels (*Mytilus edulis*) in which the valves are sufficiently transparent to allow direct observation of the gill cilia in the intact animal. In young animals, the structure of the gill filaments and their ciliature is essentially similar to that of adult mussels; some evidence was obtained that the same holds for the movements of the cilia. Our observations concerned the latero-frontal cilia, which are responsible for the filtration of suspended food particles from the sea water. With this material the frontal gill surface may be viewed. The latero-frontal cilia move to and from the observer and, consequently, are only momentarily in focus. This disadvantage was overcome by the use of Gregory's solid image microscope[1], which offers a greatly increased depth of focus when compared with the conventional microscope. With this instrument it was possible to observe the entire latero-frontal cilium during all stages of its beat.

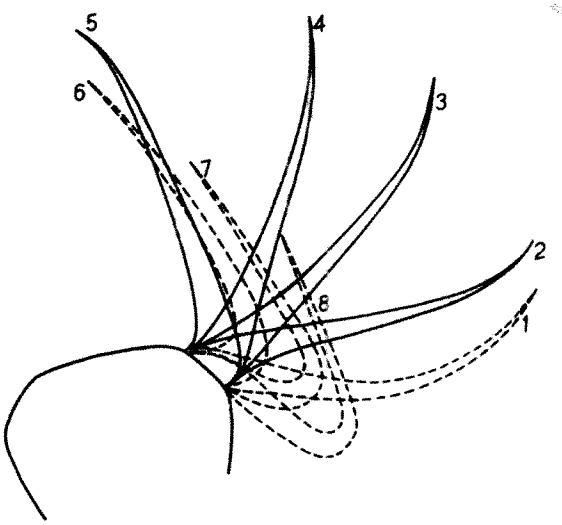

Fig. 1

Fig. 1 is a schema of the beat which is usually performed by the latero-frontal cilia of the intact mussel spat. During the effective phase of the beat (stages 2–5 in Fig. 1) only the base of the cilium bends, usually until the cilium has reached a position roughly perpendicular to the gill surface. In many cases, however, the amplitude of the beat is reduced and the movement is already reversed when the cilium has reached stage 4 or even somewhat earlier. The recovery beat (stages 6–8) starts at the base of the cilium while the distal part goes on moving in the effective direction. During recovery, the basal flexure moves distally along the cilium.

The velocity of the movement decreases after the recovery beat is completed. The movement from stage 1 to stage 2 takes at least as much time as the performance of both effective and recovery beat together. From stage 2 the movement suddenly increases in speed and reverses at stage 5 without perceptible delay.

The velocities of the effective and recovery beat differ with circumstances. When the lateral cilia are active, producing a current of water which supports the recovery beat, this phase of the beat lasts about as long as the effective one. When the lateral cilia are inactive, however, the recovery beat takes more time than the effect beat, presumably because of the increased water resistance. As a result, the duration of the whole cycle of the beat is somewhat prolonged in the latter case.

When the mussel is offered a dense suspension of food particles, one may assume that food retention by the animal diminishes[2]. In these circumstances the type of movement of the latero-frontal cilia appeared to remain unaltered, except that the trajectory of beat is shifted more or less in a frontal direction. The effective beat is now started from a position conforming to a more advanced stage, such as stage 3 in Fig. 1. In consequence of the shift the tips of the latero-frontal cilia of both sides of a filament can sometimes be seen to cross above the frontal filament surface. In most cases, however, the amplitude of beat is reduced simultaneously, in the same way as has already been described. Combination of these changes results in the effective beat again ending when the cilium is in a position perpendicular to the gill surface.

Under these circumstances the latero-frontal cilia sometimes execute quite another type of movement. While the base of the cilium stays at rest, a flexure travels along the cilium from the tip towards the base during the effective beat and in the opposite direction during the recovery beat. This type of movement, which has been described by Gray[3], is more frequently observable in excised gill fragments.

The frequency of beat of the latero-frontal cilia shows slight temporal and spatial variations, in the same way as described for the lateral cilia[4], but to a much lesser extent. On the average, a frequency of 7–8 beats/sec was most commonly found; extremes amounted to about 4 and 9 beats/sec. The prolonged duration of the beat during periods of rest of the lateral cilia mentioned earlier gives rise to a small (of the order of 0·2 beats/sec) acute decrease of beat frequency of the latero-frontal cilia when such a period sets in. The initial frequency of beat is restored as soon as the lateral cilia start their activity again.

The movements of the latero-frontal cilia are co-ordinated in such a way that cilia of one row beat alternately in phase, and each cilium differs from its immediate neighbours by half a phase. The wave-length, measured as usual between synchronously beating cilia, is equal to twice the interciliary distance, which in *Mytilus* amounts to 5–6μ. It is obvious that in a case such as this, where each 'wave' comprises two cilia only, waves as such cannot be evident. Nevertheless, a progressing movement, resembling a metachronic wave through the row of cilia, is quite often discernible. Unlike that in the lateral cilia, the 'wave' in the latero-frontal cilia moves on both sides of the filaments in a ventral direction. In many cases this direction reverses on the dorsal parts of the filaments. In between, there is a short zone, from which the 'waves' seem to originate. We are inclined to explain these phenomena by the fact that the gill filaments follow the curvature of the overlying valve, with the result that synchronously beating cilia will pass through the plane of focus in a metachronic sequence. The 'waves' originate in the part of the filament nearest to the microscope objective. Thus a metachronic movement is suggested which does not really exist. This explanation is supported by the possibility of transferring the 'origin' by moving the mussel in such a way that another part of the filament is brought nearer the objective.

The regularity of the co-ordinated latero-frontal ciliary beat appeared to be easily disturbed by external factors, such as lack of oxygen and decrease of light intensity, indicating that the automatism of the ciliary movement does not go so far as has generally been supposed. It may be for this reason that the regular movement of the latero-frontal cilia has not been observed by earlier investigators, who made their observations mainly on gill fragments taken from adult Lamellibranchs. In gill fragments we did not see the type of movement of the latero-frontal cilia, which, on evidence from our work with undamaged individuals, is considered to be normal; co-ordinated (flexural) movement is only occasionally seen in excised material. The observations above, which will be described in greater detail elsewhere[5], may illustrate the importance of the use of undamaged animals in the study of normal ciliary behaviour.

Transport of Sediment by Crustaceans and Fish

Erosion and transportation of sediment by organic agents is a well-known phenomenon, and sediment transport is known to occur over large areas in many parts of the world[1]. However, the best-known examples of organic transportation are confined almost exclusively to coarse-grained sediments. We know of no well-substantiated examples of transport of sediment finer than coarse sand over distances greater than a few centimetres.

While working on the feeding habits of the pink shrimp (*Pandalus montagui*) from the River Crouch, Essex, we noticed small but significant amounts of fine sand (grain diameter 30–200μ) in the stomachs of a considerable proportion of the specimens examined. This material is taken incidentally with food, and does not appear to serve any digestive function (cf., for example, gastroliths). When shrimps were kept without food in the laboratory the stomachs were emptied of food and sand within a period of 24–36 h. We were able, by using a Coulter counter, to determine accurately the grain size distribution of these small quantities of sand. Samples of one hundred stomachs gave ample material for accurate counts to be obtained.

In some instances, the size frequency distribution of the sediment from the stomachs was identical to that of the bottom on which the shrimps were caught. In other cases there were small but significant differences.

It was possible, after making a sediment survey over the area in which the shrimps were found, to follow small-scale migrations by comparing the size-frequency distributions of material from the stomach with that of the substrate. This work will be published in detail elsewhere.

The weight of sand carried varied from 0·00027 g to 0·0038 g per individual. Large shrimps carried more material than small shrimps. There was no difference between the distributions of grain size in separate samples of large and small shrimps.

Similar observations were made on several fish species commonly found in the River Crouch and its associated offshore channels. Significant quantities of sand were removed from the digestive tracts of each species examined, but several whiting (*Merlangius merlangus*) and one sole (*Solea vulgaris*) were found to be empty of both food and sand.

Soles (*Solea vulgaris*), plaice (*Pleuronectes platessa*), whiting (*Merlangius merlangus*) and pouting (*Gadus luscus*) all carried sediment identical in grain size characteristics to the substrate in the sampling area (see Fig. 1).

One large skate (*Raia batis*) carried sediment with a grain size distribution matching that of sediment from an area 12 nautical miles (21 km) to seaward of the sampling area (see Fig. 1). It is perhaps significant that commercial catches of skate were taken by a local fisherman from this offshore area 24 h before the arrival of several skate in our daily trawl samples.

Shore crabs (*Carcinus maenas*) carried sediment with grain size characteristics similar to that from the lower intertidal mud flats adjacent to the sampling area. Mid-

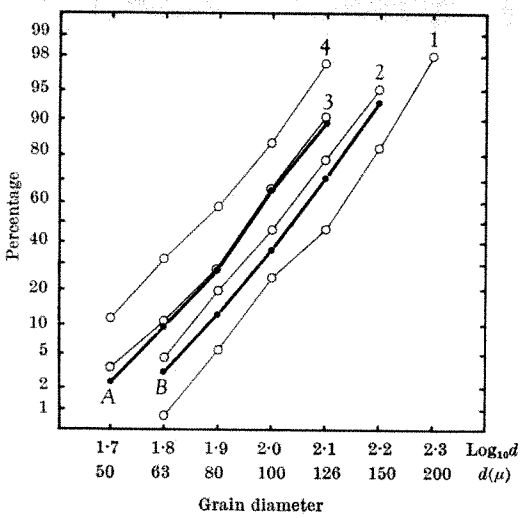

Fig. 1. Grain size distributions from stomachs and bottom sediments. Bottom sediments: ○——○, (1) East Swin Channel. 18 miles seaward of sampling area. river sediment with similar grain size characteristics is found in the River Crouch about 3 miles upstream; however, it is reasonable to assume that the shore crabs had carried sediment from the adjacent intertidal area.

We found that for individuals with significant amounts of sediment in their digestive tracts, the weight of sediment was proportional to the body weight. In the species examined, 0·1 per cent of the total body weight was found to be sediment (grain size 30–200μ). It would seem that at any one time a significant proportion of the total mass of benthonic fish and crustacea is made up of sedimentary material and in some instances it is possible that this material is moved over a distance of several miles in a few hours.

It is doubtful whether organic transportation of sediment is of great significance in the River Crouch as normal sedimentation is relatively rapid (about 2·5 mm/yr.)[2], but in areas where sedimentation is relatively slow fish and crustaceans could well be the major agents of sediment transport.

Colonization of Fresh Waters in the Republic of South Africa by *Lymnaea columella* Say (Mollusca : Gastropoda)

Lymnaea (*Pseudosuccinea*) *columella* Say 1817, described from specimens probably obtained in the vicinity of Philadelphia[1], is widely distributed in still and slow-flowing waters in the eastern United States of America, Mexico, Central America, Cuba and the northern and central regions of South America[1,2]. Fossil specimens are known from the Pleistocene of North America, and another species of the sub-genus has been described from

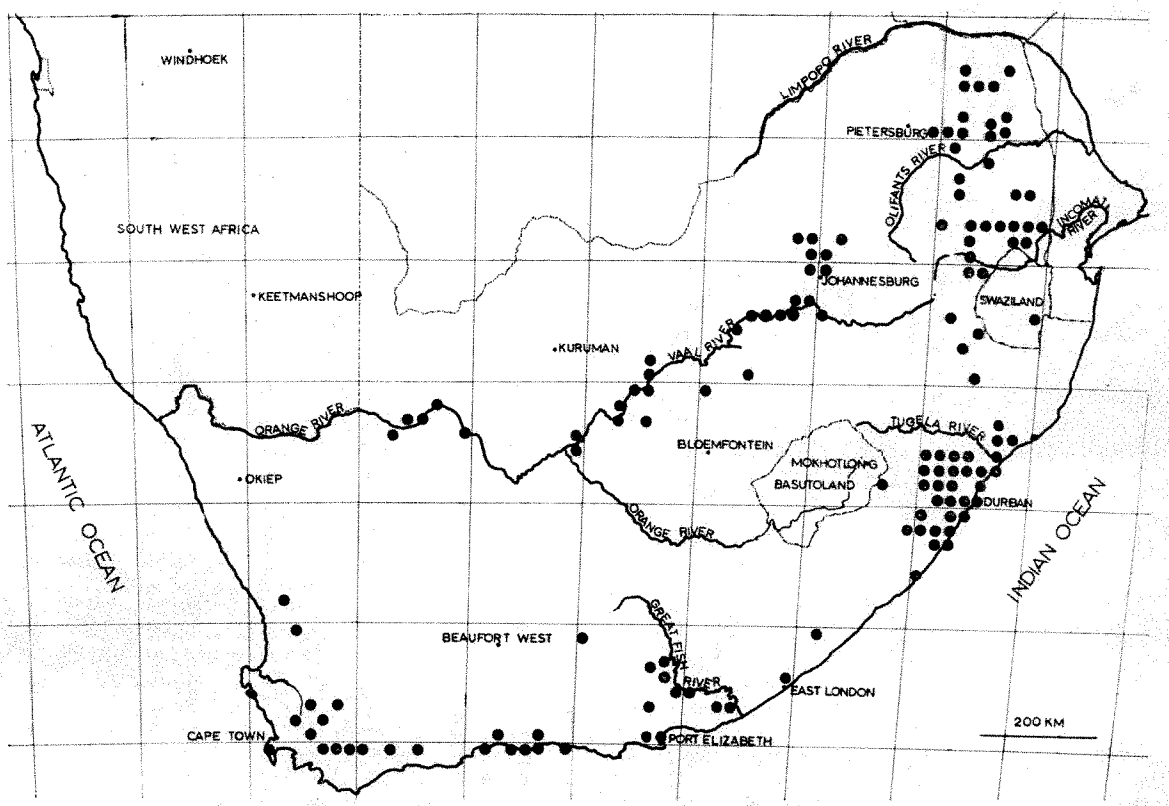

Fig. 1. Distribution of *L. columella* Say in the Republic of South Africa

e Pliocene of the same region[3]. *L. columella* is believed have been introduced by human agency, probably with aquatic plants, into Puerto Rico, Tenerife, South Africa and many European countries[4].

The earliest recorded collection of *L. columella* in Africa was made in 1944 at Jonkershoek Fish Hatchery, western Cape, South Africa[5]. While Harrison and Elsworth[6] record its presence in the Berg River, van Eeden[7] reports on its recovery from the Vaal River near Vereniging, and populations were later found in several other areas remote from the western Cape Province[8–10] and in Rhodesia[11].

During a survey, begun in 1956 and at present continuing, of the distribution of freshwater molluscs in the Republic of South Africa, many populations of *L. columella* have been found. These localities are plotted in Fig. 1, from which the impression is gained that, although first discovered in the western Cape Province, this snail could have entered the country at all the major ports, having been found at Cape Town, Mossel Bay, Port Elizabeth, East London and Durban. Although we have no records to support this theory, it seems probable that it could have spread to the eastern Transvaal via Lourenço Marques and might have been transported to Johannesburg from Durban with supplies for the aquarium trade. Once in the Vaal River catchment it could have spread down-stream in this river and into the Orange River, where it has already been located west of Upington.

It is reasonably certain that *L. columella* was either absent from South Africa or very rare before 1944 as this species was not known to Connolly[5], who thoroughly reviewed the freshwater Mollusca of the region on the basis of extensive material collected by himself and many other collectors; there are no specimens of *L. columella* in material collected during the first half of the present century in the collection of the Natal Museum. It thus appears likely that the greater part of the present distribution of *L. columella* in South Africa has been established within approximately 20 years. The rapid dispersal achieved by this snail may be related to its well-developed capacity for self-fertilization[12], and in view of proposed developments of irrigation schemes in the Orange River, whereby the ecology of large areas, at present arid, will considerably changed, it is probable that this range will be considerably extended in future.

In Europe *L. columella* has been reported only in botanical hothouses, but in South Africa this snail has in many areas become one of the most abundant freshwater molluscs, occurring in a variety of natural and artificial habitats. One factor contributing to this success may be the ability of the snails to exist on moist mud often several centimetres away from free water, thereby inhabiting a niche not occupied by any of the indigenous freshwater molluscs. On the other hand, *L. columella* also leads a submerged existence and has frequently been found in company with indigenous species, including *Bulinus* (*Physopsis*) *africanus* (Krauss) and *Biomphalaria pfeifferi* (Krauss), the snails concerned in the transmission of human bilharziasis, and *Lymnaea natalensis* Krauss. Competition might be expected to occur in this situation, but at present no evidence can be offered regarding the effect on these snails of the introduced species.

The successful colonization of a new area by a freshwater snail may have important ecological consequences that depend on the trematode parasites for which the snail is capable of providing an intermediate host. *L. columella* from Durban has already been successfully infected with South African strains of both *Fasciola hepatica* Linn. and *F. gigantica* Cobbold[13] and cercariae recovered, so that its widespread occurrence in South Africa may be expected to have serious economic consequences.

We thank Dr. J. S. Pringle and Dr. A. C. van Bruggen for the opportunity of examining specimens from the collection in the Natal Museum, and Mr. P. J. Swart (Veterinary Research Station, Onderstepoort) for unpublished observations.

PHYSIOLOGY

Formation of Acid Mucopolysaccharides by Fibroblasts and Serosal Cells

THE colloidal iron method modified for electron microscopy[1,2] has been used to investigate the distribution of acid mucopolysaccharides in the granulomatous reaction that takes place on the surface of implants of egg-white placed in the peritoneal cavity of the rat[3]. This reaction leads to the formation within 4 or 5 days of a thin layer (25–50μ) of avascular fibrous tissue which is covered 1 or 2 days afterwards by a layer of serosal cells. The fibroblasts and the serosal cells both possess a very prominent Golgi apparatus and a well-developed endoplasmic reticulum. When granulomata are reacted in bulk with colloidal iron the Golgi apparatus of both types of cell gives a positive colloidal iron reaction; this is confined to the round, more superficial vesicles (Fig. 1) and the central flattened sacs do not react. In contrast the endoplasmic reticulum never takes up iron. Isolated vesicles scattered at random throughout the cytoplasm also take up iron.

These results suggest that acid mucopolysaccharide is formed, or at least that its synthesis is completed, within the Golgi apparatus of fibroblasts and serosal cells. In the case of the fibroblasts it may be assumed that this acid mucopolysaccharide is released into and becomes a major component of the ground substance of the collagenous tissue that surrounds these cells ; and in the same way the positively-reacting Golgi apparatus of the serosal cells may be linked with a fairly thick layer of acid muco-

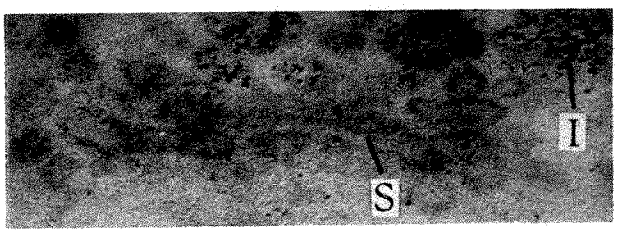

Fig. 1. Electron micrograph of part of Golgi apparatus of a fibroblast. Numerous iron particles (*I*) have collected within several of the larger vesicles, but none are present within the central flattened sacs (*S*). (× 120,000)

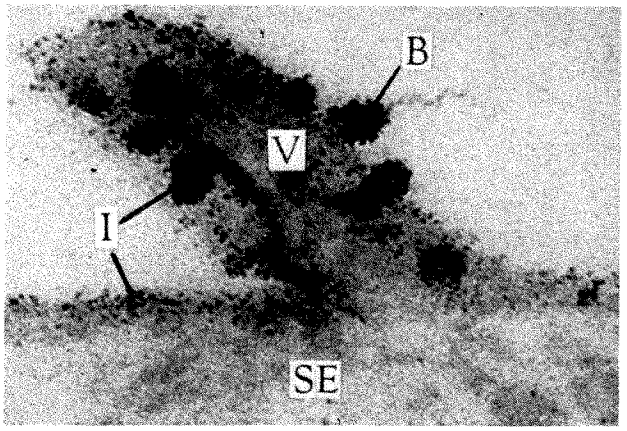

Fig. 2. Electron micrograph of the outer surface of a serosal cell (*SE*) on the surface of the implant. Iron particles (*I*) adhere to the plasma membrane of the cell and its villous process (*V*) and large numbers of them coat the surface of spherical bodies (*B*), approximately 300 Å diameter, on the surface of the villous process. (× 174,000)

polysaccharide that covers the external surface of these cells. This layer also shows focal concentrations which, when they take up colloidal iron, appear as rounded bodies 300 Å in diameter (Fig. 2). Incidentally, it is the appearance of this layer and particularly of these bodies that provides the first sign of differentiation of the serosal cells, around 5 days, from cells that also appear to act as precursors of the fibroblasts.

The colloidal iron method has good specificity, and further evidence for believing that the sites taking up iron do contain acid mucopolysaccharide is provided by the fact that when the tissues are treated with testicular hyaluronidase, after fixation and before embedding in 'Epon 812', no uptake of iron occurs.

Evidence already exists linking the Golgi apparatus with the formation of acid mucopolysaccharides. Thus in chondrocytes radioactive sulphate becomes localized within this organelle[4] and in goblet cells glucose-6-^{3}H does likewise[5]; and the Golgi zone of several varieties of normal and tumour cells gives a positive colloidal iron reaction in the light microscope[6].

The findings presented here are in accordance with this earlier work.

Plasticity of Reactions to Light in Frogs and a Possible Role for the Pineal Eye

THE reaction of frogs to light varies considerably. Negative phototaxis as high as 80 per cent has been reported with tests in a two-choice jumping stand or Y maze[1]; in another Y maze the distribution between positive and negative responses was about even[2]. In yet other tests a strong positive reaction to light was seen[3], sometimes reaching the 90 per cent level[4]. The importance of the exact behavioural situation used to assess the level of positive or negative responses to light can be demonstrated with a sequential choice apparatus (Fig. 1). In this, different batches of *Rana temporaria* showed some variability in the initial choice between a black or white surrounded water compartment. But, once in the water, there was a 5–1 probability, at the least, that at the second choice point the dark area would be selected, even if the first response had been to the lighter side. Much higher negative phototaxis scores are therefore obtained if second choice is taken into account. The first response appears to sample only part of a behavioural sequence.

What physiological mechanisms underlie this behavioural plasticity in the response to light? Muntz[4,5] has suggested that positive phototaxis is mediated by activation of a system of 'on' fibres projecting to the diencephalon, because the electrophysiological response of these fibres was maximal to blue light, and blue light was also the most effective in producing positive reaction to light. It was also proposed[2] that the red rods might act as an inhibitory mechanism and that the development of the rods in ontogeny was responsible both for the increasing relative effectiveness of blue light and the higher level of negative phototaxis in older animals. In this theory the same mechanisms control the wave-length preferences and the level of positive or negative response. However, a number of considerations suggest that there may be separate mechanisms for determining what wave-length the frog selects and those regulating the sign of the photic response.

To begin with, subsequent analysis[1] of Muntz's[4] data showed that the bulk of positive scores were not due to phototactic responses because the animals had been forced. Since the areas from which the frogs made the choice was dark the animals were, in a sense, showing a negative reaction to light, until forced, when the blue was maximally selected. But there was nothing to show that the same mechanisms controlled whether the animal moved out of the dark area or not and the selection of the wave-length. In fact, behavioural preference for blue has been seen both in situations where there are positive responses to light, and in those giving mainly negative responses. In the experiments of Boycott *et al.*[1] the level of negative phototaxis was manipulated by changing the experimental milieu of the frog, but there was a preference for blue over green in nearly every condition.

An alternative to the red rods for controlling the level of positive or negative phototaxis is the pineal eye. Boycott *et al.*[1] found that placing an opaque cover over the starting area in a black–white choice situation had two effects: the frogs stayed in the starting area longer and they showed a decrease in their preference for the black over the white stimulus (the same effects can be seen here in Table 1, cols. 3 and 4). Measurements showed that covering the starting area reduced the amount of light coming down into the frog from above much more than that reflected off the stimulus panels from in front.

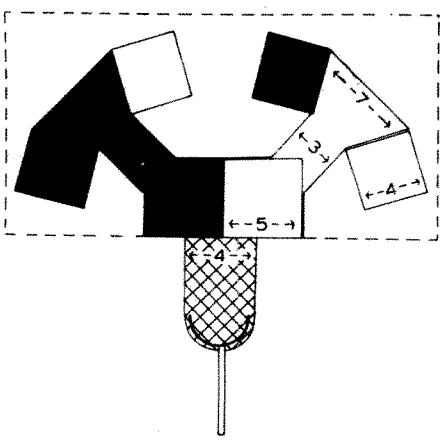

Fig. 1. Plan of sequential choice apparatus for frogs. Measurements in inches. Area within dotted line is under water, except for the walls of the apparatus not shown in this figure. Cross-hatched area is starting area about 2 in. above the water level

Table 1

Batch. Date. Experimenter	Starting area illuminated by cold cathode tube light: Opaque hats	Trans-parent hats	Differences between opaque and transparent hats, one-tailed test	Unop-erated controls	Starting area dark: Unop-erated controls

Percentage of all unforced responses made to black	36·8	57·1		63·0	11·8

W, *B*: shows unforced responses to white and black sides. In brackets are the number of forced responses to black and white sides. n = No. of animals per group. The other figures show mean latencies in sec for the unforced responses.

(For a diagram of this apparatus see Mrosovsky[6]). The pineal eye, lying on top of the head, is a structure well situated to mediate behavioural differences such as those produced by reducing the light coming down from above the animal. Moreover, the pineal nerve runs to the diencephalon and light inhibits the electrical activity of the pineal nerve[7]. Therefore it is suggested here that the pineal system interacts with other diencephalic mechanisms in controlling phototaxis. To test this hypothesis, since placing the animals in darkness will alter the contribution of the red rods (due to Purkinje shift) as well as the activity in the pineal nerve, some experiments were made with frogs in which the pineal eye was selectively covered.

A simple method for covering the pineal eye is shown in Fig. 2. Frogs, adult *R. temporaria*, were lightly anaesthetized (placed in a jar with ether for 25–75 sec). A pliable opaque plastic hat was fixed between the lateral eyes with two stitches. The position of the hat was such that it should also screen the photosensitive area in the brain itself[8] from overhead illumination. Translucent hats of similar weight were fitted on to other groups of frogs. The animals were then light adapted for at least 12 h in boxes described previously[1]. Each frog was given four trials in a two-choice apparatus. A diagram of this has been given elsewhere[1]. The starting area was illuminated from above by a cold cathode tube. The black and white stimulus panels were illuminated by a 150-watt bulb about 5·5 ft. above, and by daylight from a window behind. The starting area was painted matt black inside to restrict the light reaching the frogs from the walls as much as possible when the cold cathode tube was on. If no response was made within a minute the animals were forced by means of a rod and an attached plaque at the back of the apparatus. Animals in each batch were tested on the same day by the same experimenter, except batch 9 which was run in two replications separated by a week.

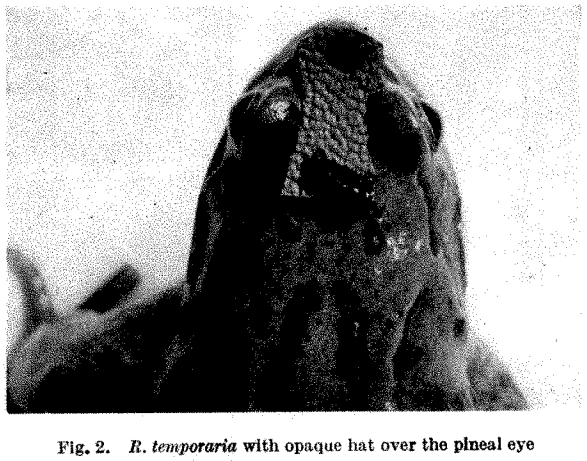

Fig. 2. *R. temporaria* with opaque hat over the pineal eye

Table 1 gives the results of these experiments. The significance of the differences between opaque and translucent hatted groups was assessed as follows: each animal was given a score for black–white choice on the basis of its unforced responses. *S* was then computed and the *z* value obtained was calculated. The test was in effect a Mann–Whitney with ties. For two batches the opaque-hatted animals showed a significantly greater choice for the white stimulus panel than the translucent-hatted ones. Somewhat similar behavioural effects have been seen in lizards: animals with the 'third eye' removed appeared easier to catch and emerged from cover more than controls[9].

However, in the third batch tested here the opaque hats did not increase the choice of white stimulus above the level for translucent-hatted frogs. A number of possibilities might account for this. The pineal system may degenerate in some animals: Dodt and Heerd[7] found that the electrophysiological response to light in the pineal nerve could not be found in about 30 per cent of the animals they tested. More probably the failure to get high scores for the white stimulus in these opaque-hatted frogs is connected with the already relatively high scores for this in other animals in this batch. It was previously suggested[1] that some of the variation in the phototaxis between different batches of frogs is associated with the latency of the response; but the relationship has not been fully worked out. These differences between different batches of frogs make it necessary to manipulate variables within given batches and test groups at the same time.

The fact that the significant differences between the opaque and translucent hatted animals were found in some batches tested on the same day, and in the same conditions, suggests that the pineal system may make some contribution in controlling phototaxis. But these effects are probably closely dependent on the details of the apparatus used. In other experiments, with an open jumping stand with grey walls of the type used by Mrosovsky[6], covering the pineal eye had slight or no effect. Moreover, in experiments shown in Table 1, covering the pineal eye with the present method did not increase the latency of the moving out of the starting area, whereas covering the starting area with an opaque lid[1] or turning off the cold cathode tube light has this effect (Table 1). Other systems must also, therefore, be important in controlling the level of the positive or negative reaction to light. If the richness and diversity of the behavioural repertoire are examined and analysed in different situations a more complete idea of the controlling systems may be found. To explain the behaviour of the frog from physiological abstractions may give too simple an idea of the mechanisms at work.

These experiments were supported by the Medical Research Council Unit for the Experimental Investigation of Behaviour, University College, London.

Failure of Thymectomy in New-born Guinea-pigs to influence Contact Sensitization

RECENT evidence indicates that thymectomy in new-born laboratory animals of some species may result in immunological deficiencies. These may become manifest as compromised capacity to form circulating antibodies[1], as delayed homograft rejection[2,3], as diminished capacity to develop tuberculin-type sensitivities[1], and as lowered resistance to infection[1]. These deficiencies may be related to a reduction in the number of circulating lymphocytes and a failure of germinal centre development, as observed in neonatally thymectomized mice[2].

There is evidence in favour of an important part played by mononuclear cells in allergic contact sensitivity. The dermal infiltrate and blister fluid generally contain significant numbers of these cells[4]. Allergic contact sensitivity has been passively transferred in guinea-pigs by means of leucocytes[5]. However, the results of attempts at such transfer in man have been conflicting[6,7]. The importance of the regional lymph nodes in the sensitization process also has been demonstrated[8].

Decreased sensitizability to dinitrofluorobenzene has been shown in some cases of ataxia telangiectasia associated with thymic aplasia[9], and in a case of lymphopenic ('Swiss') agammaglobulinaemia associated with thymic aplasia[10]. On the other hand, agammaglobulinaemias without lymphopenia or decreased thymic tissue showed normal responses to dinitrofluorobenzene[10].

The purpose of the present experiment was to test the effect of thymectomy in new-born guinea-pigs on the subsequent development of contact sensitivity to 2,4-dinitrochlorobenzene (DNCB) and to ascertain whether any observed changes correlated with any changes in blood leucocyte counts.

New-born offspring of Hartley strain albino guinea-pigs were divided into a thymectomized group, a sham-operated control group and a non-operated control group. Operations were performed under 'Nembutal' anaesthesia usually within 32 h and no later than 56 h after birth. Thymectomy, with certain minor modifications, was carried out by the method described by Park[11]. Sham-operated animals were treated similarly but without excision of the thymus. The non-operated controls were anaesthetized with 'Nembutal' but were otherwise not manipulated.

Sensitization was attempted in all animals when one month old by dropping 0·05 ml. of 2 per cent DNCB in alcohol on the clipped nuchal areas and gently spreading with a glass rod on five successive days. The degree of induced sensitivity was assayed one month later by contact skin-testing with 0·2 per cent, 0·09 per cent and 0·05 per cent dilutions of dinitrochlorobenzene in olive oil and with olive oil alone. Reactions were rated from 0 to 4, depending on the degree of erythema.

The majority of animals were killed with an overdose of 'Nembutal' when 4 months old. White blood cell counts and differential counts were carried out on blood specimens, usually obtained by cardiac puncture just before death.

No consistent differences were noted in the susceptibility of neonatally thymectomized guinea-pigs to become sensitized to dinitrochlorobenzene as compared with sham-operated or non-operated control guinea-pigs (Table 1). The total mononuclear and polymorphonuclear cell counts tended to be lower in the thymectomized animals compared with the controls. However, the differences were not always statistically significant. The wasting described by other authors in neonatally thymectomized animals of other species was not observed in the guinea-pigs.

Table 1. DEGREE OF SENSITIVITY TO DNCB ONE MONTH AFTER SENSITIZATION IN FIFTY-SEVEN NEONATALLY SENSITIZED GUINEA-PIGS*

Type of treatment	Thymectomized (23 animals)			Sham-operated (18 animals)			Non-operated (16 animals)		
Percentage of DNCB in olive oil	0·2	0·09	0·05	0·2	0·09	0·05	0·2	0·09	0·05
Average sensitivity ratings in arbitrary units	2·3	1·1	0·5	2·0	1·1	0·6	2·0	1·4	0·7

* In 7 thymectomized, 5 sham-operated and 5 non-operated animals a second course of sensitizing exposures was given after they failed to become sensitized after the first course.

Respiratory Changes during Electrical Stimulation of Rhinencephalic Structures in the Foetal Guinea-pig

THE rhinencephalon regulates a number of vegetative and somatic functions such as the respiration, blood pressure, reflexes and tonus of musculature, and movements of the intestine[1–3]. The most important role of the rhinencephalon seems to lie in the higher organization and integration of somatic and vegetative regulative functions.

As regards the different parts of the rhinencephalon, those which have the most distinct influence on the respiration are the gyrus cinguli and insulo-orbito-temporal cortex. During electrical stimulation of these areas in adult animals, there have been observed both activation and inhibition of the respiration, dependent on the parameters and localization of the stimulus, and the condition of the animal[2].

No attention has been focused on the functional role of these rhinencephalic areas during foetal life. The present work is concerned with the influence of electrical stimulation of the rhinencephalon on the respiration pattern in foetal, young and adult guinea-pigs.

Sixteen guinea-pig litters were used with an average of two to three foetuses, four young (weight 120–370 g) and five adult (weight 640–1,000 g) guinea-pigs. The foetuses were measured and their weights were ascertained for estimation of their age in accordance with Draper's length and weight curve[4]. Foetuses were aged between 28 and 64 days (the full term is 65 days). The dams were narcotized with 'Thiogenal' (methyl-thiogenyl-2[1]-penthylthiobarbituric acid sodium, Merck, 100 mg/kg). Only light narcosis was applied. After sectioning of the abdomen and the uterus, the foetuses were exposed without the umbilical cord being touched. The temperature of foetuses was maintained at a constant height (37° C) by covering the foetus with warm paraffin oil. The animals were tracheostomized, and the brains exposed for electrical stimulation. Monopolar stimulation with monophasic square wave pulses was used. The stimulus parameters were: frequency 1–150 c/s, duration 1–10 msec, amplitude 1–8 V, average current 0·002–24 m.amp, with the stimulation lasting 3–5 sec. The structures corresponding to the precallosal area, the Sylvian fissure and orbito-temporal cortex of the rhinencephalon, were selected for investigation in pursuance of the results obtained by Kaada, who,

by electrical stimulation of these areas in the cat, recorded extremely distinct responses. The precallosal area was exposed by pulling the opposite hemisphere to the side or by removing a part of it. The orbito-temporal cortex was reached stereotaxically, or by lifting the brain. The electrodes were left in position with a view to localizing the stimulation point. The respiratory volume was measured by floating chamber technique, using a photocell, and registered together with the stimulus on a two-channel graph. In the smallest of the foetuses, the respiratory movements were observed only visually. The condition of the foetus was estimated from the electrocardiogram.

In the group of adult guinea-pigs serving as controls, it was possible to reproduce only partially the results obtained earlier in the cat, rabbit and monkey. Even on application of a strong stimulus (200 c/s, 10 msec, 10 V), no changes in the respiration were obtainable from the precallosal area of the cingulate gyrus, or from the area of Sylvian fissure. When we applied the same method to cats serving as controls, we obtained a distinct inhibitory effect from the cingulate gyrus on the respiration. The orbito-temporal cortex of the guinea-pig was sensitive to the electrical stimulation (Fig. 1). Both inhibition and facilitation of the respiration appeared, depending on the localization of the electrodes. However, during stimulation the respiratory rate did on occasion become irregular, and short arrests of respiration were noticed. At times, on the other hand, the respiratory rate rose distinctly (Fig. 2, III*A*). The clearest inhibitory and facilitatory effects were obtained with stimulus parameters of 50 c/s, 10 msec and 5–8 V, although the changes mentioned above were still apparent when a pulse frequency as low as 1 c/s was applied.

In the group of young animals (2–11 weeks old), the findings were similar to those obtained with the adult animals. Both diminished and raised respiratory rates were observed. In an animal three weeks old there occurred a respiratory arrest which lasted the whole time of stimulation. Immediately after the electrical current had been switched off, the spontaneous respiration returned to normal (Fig. 2, II*A–B*).

As regards the group of foetuses, electrical stimulation of the surface of the dura mater at different points of the convexity of the brain triggered 'gasps' in those foetuses in which spontaneous gasps had previously occurred. By stimulation of the orbito-temporal cortex, the gasps became stronger and more regular from the beginning of application of the stimulus. Electrical stimulation of these areas also induced breathing in those foetuses which had not as yet breathed at all (Fig. 2, I*A–B*). All the foetuses exceeding an age of 45 days displayed respiratory movements on electrical stimulation. The youngest one which could be made to breathe was 39 days old, although no foetus showed respiratory movements in another litter of the same age. For the sake of comparison, some older foetuses were made to breathe by compressing the umbilical cord and by pinching the skin. The respiratory movements obtained in this way were similar to those resulting from electrical stimulation (Fig. 2, IV).

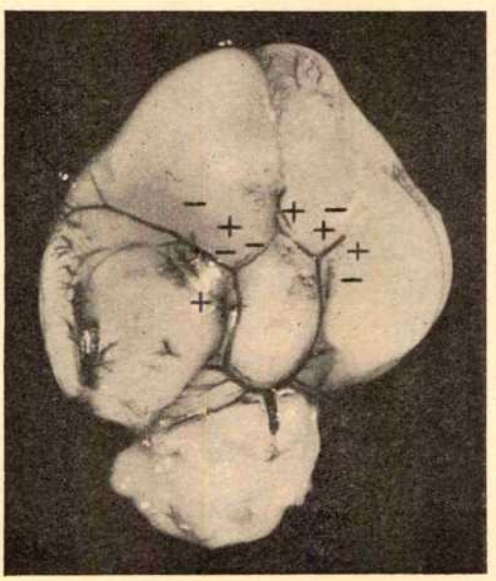

Fig. 1. The areas in the orbito-temporal cortex of the guinea-pig foetus which gave the facilitatory (+) and inhibitory (−) respiratory responses when stimulated electrically

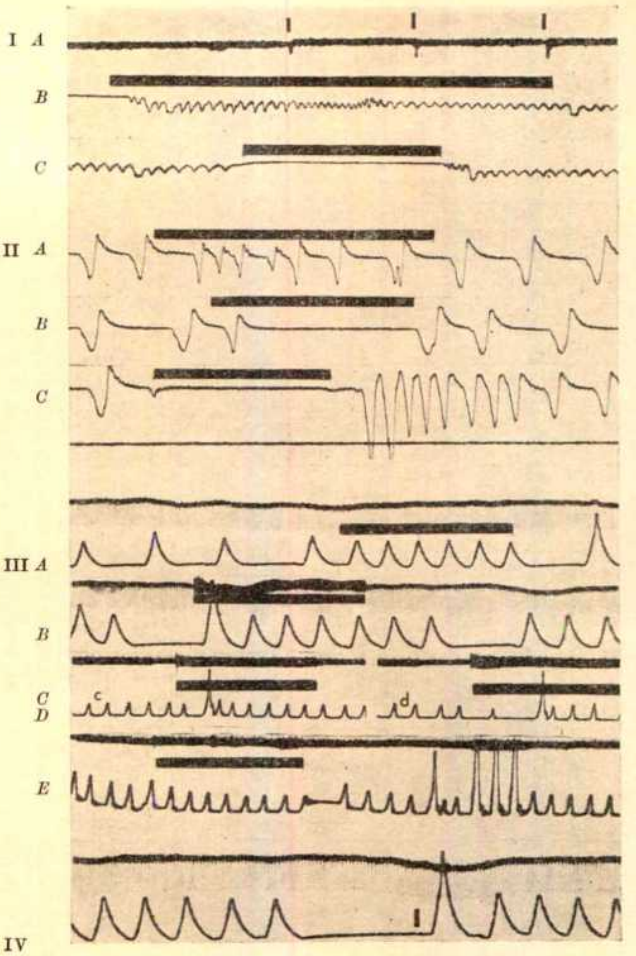

Fig. 2. The effect of electrical stimulation of rhinencephalic structures on the respiration. The stimulus is indicated with a black bar above the tracing indicating the respiration. I, *A–C* are from foetuses. *A*, A foetus, 60 days, gasping in the step of the stimulus; *B*, a foetus, 62 days, started to breathe when the stimulus was operated; *C*, the same foetus as in *B*, but another stimulation point of the cortex. A clear inhibition of respiration during the stimulus. The respiration started weakly again after the current was switched off. II, *A–C* are from a young guinea-pig, two weeks old. *A*, Acceleration of the respiratory rate; *B*, inhibition of respiration; *C*, an almost complete inhibition and a post-inhibitory acceleration of the rate and increase of the volume after the stimulus was switched off. III, *A–E* are from adult guinea-pigs. *A*, Acceleration of the respiratory rate; *B*, acceleration of the respiratory rate and increase of the first breath; *C* and *D*, two degrees of inhibition. In both cases a post-inhibitory deep breath; *E*, a weak inhibition during the stimulus, but after the stimulus a complete cessation of respiration. IV, An increase of the respiratory volume when the nose was pinched. The effect is quite similar to the effect of the electrical stimulus

The present results indicate that the higher centres of the rhinencephalon have already developed into functioning structures during the foetal life of the guinea-pig. The appearance of the different respiratory responses to electrical stimulation indicates an early differentiation of the vegetative regulatory functions in the rhinencephalon. At about the same time (41 days), electrical activity begins in the parietal cortex, indicating the functional readiness of these areas[5].

The rhinencephalic system in the adult guinea-pig apparently does not attain such a versatile development as that of the cat. Otherwise, it would be difficult to understand why the cingulate gyrus in the adult guinea-pig did not respond to stimulation, although this has been indicated as an important area for regulation of the vegetative functions in the higher mammals. The cingulate gyrus is phylogenetically younger than the orbitotemporal cortex, so it is possible that in lower animals all the functions of the cingulate gyrus have not yet developed.

The anaesthesia used in such experiments always exercises some influence on the respiratory functions; in this work, accordingly, an endeavour was made to use as light a barbiturate narcosis as possible. Such a form of anaesthesia does not affect the respiratory functions of the brain cortex[6]. To bring about muscular relaxation of the dam, curare was used; this cannot exert any effect on the musculature of the foetus, as curare in low doses does not pass the placental barrier[7]. During the experiments the reflexes of the foetuses were tested and found to be vigorous, so that it can be presumed that the respiratory changes obtained in this work are equivalent to reality.

The significance of the rhinencephalon for the functions of the human foetus and new-born infant is not accurately known. From the findings in the experiments described here, it is possible that it plays a part in initiating respiration during delivery. It has been stated that neuronal factors influence the respiration on parturition, but the exact way in which these events are regulated is not understood.

Reciprocal Influences of the Ventromedial and Lateral Hypothalamic Nuclei on Blood Glucose Level and Liver Glycogen Content

SINCE the discovery by Bernard[1] that puncture in the floor of the fourth ventricle results in hyperglycaemia and glycosuria, many investigations have been carried out on the rise in blood glucose level and the appearance of glycosuria after stimulation of the various areas of the diencephalon.

In this laboratory, Shimizu[2] has investigated the relationship between changes of blood glucose level and the nuclei of the hypothalamus by selective stimulation of each nucleus in rabbits, and has shown that blood glucose increases after stimulation of the hypothalamic nuclei belonging to the medial hypothalamic area (sympathetic area) while it decreases after stimulation of the lateral hypothalamic nucleus (parasympathetic area). Similar, but transient, changes of blood glucose following hypothalamic stimulation have also been observed in adrenalectomized, thyroidectomized and hypophysectomized rabbits[8]. The increase in blood glucose level after electrical stimulation of the hypothalamus might be due to promoted glycogenolysis or gluconeogenesis in liver, or the fall of blood glucose utilization, but the exact metabolic events involved in these changes of blood glucose are still obscure.

In the present investigations the previous observations on the changes of blood glucose following hypothalamic stimulation were extended, and the results are presented here showing that stimulation of the ventromedial hypothalamic nucleus (VMH) caused a rapid increase in blood glucose level followed by a pronounced decrease in liver glycogen content, whereas stimulation of the lateral hypothalamic nucleus (LH) resulted in a decrease in blood glucose level with an insignificant change of liver glycogen content.

Male rabbits weighing about 2,500 g were used. The VMH and the LH were stimulated electrically as previously described[4] except that 20 sec stimulations were repeated every 4 min for a 12- to 20-h period. At various times indicated during the stimulation, about 1 ml. of blood was taken from the auricular vein with a heparinized syringe. Serum was immediately separated by centrifugation and the concentration of blood glucose was determined by the *o*-aminobiphenyl method of Shibata[9]. At the end of the electrical stimulation, the animals were killed under ether anaesthesia. Liver was perfused, *in situ*, with isotonic potassium chloride solution and then immediately homogenized in a glass homogenizer with nine volumes of the ice-cold potassium chloride solution. To 2 ml. of the homogenate was added 2 ml. of cold 10 per cent trichloroacetic acid (TCA) and the precipitate of proteins was separated by centrifugation. The precipitate was washed seven times with 2 ml. of 5 per cent TCA until no detectable glycogen was extracted. The resulting supernatants were combined and diluted to 20 ml. with 5 per cent TCA. 2 ml. of this solution was analysed for glycogen according to van der Vies's anthrone method[6]. The position of the stimulating electrode in the hypothalamus was checked histologically in serial sections after the experiment.

Fig. 1 shows the changes in blood glucose level during hypothalamic stimulation. Shortly after the onset of stimulation of the VMH, blood glucose level was increased about 60 per cent, and increased level of blood glucose was maintained during 5–8-h stimulation, but the level returned gradually to normal when the repeated stimulation was continued for a longer period. On the contrary, stimulation of the LH caused a decrease of about 20 per cent in blood glucose level during 8-h stimulation, and it returned to normal level by the end of a 20-h stimulation period. In the course of a long stimulation period, such as for 20 h, hormonal balance would be shifted so as to restore the level of blood glucose to normal.

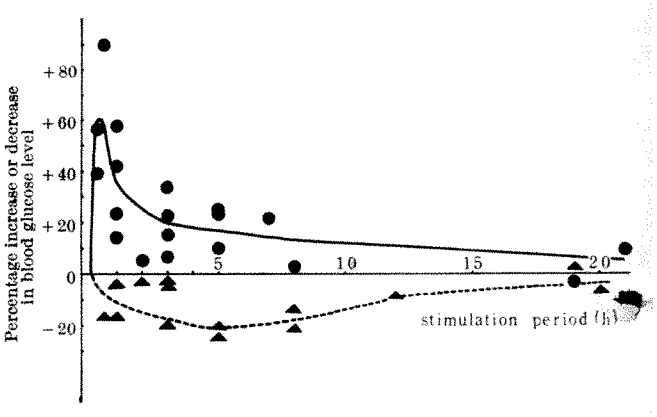

Fig. 1. Changes in blood glucose level during hypothalamic stimulation of rabbits. —●—, Stimulation of the ventromedial hypothalamic nucleus; - - -▲- - -, stimulation of the lateral hypothalamic nucleus

Table 1. Liver Glycogen Content after Hypothalamic Stimulation of Rabbits

	Control	VMH*	LH*
	(mg of glycogen/g liver)		
Summer season	20·9	0·8	19·7
	27·9	1·1	20·4
	25·7		
	21·4		
Mean value and standard deviation	24·0 ± 2·9	1·0	20·1
Winter season	56·0	28·9	56·0
	65·0	20·8	52·2
	49·3	32·0	76·5
	75·0	36·7	77·5
	67·5	19·6	62·0
	68·8		50·0
Mean value and standard deviation	63·6 ± 8·5	27·6 ± 6·6	62·4 ± 11·0

* Liver glycogen was measured in each rabbit after stimulation of the ventromedial hypothalamic nucleus (VMH) or the lateral hypothalamic nucleus (LH) for 12–20 h as described in the text.

Liver glycogen content after stimulation of the hypothalamus for a 12–20-h period is shown in Table 1. A marked decrease in liver glycogen content was observed when the VMH was stimulated. As the liver glycogen content was greatly affected by dietary composition and seasonal factors, all the animals were subjected to fasting during the day before killing and the data of two different seasons are included in Table 1. The liver glycogen content of control animals was much lower in summer than in winter. Almost all glycogen of the liver was depleted in summer, and about half the liver glycogen was depleted in winter, by stimulation of the VMH. Thus, the depletion rate of liver glycogen (ratio of level in stimulated animals to level in control animals) differed considerably between two seasons, but the absolute value depleted during stimulation of the VMH was approximately the same in both seasons (20–30 mg of glycogen per g liver was depleted). In both seasons, an insignificant effect on glycogen content was observed when the LH was stimulated.

These results lead us to assume that stimulation of the VMH promotes the degradation of liver glycogen to cause an increase in blood glucose. The VMH is one of the nuclei in the sympathetic area of the hypothalamus (and the LH is in the parasympathetic area), according to previous investigations on the hypothalamus[7]. Therefore, these results suggest that excitement of the sympathetic area would result in an acceleration of glycogenolysis in liver. This assumption is further fortified by the findings[8], recently obtained in this laboratory, that the activities of glycogen phosphorylase and glucose-6-phosphatase in the liver were rapidly and pronouncedly increased after stimulation of the splanchnic nerve of rabbits.

Hypo-osmotic Re-absorption due to Active Salt Transport in Perfused Collecting Ducts of the Rat Renal Medulla

Urine reaches its maximal osmolality in the collecting ducts of the renal medulla[1], but the mechanisms causing the transformation from isotonic tubular fluid are in dispute. Most modern attempts to explain the concentrating mechanism are based on the hypothesis of Wirz, Hargitay and Kuhn[2], that the loops of Henle function as counter-current multipliers to raise the medullary interstitial osmolality so that water can be extracted from the collecting duct urine by simple osmosis. Experimental evidence[3,4] supports the validity of this hypothesis only in the outer medulla; the major increase of osmolality occurs in the inner medulla where the loops of Henle are not capable of active salt transport[5] and so cannot be countercurrent multipliers. In this communication I shall propose an alternative hypothesis for the inner medulla and present the results of experimental tests of its more unusual features.

The collecting ducts of the inner medulla reabsorb salt actively[1]. As will be discussed later, the osmotic work provided by this active transport can concentrate the urine provided that a hypo-osmotic reabsorbate is generated. Stationary microperfusion techniques were used to explore this possibility. Male Wistar rats, 250–300 g body-weight, had free access to food and water until the time of the experiment, when they were anaesthetized with ether. The left kidney was excised and from it the entire inner medulla was removed and submerged in a bath maintained at 37° C and bubbled gently with 100 per cent oxygen. The piece of tissue was fixed in place by suction applied from below, and was allowed to incubate for 30 min before the perfusion experiments were begun. A polyethylene catheter (*O.D.* 70–100μ) filled with coloured 'Ricinus' oil was then inserted into the orifice of a collecting duct at the tip of the papilla and advanced about 1 mm up the tubule so that oil injected from the catheter filled the entire tree of collecting ducts draining into the catheterized duct. A sharpened micropipette containing a test solution was next placed in the lumen of one of these collecting ducts lying on the surface of the medulla. With this arrangement the test solution could be injected and isolated between oil columns in segments of collecting duct located 2–4 mm from the tip of the papilla. The perfusate was collected into a second oil-filled pipette after the desired perfusion period had elapsed. The osmolality of the specimens and of the bath fluid was measured in a thermoelectric microfreezing point apparatus[6]. The composition of the various solutions is given in Table 1.

The behaviour of collecting ducts perfused in this manner is qualitatively similar to that of proximal and distal convoluted tubules studied *in vivo*[7–9]: the collecting ducts reabsorb sodium against an electrochemical potential gradient, transmural water flow accompanies net solute flow, and active salt transport is inhibited by cardiac glycosides. These results will be presented in detail elsewhere, while this report is restricted to experiments dealing with the osmolality of the reabsorbate.

The purpose of these experiments was to see whether active salt transport by the collecting ducts could lead directly to reabsorption of hypo-osmotic fluid, in circumstances close to those found *in vivo*. For the first group of experiments concentration values of the bath were selected to correspond to the medullary interstitium near the junction of the inner and outer medulla. The perfusion fluid had exactly the same composition, except that it contained no vasopressin. Although there were no concentration gradients across the epithelium, the volume of the perfusate decreased with time, because of active salt reabsorption. The osmolality of the fluid remaining in the tubule increased progressively, as can be seen from Fig. 1; this could have happened only if the fluid absorbed from the tubule was hypo-osmotic to both the initial perfusion fluid and the bath.

Table 1. Composition of Bath and Perfusion Solutions

Expt.	Na	K	Ca	Mg	Cl	HCO_3	H_2PO_4	Urea	Glucose
(1) Bath	250	8·0	3·6	1·05	251	11·9	0·33	343	7·7
Perfusion	250	8·0	3·6	1·05	251	11·9	0·33	343	7·7
(2) Bath	423	16·1	3·6	1·05	432	11·9	0·33	425	7·7
Perfusion	237	49·9	3·6	1·05	280	11·9	0·33	684	0

All ionic concentrations are in m.equiv./l.; urea and glucose given as mmoles/l. Both bath solutions contained vasopressin, 20 mμ/ml.

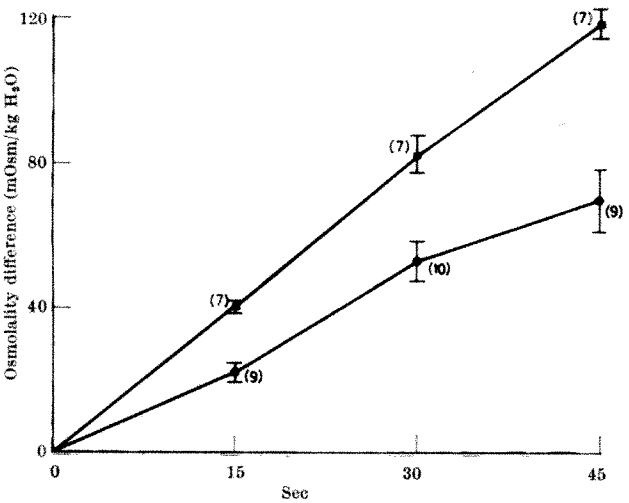

Fig. 1. Changes in perfusate osmolality as a function of time, expressed as the difference between the perfusate and a specimen taken from the bath. Bars indicate ± one standard error of the mean; figures in parentheses are the number of perfusions. Closed circles depict the results from experiment (1), while the squares are data from experiment (2)

The luminal sodium concentration *in vivo* may never be as high as in the adjacent interstitium, and in fact is known to decrease progressively toward the tip of the papilla even while the interstitial salt concentration is increasing[1]. Thus, a second set of experiments was necessary to determine whether or not hypo-osmotic reabsorption continues when bath and perfusion concentrations reflect these dissimilarities. The relative proportion of sodium chloride to urea used in the first series was retained for the bath solution of the second series, but the perfusion solution had higher urea and potassium concentrations than the bath. The osmolalities of bath and perfusion solutions were identical, but greater than those in the first series. These relationships mimic those found *in vivo* in antidiuresis at a point about midway toward the papilla. The volume of the perfusate again decreased with time while the osmolality of the perfusate increased to levels higher than the bath and the initial perfusion solution. These experiments show that active salt reabsorption by the collecting ducts leads directly to the formation of a hypo-osmotic reabsorbate under conditions close to those found *in vivo*.

At least two different models have been published that predict hypo-osmotic reabsorption coupled to active salt transport[10,11]. Whether either of these is applicable to the collecting duct cannot be decided yet, but the observations reported here provide a sufficient basis for formulating a new hypothesis of urine concentration.

Any acceptable model of the inner medulla in antidiuresis must explain certain observations: the osmolality of the interstitium increases along the corticomedullary axis to a maximum at the tip of the papilla[2]; this increased osmolality is due almost entirely to increased concentrations of sodium chloride and urea[12]; the reabsorption of a hypo-osmotic fluid causes the osmolality of collecting duct urine to increase toward the tip of the papilla[1]; the osmolality increase in the collecting ducts closely parallels that in the interstitium[4,13]. These facts cannot be explained without some source of osmotic work in the inner medulla[14]. The collecting ducts are the only structures capable of this work, and it is relevant to examine their role in the concentrating mechanism.

Consider a small element of volume in the collecting duct lumen from which salt is actively reabsorbed. Since the reabsorbate generated by salt transport is hypo-osmotic to the original tubular fluid, the fluid remaining becomes more concentrated. This element of volume then moves axially down the collecting duct lumen to the next level; again active salt transport generates a reabsorbate hypo-osmotic to the tubular fluid. Note, however, that the tubular fluid at the second level is already more concentrated than at the first level. If the absorbate osmolality is governed by concentrations in the tubular fluid, the reabsorbate at the second level will be more concentrated than the reabsorbate at the first level. Repetition of these steps along the length of the inner medullary collecting ducts would produce parallel increases of the osmolalities of collecting duct urine, of the collecting duct reabsorbate, and thus also of the interstitial fluid, all with maxima at the tip of the papilla. Because the osmolalities of all three fluids are so closely interrelated, the actual differences among them need not be large or even detectable. In this view, the collecting duct reabsorbate is the primary determinant of interstitial osmolality. The countercurrent exchange properties of the loops of Henle and vasa recta maintain the osmotic stratification achieved by hypo-osmotic reabsorption along the collecting ducts, and sodium chloride and urea accumulate in the interstitium because these are the only two solutes that leave the collecting duct lumen in appreciable quantities—the former by active transport, the latter by passive process. The high osmolality of the medullary interstitium is not only a consequence of hypo-osmotic reabsorption, but is also its necessary concomitant. If the interstitial osmolality did not increase *pari passu* with the urinary osmolality, transmural osmotic gradients would result. These gradients would cause osmotic flow of water back into the lumen of the collecting ducts and limit the maximal osmolality that could be achieved. Thus, the collecting ducts can concentrate the urine only because they penetrate a region the function of which assures the maintenance of high interstitial osmolality.

PHARMACOLOGY

Inhibition of Haemagglutination by Benzylpenicillin adsorbed on Erythrocytes

INVESTIGATIONS of the inhibition of haemagglutination have demonstrated the role of the penicilloyl group as the major antigenic determinant[1]. Coating of erythrocytes either with benzylpenicillin or with penicillenic acid leads to covalent bonding of penicilloyl haptene groups either by irreversible reaction of penicillenic acid with lysine ε-amine groups or by coupling involving the direct addition of the β-lactam carbonyl to lysine amino residues of membranous proteins. According to Levine[2] the former mechanism is more likely. Combination of penicillenic acid through disulphide linkages, as reported by De Weck and Eisen[3], has been attributed by Levine and Ovary[4] to

small numbers of penicilloyl groups in the penicillenate conjugates. However, such groups were not detected by De Weck[1] and no cross-reactions were observed with anti-penicilloyl antisera. Occasional human sera are encountered in which inhibition is more effective with other degradation compounds of benzylpenicillin, namely, penamaldate, penilloate, penicillenate and penicilloate. Consequently, it is probable that other haptene specificities may be involved in the haemagglutination system, but their role is so far unestablished. In general, unaltered benzylpenicillin is a less effective inhibitor at equimolar concentrations. Because of this and the failure of benzylpenicillin to form stable covalent bonds with proteins it has been considered unlikely that the unaltered compound can function as an effective haptene.

A characteristic feature of the agglutination of benzylpenicillin-coated cells is the occurrence of spontaneous reversal of agglutinates, the rate of which is increased by benzylpenicillin and other haptenes[5]. The effect of penicillinase on agglutination reversal was therefore investigated as a means of determining the presence of biologically active benzylpenicillin adsorbed to erythrocyte membranes and its possible role in the haemagglutination system.

Erythrocytes were coated with benzylpenicillin as described previously[6]. After storage at 4° C for variable periods up to 3 weeks, aliquot volumes were washed exhaustively in repeated changes of sterile 0·85 per cent saline. Cells were then lysed in sterile distilled water and the deposited membranes were washed in three changes of fresh distilled water. Membranes were then placed on the surface of nutrient agar plates seeded with a lawn of a 6-h culture of a penicillin-sensitive strain of *Staphylococcus pyogenes*. Similar membrane preparations treated with penicillinase and membranes from normal cells were included. Fig. 1 shows wide zones of inhibition and the effect of penicillinase in destroying the biologically active penicillin. Only slight differences were noted in zone sizes after storage of cells for 24 h or 3 weeks at 4° C.

Fig. 1. Top, zones of inhibition caused by washed membranes after storage of cells for 21 days. Bottom left, same membrane preparation after treatment with penicillinase. Bottom right, membranes from uncoated erythrocytes

Agglutinates were prepared by incubating coated group O, rhesus negative cells with 1/4 dilutions of positive human antisera (titres > 1/128). At this low dilution the agglutinates resuspend as a single mass of clumped cells. After removal of the supernatant sera, the agglutinates were resuspended in three sets of four replicate tubes containing, (*a*) penicillinase, (*b*) penicillinase solution heated to 75° C for 1 h, and (*c*) 0·85 per cent saline, respectively. Times required for complete disappearance of haemagglutination were then noted (Table 1).

Table 1. HAEMAGGLUTINATION REVERSAL BY PENICILLINASE

Serum	Haemagglutination reversal (time) Penicillinase (min)	Penicillinase (inactivated) (h)	Saline (h)
1	< 20	24	24
2	< 20	24	24
3	< 20	24	24
4	< 20	36	36
5	60	48	48
6	90	72	72

These findings indicate that biologically active penicill adsorbs to the erythrocyte surface and its destruction l penicillinase leads to the rapid reversal of agglutinatio Agglutination is not, however, due to antibody wi specificity against the unaltered benzylpenicillin hapter since we have shown previously that treating coated ce with penicillinase, followed by its removal by washin does not affect the ability of the cells to be agglutinat by positive antisera[6]. Additionally, each of the s sera was inhibited to a markedly greater extent l the monovalent haptene penicilloyl-ε-amino-caproa than by benzylpenicillin. Further experiments we carried out by incubating aliquot volumes of coat cells with penicillinase and saline respectively for 2 h 37° C, after which they were washed five times in lar volumes of 0·85 per cent saline. Cells were then aggluti ated in replicate tubes with 1/4 dilutions of the six positi antisera. Agglutinates formed were then resuspended penicillinase. Table 2 shows the effect on the tir required for haemagglutination reversal.

Table 2. EFFECT OF PRIOR TREATMENT WITH PENICILLINASE ON REVERS TIMES

Serum	Haemagglutination reversal (time) *A* (h)	*B* (min)
1	24	< 20
2	24	< 20
3	24	< 20
4	36	< 20
5	48	60
6	72	90

A, Coated cells treated with penicillinase, then agglutinated and agg tinates resuspended in penicillinase.

B, Coated cells treated with saline, then agglutinated and agglutina resuspended in penicillinase.

In this instance, prior treatment with penicillina prevented the rapid reversal of agglutination caused penicillinase added later and was again associat with loss of biologically active antibiotic from the c surface.

Haemagglutination reversal caused by penicillinase explained most readily by conversion of adsorbed benz penicillin to penicilloic acid. This compound is unable adsorb effectively to the cell surface because its fr α-carboxyl group does not combine readily with ami groups of cell protein, an observation in agreement wi the findings of Josephson[7] that penicilloic acid is r antigenic in rabbits. However, penicilloic acid is effective inhibitor of haemagglutination in virtue of close structural similarity to the penicilloyl haptene. seems probable that the spontaneous reversal of haem glutination referred to results from conversion of so fraction of the adsorbed benzylpenicillin to penicill acid.

I thank Dr. B. B. Levine, New York University Medi Center, New York University, for a supply of the hapte penicilloyl ε-amino-caproate.

HAEMATOLOGY

Nature of Haemoglobin $M_{Oldenburg}$

In 1962, Tönz, Simon and Hasselfeld[1] described a German family with forty-six cyanotic members. This cyanosis was found to be due to an abnormal haemoglobin. This abnormal haemoglobin was characterized as an Hb M type on the basis of electrophoresis on starch block at *p*H 7·0 and on the absorption spectrum of the haemolysate. The abnormal haemoglobin was called Hb $M_{Oldenburg}$.

Cyanosis was present from birth, so an α-chain abnormality was postulated. The purpose of this communication is to describe the more detailed chemical investigation to find the amino-acid replacement in this Hb $M_{Oldenburg}$.

Haemolysate was prepared in the usual manner from the blood of one of the Hb $M_{Oldenburg}$ carriers. The Hb M fraction was separated on starch block electrophoresis at *p*H 7·0 (0·025 M $Na_2HPO_4.2H_2O$ + 0·025 M $NaH_2PO_4.2H_2O$) after converting the haemoglobin into the oxidized form[2]. The purified Hb M was digested with trypsin and the peptides were separated with high-voltage electrophoresis at *p*H 6·4 (water–pyridine 9 : 1, acidified with acetic acid). In Fig. 1 the pattern is given in comparison with that of a Hb A_1 digest. In the case of Hb M, peptide αT 8·9 is missing. No new peptide could be detected. Because peptide αT 9 has the same amino-acid composition as αT 8·9, with the exception of the N-terminal lysine, which is split off, differences in the amino-acid composition must occur in both peptides. We therefore compared the Hb M peptide αT 9 with the normal Hb A_1 αT 9 peptide. αT 9 usually occurs in the neutral zone after electrophoresis at *p*H 6·4. To separate this peptide, the neutral zone was eluted, dried and again electrophoresed at *p*H 3·6 (water–pyridine–acetic acid–*n*-butanol 7·6 : 1 : 7 : 2). Instead of the normal pattern, a new peptide appeared in the case of Hb $M_{Oldenburg}$ with sulphur, histidine and tyrosine staining reactions. A second sulphur-positive peptide could also be detected almost on the site of the normal peptide αT 9 (see Fig. 2). This suggests an amino-acid replacement, which acidified the peptides αT 9 and αT 8·9. On account of this more acid character, peptide αT 8·9 shifts to the neutral zone at *p*H 6·4 on electrophoresis, and both peptides αT 8·9 and αT 9 will run less to the negative side after electrophoresis at *p*H 3·6.

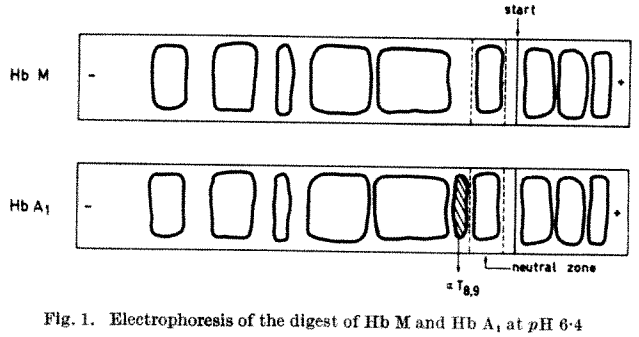

Fig. 1. Electrophoresis of the digest of Hb M and Hb A_1 at *p*H 6·4

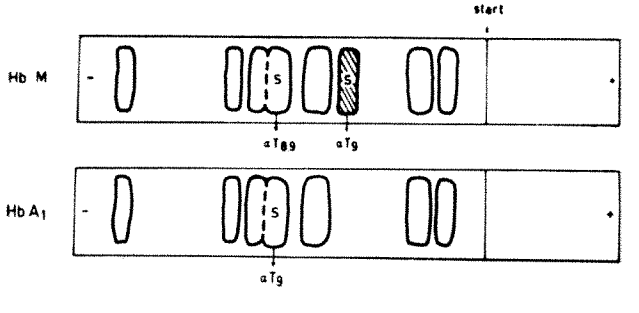

Fig. 2. Electrophoresis of the neutral zone at *p*H 3·6

The new peptide was extracted, hydrolysed and analysed. The amino-acid composition was that of the normal αT 9 peptide, except that one histidine unit was missing and a half-unit of tyrosine appeared in addition. Because of the positive tyrosine staining of the peptide and the fact that tyrosine breaks down on acid hydrolysis, it was assumed that a histidine group had been replaced by tyrosine. Which of the three histidines was replaced was not clear. It is reasonable to assume that it is histidine 87, because this histidine is connected to the iron atom of the haem group. This would explain the abnormal absorption spectrum of the haemolysate and the biochemical behaviour (lack of reduction of the methaemoglobin with sodium sulphate[1]). Such a replacement has already been described for Hb M_{Iwata} and Hb $M_{Kankakee}$ by Shibata *et al.*[3] and Jones *et al.*[4]. For this reason, Hb $M_{Oldenburg}$ is probably the same as these abnormal haemoglobins.

This investigation was supported by the Dutch Organisation for Pure Research (ZWO).

IMMUNOLOGY

Heterogeneity of Heavy (γ) Chain Preparations from Human γG-Immunoglobulins

In recent publications, Cohen[1] and Cohen and Porter[2] have presented evidence that light chain preparations from partially reduced and iodoacetamide-alkylated γ-globulins of several species are heterogeneous. In glycine-urea starch-gel electrophoresis, *p*H 7–8, some eight to ten electrophoretically distinct bands were separated. Under similar electrophoretic conditions the heavy (γ) chains migrated as a diffuse band showing approximately the same spread as the original γ-globulin. In contrast to the light chains, the heavy chains did not give a band pattern.

We have prepared heavy and light chains of γ-globulins essentially according to the method of Fleischman, Pain and Porter[3]. The experimental conditions for reduction of the γ-globulin in neutral aqueous solution were similar to those described, but the chains were dissociated by dialysis against 0·1 M formic acid immediately after alkylation. Iodoacetic acid or iodoacetamide were used as alkylating agents. The chains from either reduced and dissociated products or reduced, alkylated and dissociated products were separated on a 'Sephadex *G*-200, *A* 50' (Pharmacia *AB*, Uppsala, Sweden) column in 0·1 M formic acid[4]. The separation of γ- and light chains from reduced but non-alkylated material was carried out in 0·1 M formic acid containing 1 ml. mercaptoethanol/l.

Urea starch-gel electrophoresis was performed in horizontal trays in formate buffer[5] and in glycine buffer[2]. When non-alkylated material was subjected to electrophoresis mercaptoethanol was incorporated into the gel.

The normal human γG globulins (7*S*) used in our experiments were either (1) Cohn-fraction II (supplied by Kabi *AB*, Stockholm, Sweden), further purified by chromatography on DEAE-'Sephadex', or (2) preparations

obtained by chromatography of normal human serum on DEAE-'Sephadex' in 0·0175 M phosphate buffer, *p*H 6·5. Myeloma globulins were prepared by the latter procedure from sera of patients diagnosed as suffering from multiple myelomatosis.

The purity of the γ-globulin preparations was checked by immunoelectrophoresis against rabbit or horse anti-human sera.

The results of the glycine-urea starch-gel electrophoresis of iodoacetic acid-alkylated γ- and light chains from a normal γG preparation and from two individual myeloma γG preparations are shown in Fig. 1. The band pattern of normal light (κ and λ) chains is consistent with that published by Cohen and Porter[2]. That is, about ten distinctly separated bands were obtained (Fig. 1*A*). In contrast to Cohen and Porter's finding of only one or sometimes two bands in light chain preparations from myeloma γG material[2] several myeloma light chain fractions showed more than two distinct bands (Fig. 1*B*). However, these were fewer than those from normal γ-globulin and the number varied from one myeloma protein to another.

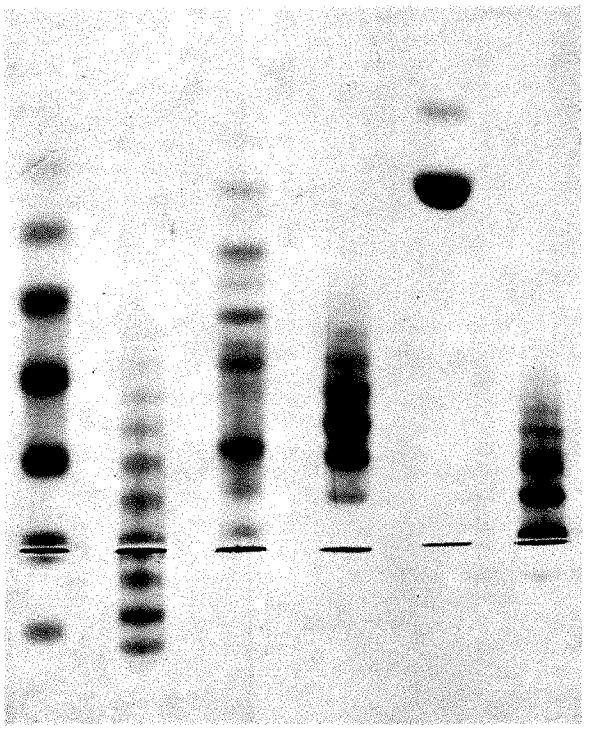

Fig. 1. Starch-gel electrophoresis in urea[2] of heavy (*H*) and light (*L*) chain preparations from (*A*) a normal γG preparation and (*B*) and (*C*) two individual myeloma γG preparations

Urea-glycine starch-gel electrophoresis of the γ-chain preparations from normal and abnormal γ-globulins also showed distinct band patterns as shown in Fig. 1. These preparations showed different band patterns, analogous to the patterns given by normal and abnormal light chains. In a γ-chain preparation from normal γG (Fig. 1*A*) some fifteen bands could be recognized. The γ-chains from myeloma proteins always gave fewer bands (Fig. 1*B* and *C*) and, in addition, the distribution of bands varied among different abnormal γ-chain preparations.

All our γ-chain preparations from normal γG-globulins gave similar band patterns. The most striking effect was obtained either with γ-chain material alkylated with iodoacetic acid or γ-chains prepared from material that had been reduced in mercaptoethanol only. In the latter case the γ-chains gave a pattern similar to that of iodoacetic acid-alkylated material except that the mobilities of the bands were somewhat less. In contrast, the material obtained by alkylation with iodoacetamide gave only a smear, although a few bands could be recognized within the smear. Obviously, the carboxymethyl groups attached to the molecules after alkylation with iodoacetic acid increase the net negative charge and thereby enhance the electrophoretic mobility of the material.

If we accept that the banding of light chain material is an expression of light chain heterogeneity[2], then it is reasonable to assume that the band pattern of γ-chain material also represents heterogeneity. Were banding a result of aggregation it would be difficult to explain the differences in band pattern between normal γ-chains and γ-chains from myeloma proteins and also the differences among γ-chain preparations from individual myeloma proteins.

The results suggest that the banding of γ-chain preparations is due to charge differences between molecules; that is, differences in primary structure. Furthermore, the observation that preparations of myeloma γG immunoglobulins are more homogeneous than those of normal γG preparations is consistent with earlier results[2]. However, in some myeloma proteins in which only one or two light chain bands could be recognized as many as five to seven γ-chain bands were detected. These results seem to indicate that a great heterogeneity also exists within individual human myeloma γG preparations and that the γ-chains of these proteins contribute most to this heterogeneity.

I thank Miss Britt Hansson for skilful technical assistance. This work was supported by the Swedish Cancer Society and by the Swedish Medical Research Council.

GENETICS

Phosphoglucomutase Polymorphism: an Unusual Type in Negroes

PHOSPHOGLUCOMUTASE is present in human erythrocytes in different forms. Spencer *et al.*[1] showed that polymorphism results from the inheritance of two autosomal-allelic genes, PGM^1 and PGM^2. The homozygous state for PGM^1 results in pattern 1, for PGM^2 in pattern 2, and the doubly heterozygous state results in pattern 2-1. In the English population the gene frequencies for PGM^1 and PGM^2 are respectively 0·76 and 0·24.

At the University of California Medical Center, San Francisco, I examined the haemolysate of 555 persons —271 Caucasians and 284 Negroes—63 of whom were healthy students and hospital employees and 492 were patients attending the out-patient clinic or admitted to the hospital wards. Results are presented in Table 1. In addition to the usual patterns 1, 2-1 and 2, an entirely different pattern was observed in two healthy female Negroes, whose strong *g* zone pattern differed from the usual very faint one (see Fig. 1). Moreover, their pattern had another similar strong, more anodic zone and a faint, even more anodic spot was also observed, especially when the haemolysate became older. The *e* and *f* zones, however, were very faint in these two individuals. The cathodic portion of the unusual pattern resembled that of pattern 1, but the anodic portion did not resemble patterns

1 or 2. This suggested the existence of a third allele or a second structural locus that determined the *PGM* patterns. This rare pattern was found constant, even when the person was re-examined several months later. To find out whether this unusual pattern was genetically determined, available relatives of one subject with the unusual pattern were examined. The mother and sister had exactly the same pattern as the propositus; the father was not available for investigation.

The calculated gene frequencies for PGM^1 and PGM^2 in the Caucasian group were respectively 0·777 and 0·223, essentially the same as those found in the English population examined by Spencer *et al.* In the Negro group the gene frequencies were PGM^1–0·801, PGM^2–0·195 and the unusual type 0·004. The gene frequencies for PGM^1 and PGM^2 in the Negro group differ little from those of the Caucasian group and no significant difference was observed between male and female in either group.

Since the completion of this study, I have read the recent publication of Hopkinson and Harris[2] on the role of a second structural locus in determining human phosphoglucomutase. The Atkinson type they described would seem to be the same as the unusual type found in the Negro group in this investigation.

Table 1. FREQUENCIES OF DIFFERENT *PGM* PHENOTYPES IN 555 UNRELATED PERSONS (271 CAUCASIANS AND 284 NEGROES)

PGM phenotypes	Caucasians	Frequencies	Negroes	Frequencies
1	169	0·624	188	0·662
2–1	83	0·306	77	0·271
2	19	0·070	17	0·060
1-unusual	—	—	2	0·007
Total	271	1·000	284	1·000

During my investigation of the electrophoretic pattern of phosphoglucomutase, several of the group of patients with different diseases produced a very dark pattern even when the haemolysates applied were adjusted to the same concentration as those of normal controls, indicating a high increase of phosphoglucomutase-level in the erythrocytes in those patients. Some variation was also apparent in the healthy group, but it was not so striking. In addition to the variation in quantity several had an abnormal distribution of quantities among the electrophoretically normal migrating spots. These findings may indicate that an abnormal variation in quantity or in relative distribution of quantities among the zones may be clinically significant, just as has been shown for the lactodehydrogenase isozymes. In one patient with chronic congenital non-spherocytic haemolytic anaemia due to severe glucose-6-phosphate dehydrogenase deficiency of the erythrocytes, a definite abnormal distribution was found that was not demonstrated in the parents or siblings (see Fig. 2).

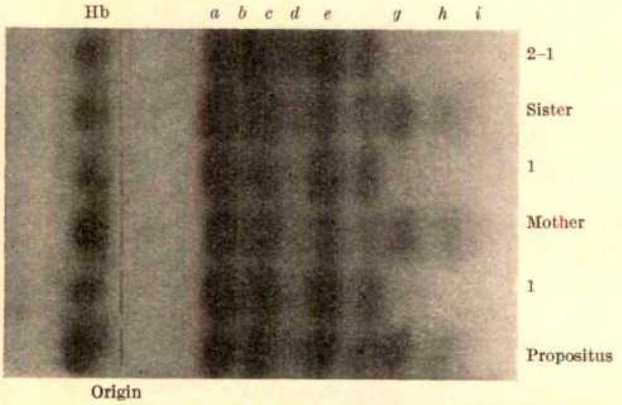

Fig. 1. Starch-gel electrophoresis with *tris*-EDTA-maleic acid and magnesium chloride buffer *p*H 7·8, stained for phosphoglucomutase (ref. 1). Note unusual pattern of the haemolysate of propositus, her mother and her sister, compared with controls 1 and 2–1

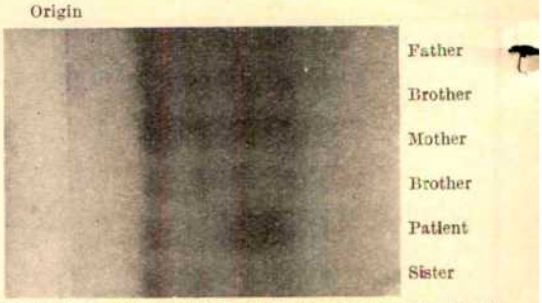

Fig. 2. Phosphoglucomutase patterns after starch-gel electrophoresis of a patient with congenital non-spherocytic haemolytic anaemia and his family. Note abnormal pattern in patient

Studies on other racial groups are in progress. Although the number in each is too small to be significant, the unusual pattern 3–1 described by Hopkinson and Harris was observed in one of fifty Malayan Aborigines examined, but the other forty-nine had the usual 1, 2–1 and 2 patterns.

I thank Miss Fermor Lloyd and her staff at the Outpatient Clinic, Department of Medicine, and Mrs. Gladys Spaulding of the Employee Health Service for collecting the blood samples. I also thank Mrs. Marlene Scham for her technical assistance.

This investigation was partly supported by the University of California International Center for Medical Research and Training (Hooper Foundation, San Francisco School of Medicine) with a research grant from the Office of International Research, National Institute of Health, U.S. Public Health Service.

Effect of Centrifugation of the Eggs on the Sex of *Carausius morosus* Br.

THE stick insect *Carausius morosus* Br. reproduces parthenogenetically. However, non-functional males appear spontaneously by loss of a sex-chromosome. This occurs with a frequency of about 0·5 per cent at 16°–20° C. Sexually aberrant individuals showing gynandromorphism and/or intersexuality are also found at frequencies of up to about 2 per cent. Higher percentages of 'non-females' are obtained when eggs are treated with high temperatures or X-rays[1–3]. The following experiment shows that centrifugation of the eggs may also influence the sex of *C. morosus*.

Eggs were collected daily and divided into two samples during September 2–11, 1964. One series was centrifuged at 2,520*g* (4,600 r.p.m.) for 2 h on September 11, while the other series was kept as control. During centrifugation the temperature of the eggs rose to ± 26° C, and so the eggs of the control series were also similarly heated. The nymphs were sexed just after hatching, using the differences in the external genitalia as the criterion. The results are summarized in Table 1 and Fig. 1.

The sensitivity to centrifugation can be expressed either as the fraction of individuals showing some further development after treatment or as the fraction hatching successfully. This function is at its peak during meiosis, decreases during segmentation and blastoderm development, and increases again during formation of the germ anlage. The period of embryonic development is lengthened by the treatment, particularly when the meiosis and the early cleavage stages are treated, while the developmental phases which follow are influenced progressively less. The

Index Kewensis

Plantarum Phanerogamarum
Supplement XIII 1956–1960

Compiled at the Herbarium of the Royal Botanic Gardens, Kew, under the direction of SIR GEORGE TAYLOR

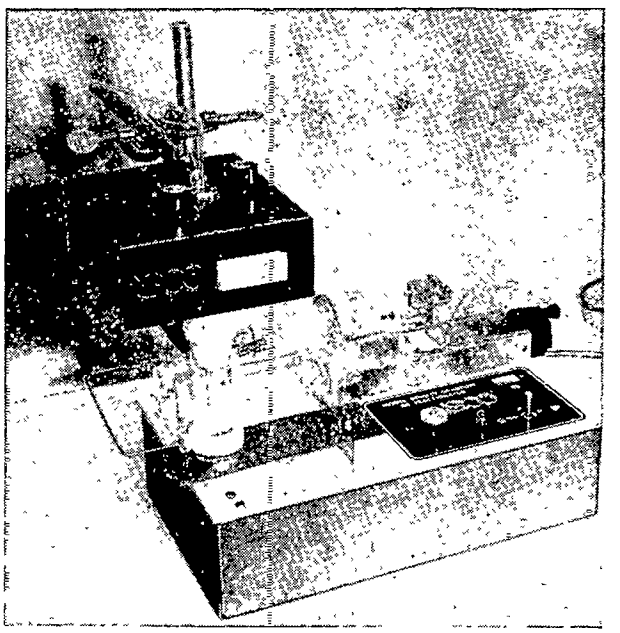
The *Index Kewensis* provides a reference to the first description of every species of flowering plant in the world, starting from the year 1753, and indicates its author and native country. It also records the transference of a plant species from one genus to another, following a change of opinion as to its taxonomic position. Books and scientific periodicals of all nations are systematically examined and a supplement is issued every five years. Such a work of reference is indispensable to botanists throughout the world. *£5 15s 6d net*

Applications of Statistical Mechanics

E. A. GUGGENHEIM

This book may in a sense be regarded as a modern appendix to *Statistical Thermodynamics*, since it describes examples of work over the interval 1939 to 1964. In the spring of 1963 the author was George Fisher Baker Lecturer at Cornell University, where he delivered a course of eleven lectures. Each chapter of this book is an expanded version of one of these lectures. *Illustrated 55s net*

Mathematical Theory of Creep and Creep Rupture



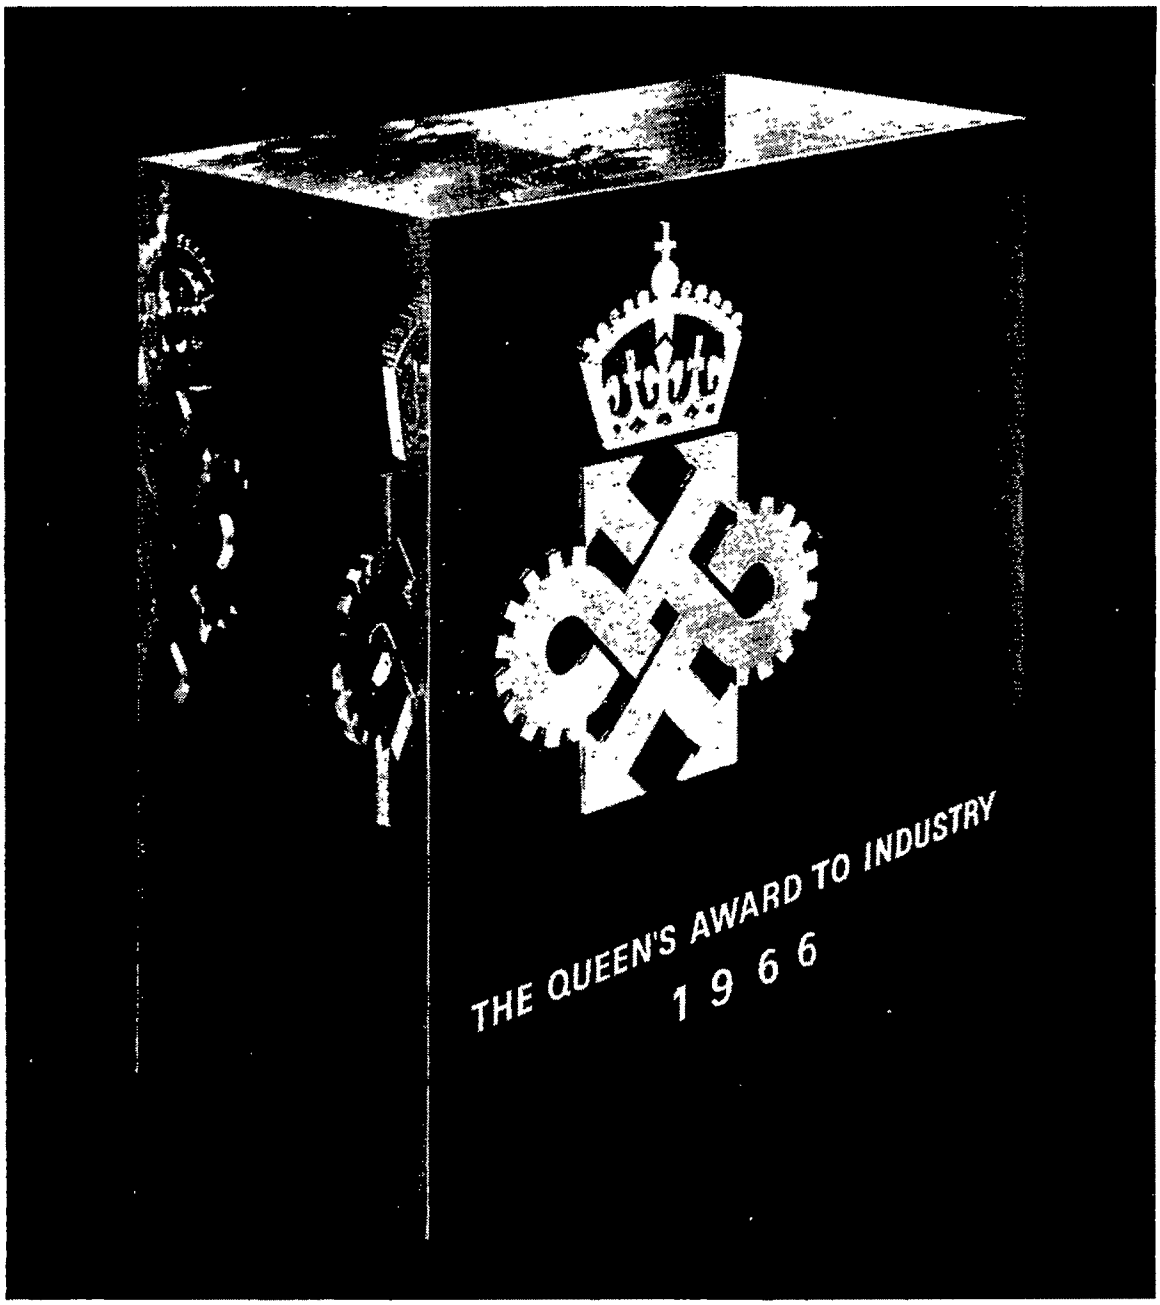
FOLKE K. G. ODQVIST

The main part of the book is devoted to a study of rigid-viscoplastic-deteriorating bodies. A mathematical theory of such bodies, valid also for multi-axial state of stress, is built up, analogous to the theory of elasticity, comprising theories of beams, membranes, plates, shells, thick-walled tubes, etc. In most cases the body in question is loaded at time $t=0$ with a constant load from a state of no load and the ensuing creep motion is studied. Special attention is devoted to finite deformation, stability, creep rupture, and relaxation. *6 half-tone plates, 103 text-figures 48s net*

OXFORD UNIVERSITY PRESS

THE NEW, SIMPLIFIED ISCO Model 180 DENSITY GRADIENT FRACTIONATOR

with UV Analyser, for Absorbance Recording and Preparative Fractionation of Density Gradient Columns



The ISCO Model 180 Density Gradient Fractionator presents the density gradient column to the optical system of the ISCO Model 220 UV Analyser at one of three constantly controlled and highly reproducible speeds. The signal from the UV Analyser can be recorded and shows the complete, detailed absorbance profile along the length of the column. The sensitivity of the syringe drive and resolution of the UV Analyser enable quantities of nucleoprotein in concentrations as small as 1 μg per ml. to be detected.

The illustration shows the ISCO Density Gradient Fractionator with UV Analyser mounted above the centrifuge tube.

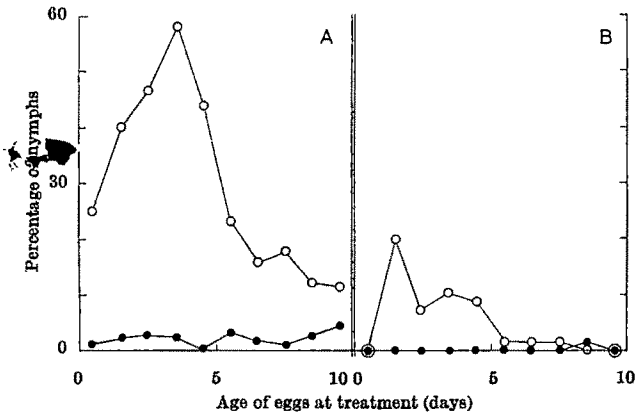

Fig. 1. The production of 'non-females' (*A*) and males (*B*) by centrifugation of eggs of *Carausius morosus* Br. at different stages of development. ●, Control; ○, treated

increase in the average time needed for development in the treated series cannot be attributed to an increase in the number of non-female individuals despite the fact that these have a longer development period than is normal. In the treated series, both normal and abnormal individuals show an appreciably longer period of development. The total numbers of 'non-females', gynandromorphs and/or intersexes, and males are increased significantly (χ^2_1's $\gg$ 10, P's $\ll$ 0·001) by centrifugation. As centrifugation may cause chromosome elimination[4] and can induce males, it seems likely that gynandromorphs rather than intersexes arise. Whether the sex chromosome elimination arises through direct or through indirect effects of centrifugation cannot be inferred from this experiment (due to the paucity of data on the effect on meiotic stages). Most of the gynandromorphs and males are induced when cleavage stages during segmentation are treated. The effect of treatment at later stages of development decreases progressively. The decrease in the number of induced gynandromorphs may be explained by a decrease in the expressivity of the gynandromorphism. This arises because proportionately fewer nuclei mutate at the more advanced stages of embryonic development. The fact that males can also arise through treatment of cleavage stages implies either that all the treated nuclei must mutate, or that there is chance mutation of those blastoderm nuclei which ultimately give rise to the germ anlage. This explains the observation of a decrease in the frequency of induction of males with the stage of development at treatment.

I thank Prof. J. A. Beardmore for his help and advice.

MICROBIOLOGY

Reciprocal Genetic Changes in Mycobacterial Host–Virus Systems: Effect of Lysogeny on the Phage

Mycobacteriophage phlei B2, one of several bacteriophages, isolated in Borstel in 1963 (ref. 1) was used in this investigation.

Phage *phlei B2* was obtained from dung and the slightly polyvalent original filtrate could be rendered specific for *Mycobacterium phlei* in two transfers on *M. phlei* strain *F89*. The host range of phage *B2* proved to be stable in more than thirty passages. Phage *B2* showed a drastic change in host range only on establishment of lysogeny and subsequent re-isolation from lysogenic complexes.

In the course of screening for lysogenic mycobacteria, organisms were picked from the residual growth in centres of massive (phage-) lysis and were purified by serial single-colony transfers on solid media. Phages re-isolated from lysogenic complexes, on the other hand, were purified by single-plaque transfers. The experiments were carried out with the agar overlay method of Gratia as modified by Froman *et al.*[2]. Phage stocks were maintained in 'Difco' heart infusion broth.

The first series of lysogenization experiments led to the formation of *SN*109(*B2*) complexes, the second to the formation of *F*89(*B2*) complexes.

On re-isolation from several *SN*109(*B2*) complexes, phage *B2* showed a genotype which differed in several respects from wild *B2*. Table 1 shows the changes which were in host range (extension of host range to *M. smegmatis SN2*), immunity and, to some extent, in plaque morphology. Concurrently with these changes in phages, respective lysogenic hosts showed an altered colony morphology and a decrease in growth rate (lysogenic conversion).

Table 1. HOST RANGE, IMMUNITY AND PLAQUE MORPHOLOGY CHARACTERISTICS OF PHAGE *B2* AND ITS *B2h* . . . DERIVATIVES

	Host range*	Immunity†	Plaque morphology‡
Wild *B2*	h^+	imm^+	c^+
*B2h.SN*109			
*B2'h.SN*109	h^-	imm^-	$c^{(-)}$
*B2"h.SN*109			

* h^+: propagates only on *M. phlei*; h^-: host range extension to *M. smegmatis*.
† imm^+: *B2* immunity; imm^-: insensitive to *B2* immunity.
‡ c^+: hazy plaque; c^-: mutation from hazy to clear plaque; $c^{(-)}$ intermediate between hazy and clear plaque.

It was clear that modification could not account for the emergence of the *B2h.SN*109 series of phages in view of the stable hereditary character of changes and to the absence of any previous contact with *M. smegmatis*.

A mutational hypothesis for the origin of the phages *B2h.SN*109 could not be discarded so easily as was the case with modification. Nevertheless, in view of the multiplicity of changes, it appeared to be somewhat less probable than recombination. The question of origin of the *B2h* genotype, however, could not be resolved at this stage and had to remain unanswered until lysogenic

complexes between *M. phlei* *F*89 and phage *B*2 had been established.

The variant phages emerging from *F*89(*B*2) strains appeared on re-isolation to be different from wild *B*2 as well as from each other. Some showed host range extension similar to that of phages *B2h.SN*109 (examples of this are *B2h.F*89 and *B2′′′′h.F*89). Others, such as *B2′.F*89, kept the wild-type host range. While all host-range variants proved to be immune variants as well, the immunity variant *B2′.F*89 had the wild *B*2 host range.

By grouping the newly obtained *B*2-variants according to the extent of the change in their immunity and subgrouping them according to a change in host range, a definite pattern could be demonstrated: a gradient of reciprocal changes in phages and respective lysogenic organisms.

* +, Lysis; 0, no lysis: protection due to immunity or species barrier.
† "Dismune" mutants of *B2‴h* can lyse *F*89(*B*2)‴.
‡ Recent segregation into *B2h* type phage changed this picture. *B2h* segregants of *B2′.F*89 can lyse strain *SN*2.

Table 2 shows that *F*89(*B*2)″, which differs from wild *M. phlei* *F*89 only with respect to lysogeny, releases a phage (*B2″*). This phage behaves as wild *B*2. At the other extreme, in *F*89(*B*2) phage *B*2 underwent the most drastic changes in the whole series. The resulting phage (*B2h.F*89) has a distinctly different plaque morphology—it forms clear plaques—and in contrast to *B*2, it does not respect either species or immunity barriers. It attacks *M. smegmatis* *SN*2 as well as related complexes of *F*89 lysogenic for phage *B*2. The change in its host seems as drastic as that in the phage. *F*89(*B*2) shows a two- to three-fold decrease in growth rate in conjunction with definite changes in colony appearance. *B2′F*89 and *B2′′′′h.F*89 represent intermediates between these two extremes.

The hypothesis of recombination as the mode of origin of the *B2h* series of phages gained powerful support by the establishment of a gradient of reciprocal changes in host *F*89 and phage *B*2. Subsequent serological, ultra-violet, and heat inactivation experiments confirmed the results of previous findings and contributed valuable additional support to this view.

The analysis of serological data revealed that (1) *B2h.F*89 and *B2′′′′h.F*89 are very closely related or identical phages; (2) the former group can be sharply delineated from the *B*2 group which comprises *B*2, B2″ (and *B2‴*) by the latter's very high sensitivity to inhibition by normal serum; and (3) *B2′F*89 shares antigens with both *B*2 and *B2h.F*89. (This, in view of a *B*2-host range and a *B2h.F*89 immunity, and the segregation of phage *B2′*F89 into parental *B2h.F*89, established this phage as a hybrid between *B*2 and *B2h.F*89.)

On the basis of heat and ultra-violet inactivation studies, an even sharper line could be drawn between members of group *B*2 and that of *B2h*, and in addition to this, the ultra-violet and heat sensitivity of *B2h.F*89 (or *B2′′′′h.F*89) has been shown to be intermediate between that of phage *B*2 and *M. phlei* strain *F*89.

A more detailed account of serological and physical characteristics of phages belonging to the *B*2- and the *B2h*-group will be presented at the International Symposium on Mycobacterial Variation (Borstel, W. Germany).

To sum up, we have presented evidence to show that phages of the *B2h*-type do not emerge from wild *B*2 due to modification or mutation. Observations supporting their recombination origin and nature are as follows: (1) they were invariably isolated from lysogenic complexes; (2) reproducible changes in the phage were accompanied by reproducible changes in the bacterium; (3) in heat and ultra-violet inactivation studies, the *B2h*-group behaved as would be expected if they were hybrids formed between phage *B*2 and *M. phlei* *F*89. The number of *B*2-variants was not sufficient to construct a chromosome map of phage *B*2; nevertheless, immunity appeared to be closely linked to host range and we would not be surprised to find later that immunity, virulence and 'clear' mutation lie within the same region somewhat similarly to phage λ (ref. 3).

This research was supported by a Medical Research Council of Canada grant which is gratefully acknowledged. We also thank Mrs. Mary S. Lamb for her assistance.

Comparative Gel-electrophoretic Investigation of the Protein Patterns of *Septoria* Species

THE genera *Septoria* in the class Fungi Imperfecti comprises some 1,200 species, each parasitic on one or several closely related genera of host plants. Little is known regarding their phylogenetic relationships since only a few perfect stages have been found. The host range and spore morphology have therefore been the main bases for the determination of species. However, the value of these characteristics for delimiting *Septoria* species has been questioned[1].

Recently, protein patterns obtained by electrophoresis have also been used to demonstrate taxonomic relationships. Clare[2] suggested that they may be helpful in classifying *Pythium* species; he found that isolates from different locations of any one species were similar in their protein patterns. Chang, Srb and Steward[3] demonstrated differences among patterns from species of *Neurospora*. They also showed that a mutant strain of *N. crassa* possessed a number of slow-moving bands not present in the pattern of the wild-type strain which they used. The last finding suggests that the protein patterns of fungi, such as *S. avenae*, the wild-type isolates of which are known to be highly variable in cultural type and pathogenicity[4,5] may also vary significantly. This communication describes the results obtained when the soluble proteins from several species of *Septoria*, parasitizing plants in the family Graminae, were analysed using disc electrophoresis.

Twelve isolates of *S. avenae*, varying in pathogenicity and cultural characteristics, were collected from the North Central oat-growing area of the United States. A similar series of isolates of *S. nodorum* and *S. tritici* were obtained. They were grown in Czapek's 2 per cent sucrose medium for 10–14 days on a reciprocating shaker at 24° C. The colonies were collected by filtration, and washed with distilled water. The soluble proteins were extracted in a

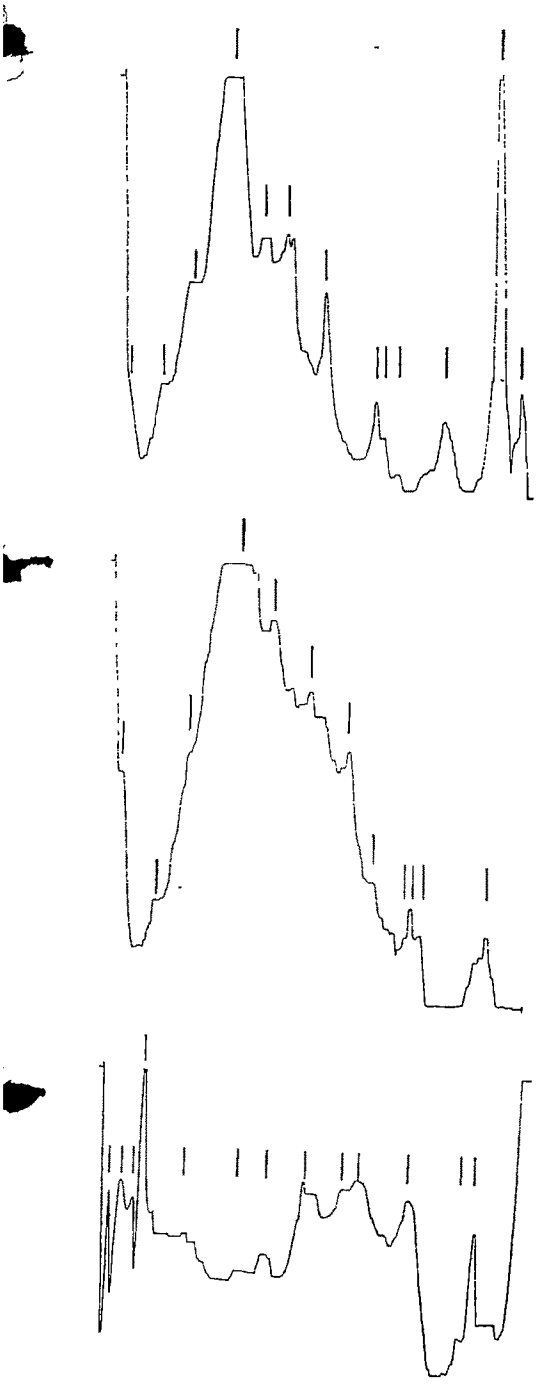

Fig. 1. Densitometric traces of amidoschwarz 10*B*-stained protein patterns from three isolates of *S. avenae* showing the variability among isolates. Tracings were made with a Joyce 'Chromatoscan' and the position of each band was marked with a vertical line

nitrogen atmosphere at 2° C with a Pirie press[6] using 0·1 M *tris* buffer, *p*H 7·8, containing 0·1 per cent ascorbic acid, 0·1 per cent cysteine-hydrochloride and 17 per cent sucrose. The extract was centrifuged, and a portion of the supernatant containing 200γ protein layered on top of the spacer gel just before electrophoresis. The electrophoretic procedure of Ornstein and Davis[7] was followed.

The protein pattern of any single isolate of *S. avenae* was not altered even though colonies of different ages were used or the fungus was grown on Czapek's, Fries's or Richard's medium. The majority of the patterns were either identical or quite similar, there being in some cases small variations in band position. However, there were significant differences between this 'type' pattern and those of the remainder of the isolates. The differences, although occasionally quantitative, were usually qualitative (Fig. 1). Similar results were obtained with the other two species investigated.

These findings indicate that the use of protein patterns for identifying *Septoria* species could become a valuable adjunct to other techniques for investigating *Septorias* parasitic on grasses, where the problem is relatively restricted in scope. However, it should be viewed with caution until the limits of natural variability within each species are established and the various species compared. Variability within *S. avenae* is considered, but has not conclusively been proved, to arise as "a process of continuing mutation within a heterocaryotic system"[5]. The probable occurrence of these processes in other fungi does suggest that here, too, variants may arise which differ in protein pattern much as they do in morphology and pathogenicity. As yet, the extent to which these findings can be applied to other fungi is not known.

I thank A. L. Scharen for supplying many of the isolates of *S. nodorum*. This work was supported in part by a grant from the National Science Foundation.

SOIL SCIENCE

Stimulation of Nitrification following Temporary Acidification of Soil

THE use of acidifying materials for reducing soil *p*H and the concentration of soluble salts in saline and alkali soils in order to improve structure and mineral nutrient relations is commonly practised. Sulphur and the sulphates of aluminium or iron are often used for this purpose[1,2]. During an investigation of the effects of varying degrees of acidification of soils on nitrogen metabolism during subsequent incubation some interesting results were obtained on nitrification rates when the *p*H of the acidified soils was increased before incubation. These results are presented here, since a search of the literature revealed that no similar effects have been reported.

Two soils (a saline soil, *p*H 7·2, and a degraded saline–sodic soil, *p*H 7·6, from Colombia, South America) of poor fertility were mixed with varying amounts of the three acidifying materials at similar sulphur-equivalent levels (0–0·5 per cent) and kept moist with intermittent leaching for 20 weeks. The soils were then air-dried and ground to pass a 2-mm sieve. *p*H values of the acidified degraded saline–sodic soil in relation to level of acidifying material are shown in Fig. 1. *p*H values for both soils were very similar irrespective of the type of acidifying material used. 10-g portions were incubated (30° C) under aerobic conditions (33 per cent of maximum water-holding capacity) with and without addition of 1 per cent calcium carbonate before incubation. This amount of calcium carbonate was sufficient to neutralize the acidity of even the most acid samples. After 6 weeks incubation ammonia and nitrate were extracted with N sodium chloride and determined by a microdiffusion method[3].

In the absence of added calcium carbonate, nitrate accumulation during incubation was negligible in all

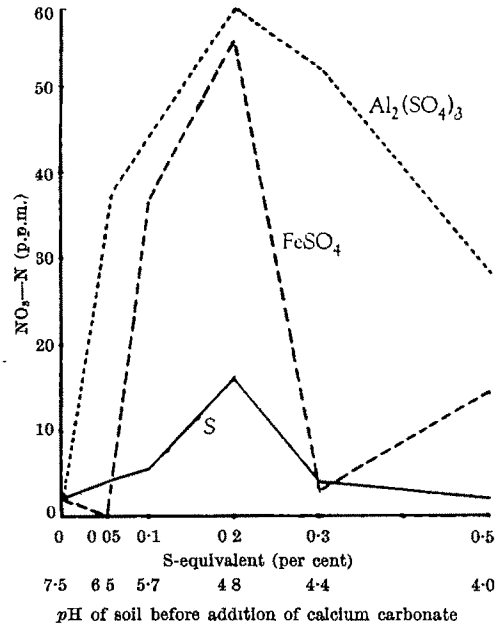

Fig. 1. Nitrate production during incubation of acidified soils treated with 1 per cent calcium carbonate

samples irrespective of *p*H. This would be expected in the soils of low *p*H because of the negligible activity of nitrifying organisms under these conditions[4,5]. At the higher *p*H values, low nitrate production was probably due to the absence of easily ammonifiable, and thus nitrifiable, organic nitrogenous compounds.

Of more interest, however, are the results obtained with added calcium carbonate. These are shown (for the degraded saline–sodic soil) in Fig. 1. Nitrate production increased with decreasing original *p*H (that is, *p*H before calcium carbonate addition) up to a maximum at original *p*H of 4·8 and then decreased with further increasing original *p*H. The same trend was noted irrespective of the type of acidifying material which had been used. The effects were, however, greater where aluminium or iron sulphate than where sulphur had been used. Similar results were obtained with the other soil investigated, namely, maximum nitrate production occurred where an intermediate level of acidifying material had been used. The original *p*H corresponding to this optimum nitrate level was also 4·8, as with the first soil.

Many reasons may be put forward to explain the results, but the most probable explanation lies in the changes occurring when the soils were being acidified. During this period stable organic compounds were probably being degraded to simple organic nitrogenous compounds. On increasing the *p*H before incubation these simple organic nitrogenous compounds were then easily ammonified and then nitrified. The extent of degradation of the complex to the simpler organic nitrogenous compounds appeared to increase with intensity of acidity during the acidifying period, being at a maximum in the region of *p*H 4·8. The low nitrate production in samples which had been brought to *p*H values less than 4·8 before incubation with added calcium carbonate may have been due to much reduced degradation of organic compounds during acidification. Alternatively, at the very low *p*H values the population of nitrifying bacteria may have been reduced to such low levels[6] that even after neutralization of the soils they could not multiply at a sufficiently high rate to nitrify all the ammonia produced. This is confirmed by the fact that ammonia accumulated during incubation of neutralized soils only where *p*H had been reduced below 4·8. The absence of ammonia accumulation where soils of *p*H 4·8 or higher were neutralized indicates that the rate of nitrification exceeded the rate of ammonification so that the rate-limiting factor was organic nitrogen which could be mineralized.

Weathered Biotite from Strathdon, Aberdeenshire

WALKER[1] showed that biotite weathered to vermiculite in the soil. This transformation involved the complete replacement of interlayer potassium ions by water molecules and exchangeable magnesium ions together with various changes in the silicate layers such as oxidation of ferrous iron and the substitution of octahedral iron by magnesium. MacEwan[2], however, found that in poorly drained soils biotite broke down into a macroscopic trioctahedral montmorillonite. Recent work, summarized by Jackson[3], reveals that the interlayer positions of expanded 2 : 1 layer silicates in soil clays may be incompletely filled with positively charged hydroxy aluminium, such as $Al_8(OH)_{12}(OH_2)_{12}^{4+}$. Thus the expanded 2 : 1 layer silicates are effectively converted to a 2 : 2 intergrade in which the interlayer positions are partially occupied by hydroxy aluminium islands. These intergrades which usually show a 14 Å *c*-spacing have been referred to as 'dioctahedral vermiculite' or 'chlorite-like' and possess properties intermediate between homogeneous 2 : 1 or 2 : 2 layer silicates.

Experiments at this Institute appear to indicate that biotite may weather in a similar way to expanded 2 : 1 soil clays. Samples of weathered biotite were collected from the fine and coarse sand fractions of two freely drained soils and also from a weathered biotite-rich gabbro near Strathdon, Aberdeenshire. X-ray diffraction measurements of both powdered material and single flakes almost invariably showed a strong line at approximately 14 Å and a weaker, more diffuse, line at about 7·3 Å. At first it was thought that the 14 Å line indicated vermiculite, but the behaviour of the mineral on heating and on potassium saturation was inconsistent with this interpretation. Heating at 400° C for several hours followed by sealing in a glass capillary tube to prevent rehydration caused a shift in spacing to between 11·0 Å and 11·4 Å. Had true vermiculite been present as a component, this treatment should have caused a collapse to 10 Å (ref. 4). The weathered material was also treated with 1 N potassium chloride, potassium hydroxide and potassium oxalate for periods up to a week, but this failed to produce any significant change in the *c* dimension. These results pointed to the presence of interlayer contaminants, suggesting in particular the occurrence of non-exchangeable aluminium in interlayer positions which is known to inhibit lattice contraction of vermiculite[5]. Using the method of Follett *et al.*[6] for the dissolution of amorphous alumina and silica, the weathered biotite flakes were repeatedly treated with cold and then hot 5 per cent sodium carbonate in an attempt to remove any less well ordered alumina and silica present. The weight percentage total of alumina extracted by this means varied from 2·5 to 5·4 per cent; the extracted silica ranged from 2·9 to 4·6 per cent. After this treatment, the weathered biotite flakes were re-examined by X-ray diffraction. It became clear that the behaviour of the mineral on heating to 400° C and on potassium saturation had been considerably modified. Heating to 400° C now caused a

collapse to between 10·0 and 10·6 Å, and potassium saturation contracted the lattice to between 11·3 and 11·8 Å. These results indicate that much of the dissolved material must have come from inter-layer positions and appear to confirm the existence of non-exchangeable alumina, possibly associated with silica, in this part of the biotite structure.

The line at about 7·3 Å referred to already is observed in powders and in single flakes and is invariably associated with a (060) dioctahedral line at 1·49 Å. When the flakes are heated to 600° C, both the 7·3 and the 1·49 Å lines disappear, while the trioctahedral line at 1·53 Å associated with the biotite remains unchanged. These results strongly suggest the presence of a kaolin zone within the weathered biotite, possibly possessing a definite crystallographic orientation with the host mineral. Using the potassium acetate method of Wada[7], it was shown that the kaolin mineral behaved like kaolinite and not halloysite.

It may be seen, therefore, that in this particular instance the weathered biotite consists of a 14 Å intergrade alumino vermiculite–chlorite, together with zones of kaolinite. This transformation seems to take place fairly rapidly, since biotite weathered in such a manner has been found in slightly disintegrated rock, where the visual appearance of the mineral is fairly fresh. Normal 10 Å biotite was found only in the completely unweathered rock. This suggests that the alumination of the interlayer positions takes place at the same time as the expansion of the lattice in the *c* direction. It is of interest to note that Kato[8] has found that the weathering product of biotite of a granodiorite at Shinshiro City, Japan, is somewhat similar to that described here and that it is characteristic of an open, freely drained environment. Walker[1] and MacEwan[2] found that the transformations of biotite to vermiculite and biotite to trioctahedral montmorillonite occurred under intermediate and poor drainage conditions respectively. It is clear, therefore, that the nature of the weathering product of biotite in the soil depends on several environmental factors, one of which is drainage. A more detailed report of the weathered biotites described above will be published elsewhere.

I thank Mr. W. A. Mitchell, Mr. B. D. Mitchell and Mr. A. Thomson for encouraging discussions and for helpful advice on techniques. I also thank Mr. B. F. L. Smith, who did the alumina/silica determinations, and Mr. E. L. Birse for considerable help in the field.

PSYCHOLOGY

Control of Time Estimation by a Chemical Clock

THE hypothesis of a temperature-dependent internal chemical clock as a basis for man's estimation of time intervals of short duration was made more than 30 years ago.

Francois[1] had found that the speed of tapping a Morse key at a rate estimated to be 3 taps/sec increased in a total of sixteen experiments on three subjects when their axilla temperature was raised by diathermy by between 0·3° C and 1·0° C. He found, also, that the frequency of a metronome beat which was perceived as 4 beats/sec increased in a total of five experiments on three subjects when their axilla temperature was raised by diathermy by between 0·3° C and 0·8° C.

Six years later Hoagland[2] had observed that his wife's speed of counting at an estimated rate of 1 digit/sec increased as her oral temperature rose due to influenzal fever. He obtained average counting speeds over three to six judgments at five levels of oral temperature between 36·33° C and 39·44° C. In 1880, Arrhenius had described an empirical equation relating chemical velocity to temperature, and directly from the slope of the line it was possible to calculate a constant of much theoretical importance to the physical chemist known as the energy of activation (μ) (refs. 2 and 4) from the formulae:

$$\log_e \frac{k_1}{k_2} = \frac{\mu}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \text{ or } \log_{10} \frac{k_1}{k_2} = \frac{\mu}{2{\cdot}30258R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

where k_1 and k_2 are proportional to the velocity constants of an irreversible chemical reaction (log speed of counting, tapping etc.) at the respective absolute temperature (°K) T_1 and T_2, R is the gas constant with a value of 1·987 calories/degree/mole, $\log_e x = 2{\cdot}30258 \log_{10} x$, and μ is the energy of activation or temperature characteristic in calories. Hoagland, therefore, analysed the time estimation data from his wife and obtained an energy of activation value of μ = 24,000 calories (to the nearest 1,000 calories) which he suggested "falls within one of the major modal groupings of temperature characteristics found for a variety of rhythmic processes investigated in poikilothermic animals"[2]. Data from a similar experiment on a colleague with influenzal fever revealed an oral temperature increase from 36·57° C to 38·15° C and an increased speed of counting with an energy of activation value, μ, of 18,500 calories. Data from a student heated by diathermy revealed an increase in counting speed over three occasions at oral temperatures between 38·15° C and 38·74° C and a μ value of 24,000 calories (to the nearest 1,000 calories).

Hoagland[2] then plotted the full results (three subjects, sixteen experiments, of Francois's study of Morse key tapping at an estimated rate of 3 taps/sec together with his own data from three subjects engaged in estimating a counting rate of 1 digit/sec, and found a composite plot with a value of μ = 24,000 calories. "These results definitely imply the existence of a unitary chemical process serving as a basis for the subjective time scale, a process quite possibly irreversible in nature and perhaps catalysed in a specific way, since the critical increment of 24,000 calories corresponds to one of the modal groups characteristic of kinetics in living organisms . . . (and) . . . indicate that our sense of time depends on the speed of a chemical step in some group of cells, presumably in the brain, that acts as a chemical clock"[2,3].

In order to subject this hypothesis to further experimental testing, two series of experiments have been performed in which the subjects' speed of counting at a rate estimated to be 1 digit/sec and speed of tapping at an estimated rate of 3 taps/sec was compared with increase in body (oral) temperature[5,6]. In both experiments, body temperature was raised significantly by immersion of the legs below the knee in a bath of warm water. Eight subjects estimated the 1 digit/sec counting rate over an estimated 60 sec interval. Their body temperature rises during the experiments ranged from 0·4° C to 1·2° C. A '*t*' test assessment of the significance of the difference between the counting speeds at the lowest and highest temperatures recorded revealed a significant increase in counting speed with the increase in body temperature. There was, however, no significant association as assessed by the calculation of a product moment correlation coefficient between the extent of rise in oral temperature and the magnitude of the change in time estimation performance. One subject failed to demonstrate a change in his counting speed in the predicted direction. When the energy of

activation constant was calculated, for the data from each of the seven subjects whose counting speed had increased, in order to assess the constancy of the μ value on which the biochemical clock hypothesis is based, it was found that μ had a mean value of 74,000 calories within a range over the seven subjects of 9,000 to 139,000 calories.

The eight subjects examined on the 3 taps/sec task had increases in oral temperature of 0·3° C to 1·2° C. A product moment correlation coefficient of $r = +0{\cdot}84$ ($P < 0{\cdot}05$) revealed a significant association between the extent of rise in oral temperatures and the magnitude of the changes on the tapping task. However, three subjects failed to show an increase in tapping speed with raised body temperatures, and for the five subjects whose performance changed in the predicted direction energy of activation constants ranged from 20,000 calories to 138,000 calories about a mean of $\mu = 83{,}000$ calories.

In view of the very great discrepancies between these findings and those of the original research, Arrhenius equation analyses were performed on Francois's[1] data. It was found that with increases in axilla temperature of between 0·3° C and 1·0° C, the energy of activation constants ranged between 14,000 and 34,000 calories in sixteen experiments on three subjects.

In view, therefore, of this variability in the Arrhenius equation energy of activation value, the constancy of which is essential to the hypothesis of a potent biochemical influence on time estimation performance in humans, and because Hoagland[2] has pointed out that "a temperature range of 3·2° C is too short to enable one to say with certainty that the Arrhenius equation adequately describes the data", the position that man has demonstrated a control of his time estimation of short intervals by a chemical clock would seem to be untenable.

MISCELLANEOUS

'Significant' and 'Highly Significant'

Frequently in scientific papers one finds the terms 'insignificant', 'significant' and 'highly significant' used in discussing the difference between control and experimental, with their ranges usually established by $P = 0{\cdot}05$ and $P = 0{\cdot}01$. Statistics text-books provide little or no guidance as to their proper usage because statisticians apparently disapprove of the convention. Yet the universality of the convention attests to the need for clearly defined, commonly accepted terms which properly weight the results of the experiment. The present convention is commonly accepted among non-statisticians, but, as will be shown here, is not clearly defined. Therefore an improved convention is proposed for the consideration of those who would benefit from it—the non-statisticians in research. Perhaps by improving the convention, it can be made more palatable to statisticians, as well as more useful to non-statisticians.

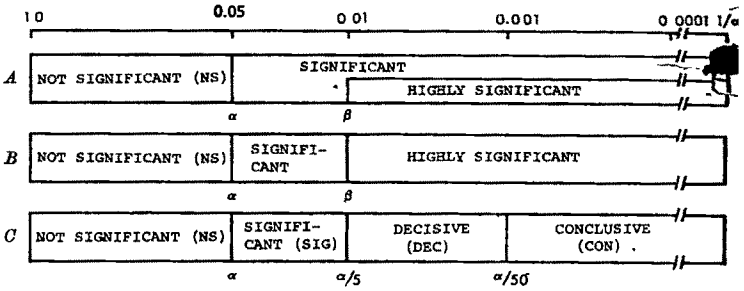

Fig. 1. Range of probabilities covered by present and proposed terms. *A*, Present convention, by definition. *B*, Present convention, as commonly used. $\alpha = 0{\cdot}05$ and $\beta = 0{\cdot}01$ unless otherwise specified (no set relation between α and β). *C*, Proposed convention: $\alpha = 0{\cdot}05$ unless otherwise specified, other values always $\alpha/5$ and $\alpha/50$

The proposed convention is as follows: The significance level, α, for rejection of the null hypothesis will be 0·05 unless otherwise specified. The significance zones will be established by the points 0·05, 0·01 and 0·001; or, in general, α, $\alpha/5$ and $\alpha/50$. When a statistical test is not designed to distinguish, for example, a probability between $\alpha/5$ and $\alpha/50$ from one which is less than $\alpha/50$, any P less than $\alpha/5$ will be designated by the term for P between $\alpha/5$ and $\alpha/50$. The terms that follow are capitalized to indicate that the idiomatic definition is intended.

The abbreviations may be used in conjunction with the symbols greater than, less than and different from, as follows: $A \overset{\text{DEC}}{>} B$; $B \overset{\text{NS}}{\neq} C$, meaning A is decisively greater than B, and B is not significantly different from C.

The present convention has several defects which the proposed modification will remedy. 'Significant' at present is defined as $P < 0{\cdot}05$, and 'highly significant' as $P < 0{\cdot}01$, unless otherwise specified. Since the latter is included within the former, either term could be applied to values less than 0·01. This ambiguity is avoided in practice because, when using both terms, one never refers to values less than 0·01 as merely 'significant'. In practice, the terms are mutually exclusive, with significant restricted to P between 0·05 and 0·01. In the proposed convention, there is no overlap of definitions, and usage agrees with definition (see Fig. 1).

Flexibility in designating the chosen significance level, α, for rejection of the null hypothesis is retained, but in the proposed system the three levels of significance bear a constant relationship to each other. Since the same criteria would be used to establish each significance level these should have a constant relationship. Only in the proposed convention is this found. In addition, the present scale of probabilities is too compressed, for the two extreme terms are separated by only 5 per cent. The proposed terms, as one may see in Table 1, allow a more precise discussion of probabilities.

Finally, there are semantic difficulties with the old convention. 'Significant' and 'highly significant' sound so much alike that clarity is lost when both must be used several times. Also, the adverbial form, 'highly significantly greater than' is awkward construction. The proposed terms, by contrast, are single, easily distinguished, easily used words with meanings which suggest their idiomatic use.

The foregoing is proposed in the hope of clarifying and simplifying the use of statistics in research, and thus encouraging investigators to make use of statistics in evaluating their data.

Table 1. Definitions of Proposed Terms for Statistical Significance

Term	Abbreviation	Conventional meaning	General meaning
Not significant (ly)	NS	$P \geq 0{\cdot}05$	$P \geq \alpha$
Significant (ly)	SIG	$0{\cdot}05 > P \geq 0{\cdot}01$	$\alpha > P \geq \alpha/5$
Decisive (ly)	DEC	$0{\cdot}01 > P \geq 0{\cdot}001$	$\alpha/5 > P \geq \alpha/50$
Conclusive (ly)	CON	$P < 0{\cdot}001$	$P < \alpha/50$

David A. Miller

Department of Physiology,
Tulane University School of Medicine,
New Orleans, Louisiana.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, June 13

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 3 p.m.—Annual General Meeting.

Tuesday, June 14

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in Committee Room 11, House of Commons, Westminster, London, S.W.1), at 5.30 p.m.—Discussion on "Air Pollution—Progress since the Passage of the Clean Air Act and Future Developments in Connexion with Air Pollution".

Wednesday, June 15

GEOLOGICAL SOCIETY OF LONDON, ENGINEERING GROUP (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. C. S. Hitchen: "Materials Problems Connected with the Kainji Multi-Purpose Project"; Mr. D. B. Morris. "The Application of Ground and Marine Geophysical Methods to Material Surveys"; Mr. A. A. Archer: "Economic Minerals Survey".

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. F. Pasquill: "Lagrangian Similarity and Vertical Diffusion from a Source at Ground Level"; Mr. A. J. Dyer: "The Flux-Gradient Relation for Turbulent Heat Transfer in the Lower Atmosphere"; Mr. K. L. Calder: "Concerning the Similarity Theory of Monin/Obukhov".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—132nd Annual General Meeting. 6 p.m.—Mr. L. H. C. Tippett "Statistics in Manufacturing Industry" (Presidential Address).

Thursday, June 16

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. R. G. W. Norrish, F.R.S.: "The Progress of Photochemistry Exemplified by Reactions of the Halogens" (Bakerian Lecture).

INSTITUTION OF MINING AND METALLURGY (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. Murrogh V. O'Brien: "Review of Mining Activities in the Republic of Ireland".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. G. W. Whitehead: "Stable Homotopy Theory".

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—59th Annual General Meeting, followed by Prof. A. W. Woodruff. "Medicine in Burma".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER or ASSISTANT LECTURER (with an interest in electrochemistry or thermodynamics) IN CHEMISTRY—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (June 13).

SECOND TUTORIAL FELLOW IN PHILOSOPHY—The Warden, Merton College, Oxford (June 14).

SENIOR DEMONSTRATOR IN THE DEPARTMENT OF CHEMISTRY to help with the practical teaching of physical chemistry and to carry out research in the general field of mechanisms of reactions in solution—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (June 14).

ASSISTANT LECTURER IN ARCHAEOLOGY (including Roman Britain)—The Registrar, University of Bristol, Senate House, Bristol, 2 (June 17).

ASSISTANT LECTURER or LECTURER (preferably with experience in the application of quantitative techniques in human geography) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Liverpool, quoting Ref. CV/76/N (June 18).

LECTURER (with an honours degree) IN MATHEMATICS; and a GRADE B ASSISTANT LECTURER (with an honours degree) IN MATHEMATICS IN THE DEPARTMENT OF MATHEMATICS AND PHYSICS, College of Engineering and Science—The Director of Education, The Polytechnic, 309 Regent Street, London, W.1 (June 18).

ASSISTANT LECTURER (preferably with interests in reaction kinetics, surface chemistry, or in thermochemistry and of doctoral standing) IN PHYSICAL CHEMISTRY—The Registrar, The University of Manchester Institute of Science and Technology, Sackville Street, Manchester, 1 (June 20).

LECTURER (preferably with experience or interest in neurophysiology) IN PHYSIOLOGY—The Secretary, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (June 20).

LECTURER IN PSYCHOLOGY in the Institute of Education—The Registrar, The University, Hull (June 23).

LECTURER IN ENGINEERING MATHEMATICS (Computation)—The Secretary, The Queen's University, Belfast, Northern Ireland (June 24).

LECTURER (with special qualifications in petrology (igneous or metamorphic) or in economic geology) IN GEOLOGY—The Registrar, The University, Sheffield (June 27).

CHAIR OF BIOLOGY—The Secretary, University of Stirling, Stirling (June 30).

FOOD TECHNOLOGIST, SCIENTIFIC OFFICER GRADE (with a university degree, preferably with honours) IN THE DEPARTMENT OF AGRICULTURE AND HORTICULTURE, Long Ashton Research Station—The Registrar, University of Bristol, Senate House, Bristol, 2 (June 30).

LECTURER (with a distinguished academic record, and preferably with interests in some field of invertebrate zoology) IN THE DEPARTMENT OF ZOOLOGY, School of Biological Sciences, University of New South Wales—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 30).

LECTURERS IN STATISTICS IN THE DEPARTMENT OF MATHEMATICS—The Deputy Secretary, The University, Southampton (June 30).

ASSISTANT LECTURER IN THE DEPARTMENT OF MATHEMATICAL PHYSICS—The Assistant Registrar (Science and Engineering), The University of Birmingham, Birmingham, 15 (July 1).

ASSISTANT LECTURER or LECTURER IN THE DEPARTMENT OF VETERINARY ANATOMY, Royal (Dick) School of Veterinary Studies—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (July 1).

CHAIR OF THEORETICAL PHYSICS at Westfield College—The Academic Registrar, University of London, Senate House, London, W.C.1 (July 1).

LECTURER or ASSISTANT LECTURER (with research or industrial experience in one of the following fields: theoretical and experimental fluid dynamics, advanced propulsion systems, aircraft structures, aircraft control systems or automatic control) IN THE DEPARTMENT OF AERONAUTICS AND ASTRONAUTICS—The Deputy Secretary, The University, Southampton (July 1).

READER IN EXPERIMENTAL PHYSICS at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (July 1).

SENIOR EXPERIMENTAL OFFICER IN THE DEPARTMENT OF MICROBIOLOGY whose main duties will be the operation and maintenance of an electron microscope, examination and preparation of specimens of micro-organisms and infected tissues, and to develop or improve techniques for the examination of such specimens—Secretary to the Academic Council, University of Belfast, Belfast, Northern Ireland (July 1).

CHAIR AND HEAD OF THE DEPARTMENT OF BIOCHEMISTRY—The Registrar, The University, Leeds, 2 (July 4).

LECTURER IN HAEMATOLOGY AND BLOOD TRANSFUSION IN THE DEPARTMENT OF PATHOLOGY, University of Ibadan, Nigeria—The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W.C.1 (July 11).

LIBRARIAN at the University of Ife, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (July 11).

ASSOCIATE PROFESSOR IN BIOLOGY (in the field of cellular biology) at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 15).

LECTURER (Member of the College of Pathologists, or with an equivalent higher qualification, and experience of teaching students) IN MORBID ANATOMY IN THE DEPARTMENT OF PATHOLOGY, University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, July 15).

READER IN MICROBIOLOGY at King's College Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (July 15).

CHAIR OF PSYCHOLOGY at the Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 18).

READER (with at least ten years experience in the petroleum industry and preferably interests and experience in petroleum reservoir engineering) IN PETROLEUM ENGINEERING at Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (July 20).

CHAIR OF MINING AND METALLURGICAL ENGINEERING at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, July 29).

SENIOR LECTURER IN GEOPHYSICS at the University of Tasmania, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 29).

SENIOR LECTURER/LECTURER (with an honours degree in an appropriate branch of science, applied science or engineering, a number of years of research and/or industrial experience, and preferably with experience in the use of modern analytical techniques and their application in the process industries) IN APPLIED CHEMISTRY IN THE DEPARTMENT OF INDUSTRIAL SCIENCE, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office) Marlborough House, Pall Mall, London, S.W.1 (August 8).

LECTURER/SENIOR LECTURER IN AGRONOMY at Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 15).

BIOCHEMIST (basic grade) in the Biochemistry Laboratory of the Endocrine Unit—The Secretary, New End Hospital, London, N.W.3.

CHAIR OF PHYSIOLOGY in the Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

CHAIR OF THEORETICAL SOLID STATE PHYSICS—The Registrar and Secretary, The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex, marking envelope "Confidential".

CHEMISTS (with a good honours B.Sc. degree and preferably of Ph.D. standing) to work in the fields such as relation between structure and properties in polymeric materials, modification of polymer properties by cross-linking and grafting, the application of reverse osmosis to the desalination of water and to non-aqueous systems and biomedical applications of new membranes—The Director, Arthur D. Little Research Institute, Inveresk, Musselburgh, Midlothian, Scotland.

LECTURER and an ASSISTANT LECTURER (with a good honours degree in electrical engineering or an honours diploma in technology) IN THE DEPARTMENT OF ELECTRICAL AND ELECTRONIC ENGINEERING—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1, quoting Ref. EE/N.

PROFESSOR (with high academic qualifications and substantial industrial and/or research experience in some aspect of the broad field of automotive engineering, preferably in vehicle dynamics) IN AUTOMOTIVE ENGINEERING WITHIN THE DEPARTMENT OF AERONAUTICAL AND AUTOMOBILE ENGINEERING—The Academic Registrar, Loughborough University of Technology, Loughborough, Leicestershire.

RESEARCH FELLOW (theoretical physicist or mathematician, preferably of post-doctoral status) IN THE DEPARTMENT OF PURE AND APPLIED CHEMISTRY, to work under Dr. Pugh on the theory of electronic states near dislocations in iron crystals—Prof. M. Gordon, Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, C.1.

RESEARCH OFFICER (with a background in forestry and a sound knowledge of the structure of wood in relation to its use) IN THE DEPARTMENT OF ORGANIC CHEMISTRY (at present the research programme centres on the quality of Eastern Canadian softwoods in relation to their use in the pulp and paper industry)—Personnel Officer, Ontario Research Foundation, 43 Queen's Park Crescent East, Toronto, 5, Ontario, Canada.

SENIOR GRADE PHYSICISTS (2) (with previous experience in radiation protection, and preferably experience with radio-isotopes) IN THE PHYSICS DEPARTMENT—The House Governor, The London Hospital, Whitechapel, London, E.1.

SENIOR LECTURER IN ZOOLOGY/PHYSIOLOGY, a SENIOR LECTURER IN PLANT PHYSIOLOGY; LECTURERS IN CHEMISTRY (2); and a LECTURER IN MICROBIOLOGY—The Principal, Barking Regional College of Technology, Longbridge Road, Dagenham, Essex.

SENIOR SCIENTIFIC OFFICER (veterinary graduate, preferably with experience in physiological research, and an interest in, and aptitude for, experimental surgery) IN THE PHYSIOLOGY DEPARTMENT, to collaborate with members of the Physiology and other Departments in experiments involving surgical procedures and to carry out physiological research in some field related to experimental surgery—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berkshire, quoting Ref. 66/19.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Edwards High Vacuum International, Ltd. Report and Accounts for the year ended 31st December 1965. Pp. 16. (Crawley: Edwards High Vacuum International, Ltd., 1966.) [194

Rubber and Plastics Research Association of Great Britain. Forty-sixth Annual Report 1965. Pp. 38. (Shawbury, Shrewsbury: Rubber and Plastics Research Association of Great Britain, 1966.) [194

Proceedings of the Royal Irish Academy. Vol. 64, Section A, No. 6: A Survey of the Heitler-Arnous Non-Local Field Theory. By J. C. Guillot, W. Jaus and L. O'Raifeartaigh. Pp. 93–106. 3*s*. Vol. 64, Section A, No. 7: On Affine Laws. By Ferit Oktem. Pp. 107–113. 2*s*. Vol. 64, Section B, No. 10: An Orbicular Facies of the Leinster Granite. By J. G. Thieme, Pp. 155–164+plate 9. 2*s*. 6*d*. Vol. 64, Section B, No. 11: The Old Red Sandstone of Slieve Mish, Co. Kerry. By J. G. Capewell. Pp. 165–174+plate 10. 3*s*. Vol. 64, Section B, No. 12: Light and Electron Microscopy of the Female Cells of *Proteocephalus pollanicola* (Cestoda). By R. A. R. Gresson. Pp. 175–185+plates 11–13. 4*s*. Vol. 64, Section B, No. 14: The Siphonaptera of the Hirundinidae in Ireland. By A. J. M. Classens. Pp. 195–209. 2*s*. 6*d*. (Dublin: Royal Irish Academy, 1965.) [204

The Institution of Chemical Engineers. Annual Report of the Council for the year ending 31 December, 1965. Pp. 14. (London: The Institution of Chemical Engineers, 1966.) [204

BOMBS AWAY

THE common interest that there should be a limit to the spread of nuclear weapons is uncommonly difficult to ensure by technical means. It is now more than three years since the international agreement was made between most countries except China and France not to test nuclear weapons in the atmosphere. For much of that time the Disarmament Sub-Committee of the United Nations Assembly has been talking about other steps that might be taken. Governments and groups of governments have proposed various devices for limiting the spread of nuclear weapons including an extension of the test ban to underground tests and nuclear-free zones, as they are called, in various parts of the world. Unofficial groups have zealously pursued the same objectives. Most often, frustration has won the day.

By now the reasons why these problems are difficult should not be a surprise. The spread of the technology of nuclear weapons is not a process of unrestrained contagion, like the spread of plague. Refrigerators and motor-cars may be diffused to the corners of the Earth, but nuclear weapons need not follow. So far, five nations have embarked on the manufacture of nuclear weapons. Nuclear powers appear to have been created at a rate of one every five years. Yet for every nation which manufactures nuclear weapons, there is at least one other which has deliberately decided not to do so. The causes of this self-restraint are only occasionally technical, and concerned with such things as the cost of making nuclear weapons in meaningful numbers, or the difficulty and cost of delivering them in anger. Political restraints have usually been more telling. Some nations have been discouraged from making nuclear weapons, or otherwise obtaining them, by the fear of political and even military repercussions. Others have sought to preserve an international reputation for pacific ways of conducting international business. The influence of the Soviet Union and the United States has frequently been decisive in preventing the spread of nuclear weapons.

The political disincentives to the independent manufacture of nuclear weapons are so many and so powerful that it is even possible to argue that there are natural limits to the extent to which nuclear weaponry will spread throughout the world. If nuclear weapons are like an infection, only some nations are susceptible. The trouble with this line of argument is that, even if it should be sound, nobody can risk relying on it. The same is true of the beguiling, but less plausible, analogue of Le Chatelier's principle that the spread of nuclear weapons does not matter, because the pattern of international relations will quickly adjust to nullify the consequences of the acquisition of nuclear weapons by one nation. The view, fashionable in France, that the world would be more stable if all nations were possessed of nuclear weapons somehow commensurate with their importance as prizes to potential enemies is equally suspect as an over-simplification. The plain truth is that it seems to be most sensible to pursue all ways of reinforcing the natural restraints of the spread of nuclear weapons. The difficulty is that there can be no single recipe for doing this, but only an awkward mixture of several ingredients, some political and some technical.

What, then, can be accomplished by technical devices for limiting the spread of nuclear weapons? There are obvious limits to what can be done. A device such as the test ban is less than perfect not merely because of the possibility, now remote, that violations might not be detected, but also because abrogations by individual nations of the international treaty to ban tests in the atmosphere entail no formal penalties. Only if the number of exceptions to the rule was indecently great would the other signatories of the treaty abandon it. From this it follows that an extension of the treaty on tests to inhibit underground tests would be valuable but not crucial. Persuading China to sign the existing treaty—a political task—would be more valuable than solving the technical problems which still prevent an agreement on underground tests.

Similar problems attend other proposals of a technica character for limiting the spread of nuclear weapons. Thus the several proposals that there have been for nuclear-free zones in parts of the world as different as Latin America and Central Europe are open to the general criticism that they refer either to groups of nations which are unlikely to acquire nuclear weapons anyway, or to parts of the world where international tensions are acute, and where a simple declaration of intent would be unconvincing if it were not accompanied by full-blooded inspection.

It is the same with the proposals for an international treaty under the terms of which nuclear powers would undertake not to help disseminate nuclear weapons, and other nations would agree not to acquire them. There are obvious but formidable difficulties in inspecting such a treaty, and indeed it seems now to be agreed that any agreement would have to rest on a declaration of good faith. But then there are the problems of how nuclear powers falsely accused of helping with the spread of weapons can publicly prove their innocence. There is the difficulty of knowing what will happen if signatories abrogate the treaty by a sudden declaration. And there is the over-riding unwillingness of the nations not now possessed of nuclear weapons to sign an instrument which will perpetuate what frequently appears as the overweening arrogance of the existing nuclear powers. Here, too, the existence of problems should not destroy the will to solve them, but progress must be slow.

In these circumstances, it may well be that the best contribution which technical people can make to the restraint of the spread of nuclear weapons lies in the design of procedures for controlling the uses to which fissile material is put. The International Atomic Energy Agency in Vienna has been occupied for several years in working out means of supervising research reactors, and some progress has now been made towards dealing with power reactors. By all accounts, there is a good chance of working out an effective system. Though it will certainly need several years before the international supervision of the IAEA could so win the trust of the nuclear powers that the Agency could take over the supervision now vested in a host of bilateral treaties, that goal is well worth working towards. Sooner or later, fears about the spread of nuclear weapons will inhibit the full use of civil nuclear power if convincing international supervision does not exist. And there is always the possibility that diplomatic ambitions will reach—as they did a decade ago—towards an inter-

national agreement to refrain from the manufacture of military nuclear explosives. The cut-off, as it is called, would be a more valuable agreement than any now in prospect.

WRONG REPENTANCE

WHAT seemed a week ago to be the near certainty that the European Launcher Development Organization would be torpedoed has in the event been transformed by compromise. The British Government seems to have recognized the force of the arguments against what amounted to its withdrawal from ELDO, and the Minister of Aviation at Paris a week ago played a much less intransigent part than he had at first announced. It is now likely that there will be a reapportionment of the costs of running ELDO in such a way that the three principal partners—Britain, France and West Germany—will pay roughly equal shares. There is also to be a technical examination of the programme of ELDO, though at this stage it is not clear whether this will be a thorough reappraisal of the somewhat shaky plans at present being followed, or merely an exercise in face-saving. More should be known when European ministers resume their debate on the future of ELDO on July 10. Meanwhile there is no doubt that the retreat of the British Government from its previously ill-prepared position is to be reckoned a sign of grace, though one that does not entirely cancel out the ostentatious tactlessness of the original decision to withdraw, for practical purposes, from ELDO.

The chief cause for continuing regret is that the survival of ELDO is now made to seem conditional on the reduction of the cost to the United Kingdom. With luck, the British Government can now expect to reduce the cost of its involvement in ELDO by just less than a third, and this is no doubt significant. But it is still a fact that the commitment is open-ended. It is also as true now as it was a week ago that the present plans of ELDO cannot bring the economic and technological benefits which the original sponsors of the organization looked for. The launching rocket based on *Blue Streak* is inconveniently cumbersome for launching the kinds of scientific satellites with which European work in this field would best begin, and at the same time is inconveniently small for launching communications satellites. Fallen as it has between two stools, it is no wonder that ELDO has found it hard to decide why it exists. The best outcome of the crisis that there has been would be a coherent definition of a sensible long-term objective. It would have been better if the British Government had insisted on such a reappraisal, and not a redistribution of the financial burdens, as the price of its continued membership.

But what can Europe accomplish on its own? The most conspicuous error in the past few years has been the illusion that a research and development programme which is tiny by American and Russian standards, and intended to make use of a number of components designed for purposes now forgotten, should somehow enable Europe to attain a position of equality in space technology. Even if the first ELDO programmes had been outstandingly successful—and they have not been—it is not realistic to suppose that Europe would then have been able to embark on a comprehensive programme of satellite research, or to help substantially in the construction of an international system of communications by satellite. For a long time to come, the only attainable objective will be to lay the foundations in Europe of a technology already widely practised elsewhere.

GOOD ENOUGH FOR MOSES?

D-Days at Dayton

Reflections on the Scopes Trial. Edited by Jerry R. Tomkins. Pp. xii+173+8 plates. (Baton Rouge, Louisiana: Louisiana State University Press, 1965.) 5 dollars.

ANYONE attentive to theatre, cinema, or television in recent years knows that in 1925 a teacher named John Scopes was hauled into court for discussing evolution in a tax-supported school in Dayton, Tennessee. With the exception of Scopes himself, who played no part other than that of warm body, everyone involved sought public attention for a variety of motives. Two of the most flamboyant characters in a country that never lacks such seized the opportunity. The summer of 1925 was hot and dull, and it produced no important news. The desire for publicity was requited in excess. The two characters, William Jennings Bryan and Clarence Darrow, staged a debate marked on both sides by inanity exceptional even in the long history of inane debates. The debate was stricken from the court record, but became the only reason why this trial is remembered. Three teachers produced affidavits favouring evolution, but their evidence was not admitted in court and was (of course) given to the newspapers instead. The decision of guilty, obviously mandatory and desired by all parties before the trial even started, was reversed on a technicality. Scopes was never retried. A test of the constitutionality of the anti-evolutionary law, the only rational reason for the procedure, was never made. The law is still on the books in Tennessee and also in the other southern states of Arkansas and Mississippi, but no other effort has ever been made to enforce it. Indeed, the Scopes trial involved no such effort, being instigated by non-Tennesseeans hoping to nullify the law and not by any State or local authorities hoping to enforce it.

D-Days at Dayton is intended to provide judgement on the effects of the trial after 40 years. It contains the contemporaneous accounts of an iconoclastic reporter, H. L. Mencken, and the contemporaneous affidavits of the three teachers of science, W. C. Curtis, K. F. Mather and F.-C. Cole. The main offering, however, is a series of eight newly written essays by two ministers, a theologian, three scientists, a scientific journalist, and a former director of the American Civil Liberties Union. Some of these were present at the trial, but none had an active part in it and for some the only connexion is that they remember hearing about the trial when they were children. There is also an essay by Scopes himself, and this is extraordinary. Scopes apparently had little interest in the trial at the time, has virtually none now, and is most nearly moved by his belief that Bryan, his rabble-rousing, anti-intellectual prosecutor, was "the greatest man produced in the United States since the days of Thomas Jefferson".

The not very clearly expressed thesis of the editor and some contributors seems to be that the Scopes trial has current relevance because it marked the opening of a largely successful attack on anti-evolutionism in the United States. As one contributor (Carlyle Marney, a Southern Baptist minister and evidently a unique one) does point out, the thesis is flatly wrong on both counts: the battle against anti-evolutionary fundamentalism began long before 1925 and was far from won in 1965. The strongest argument is that Tennessee was so ridiculed that no other States dared be so foolish. But all the evidence suggests that Tennesseeans were delighted by the publicity and unconscious of the ridicule. And in fact to-day the teaching of evolution is prevented in an enormous number of school districts (locally almost autonomous in the United States) by devices much more effective than unenforced State laws.

This somewhat interesting but unconvincing and patchwork volume does nothing to alter the feeling that the Scopes trial was a farce and that its only present importance

is that it inspired a more successful and more frank farce, the play *Inherit the Wind*. A serious enquiry into present-day anti-evolutionism, not attempted by this book, is urgently needed. GEORGE GAYLORD SIMPSON

IN DEFENCE OF PERSONAL KNOWLEDGE

The Knower and the Known

By Marjorie Grene. Pp. 283. (London: Faber and Faber, Ltd., 1966.) 42*s*. net.

THE first thing to notice about *The Knower and the Known* is its dedication to Prof. Michael Polanyi; a direct pointer to an emphasis on personal knowledge, indeed an extension and defence of that outlook. Prof. Grene's contribution has come at an appropriate moment, and her analysis, coupled with a pleasant style, will repay careful study. There are three main sections: knowledge as conjecture; the structure of experience; and the complexity of things. At the end is a competent discussion of the late Sir Ronald Fisher's *Genetical Theory of Natural Selection*, which forms a separate appendix. If there is one quality which these pages rightly place on a pedestal, it is that of intellectual humility. Descartes believed that he had solved every problem which had confronted, or could confront, the human race, while the genius of Newton had produced the perfect picture of a mechanical cosmology. Yet, all this was to predict and, if need be, to falsify, but not to understand. Whitehead once remarked that it was the medievalists who walked by reason, whereas we walk by faith. Nevertheless, credulity will always seek to understand, and that is what personal commitment means, as contrasted with sheer objectivity. If we are to recover from dead things, then we have to reckon with the unspecifiable element in knowledge, which is never explicit. It is possible, naturally, to cogitate in terms of billiard balls, hard lumps of matter, and so forth, but this is not comprehension, which involves an element of passion, which lies at the root of all great discovery. Aristotle's taxonomy was magnificent, and his logic superb, yet devoid of commitment or revelation.

This throw-back to the Stagirite is no accident: Grene is at home with the philosophy of the Lyceum; one can almost hear the steps of the peripatetics in the background. An epistemology fitted for the study of the living there must be, if existence in an arid waste is to be avoided. This connotes a large measure of responsibility in research; discovery is not detached spectatorship.

Now the odd feature about all this—as everybody will realize who has worked in any branch of higher education during recent years—is that the present generation of students has sensed this very thing without any trained ratiocination or prompting. There is a widespread reluctance to enter the (purely) mathematical sciences; the urge is to do something more in keeping with the needs of the living. Hence the pressure on the biological and social sciences. That there is a lurking danger in this, nobody can deny. (Lord Rutherford is reported as having observed, on one occasion, to Sir Gowland Hopkins, "How delightfully easy it must be to be a biologist".) If there are many unable, or unwilling, to face a mathematical discipline, there are a few who are looking towards a new kind of differential equation, capable of dealing with systems of giant molecules. It remains to be seen whether this attitude will prove constructive or destructive: whatever happens cannot obliterate the quest for personal knowledge, but it may well shift the burden of appreciation from a direct aesthetic appeal to one of more abstract type. In which case, the battle for subjective entailment will begin all over again.

Prof. Grene, in her copious references, seems to have overlooked the particular approach of the late Dr. Agnes Arber in this very context of morphology. She demonstrates the influence of Spinoza as a turning-point in the exploration of form.

Perhaps this volume reaches its zenith in Chapters 8 and 9, where the discussion ranges over the multiplicity of forms, time and teleology. We are still bidden—almost coerced—'to understand', but the price of doing so is clearly revealed. In terms of psychology this is very close to the Gestalt-concept, the apprehension of the whole in terms of its parts, and not only so, but the explicit recognition that an aim is a function of the means taken to attain it. The transition from here to teleological processes is easy in principle; few ventures have generated greater heat than this in scientific argument. To the naturalist, ends, goals, and even purposive behaviour, stand out sharply against the strict 'yes–no' of classical thought. Nobody expressed the fundamentals of the situation better than the late E. S. Russell (*The Directiveness of Organic Activity*), though not in the exact idiom of the author of *Personal Knowledge*. Probably such tendencies in natural systems can be transferred to the creative arts, wherein theories of minimal energies can suggest, even if they cannot prove, the existence of an *extremum*, in which satisfaction is found for eye or ear. It was not for nothing (p. 204) that Kekulé dreamt of snakes chasing their tails, which is alleged to have been the basis of his discovery of the benzene ring. Quite recently, in Holland, a concept of this character has produced a number of patterns of surprising beauty, dependent on the crystallographic symmetry of close-packing.

All in all, there is little doubt that we are moving away from mechanics as a powerful element in methodology (never to be confused with logic) in brave attempts to create a new theory of knowledge which will abandon explicit knowing as unattainable in this life. Having made this sacrifice (if ever we do), a happier epistemology may arise on the embers of determinism in the seventeenth century sense. Volumes like the one now under review will help. It should appeal to a wide circle of readers, who would do well to keep it near at hand if any of them are directors of research. For no discovery has ever been made without zeal—zeal to believe that there is a problem to be solved, and joy of a passionate kind on reaching journey's end. Prof. Polanyi himself pleads for a strong measure of patience and forbearance with existing theories before they are deliberately overthrown. Savants are not professional iconoclasts, and reverence for tradition is at least an element in true scholarship.

On p. 252, Prof. Grene refers to the problem of pain, and considers that "it makes life wholly present, and therefore wholly meaningless". One may doubt whether this view, plausible as it sounds, represents much more than a superficial reaction. To judge from their writings, this was not the experience of the saints and mystics (experts in the pursuit of personal knowledge) who, far from being deprived by it of their transcendence, found in it their finest hour. F. I. G. RAWLINS

AN IMPERFECT ANALOGY

The Railroad and the Space Program

An Exploration in Historical Analogy. Edited by Bruce Mazlish. (Technology, Space and Society.) Pp. xix+223. (Cambridge, Mass., and London: The M.I.T. Press, 1965.) 7.50 dollars; 57*s*. net.

IN 1962 the U.S. National Aeronautics and Space Administration, wishing to find out more about the probable long-term effect of its space activities, made a modest grant for an academic study of the subject. A committee of the American Academy of Arts and Sciences decided that the study should take the form of a historical analogy with some previous enterprise, and Bruce Mazlish, the editor of this book, chose to direct attention towards the development of the American railroad. After

a long introduction, in which Dr. Mazlish himself discusses historical analogy, deftly but inconclusively, we are treated to seven separate surveys of United States railroad history. These reveal in convincing detail the economic, social and political effects of the railroad expansion, but tell us virtually nothing about the likely effects of the space programme. Each contributor dutifully mentions space exploration at the end of his chapter, but often only to say that any analogy is doubtful. In short, the question that NASA wished to see answered is never properly tackled at all: the authors are like a pack of industrious detectives who efficiently scour the ground while their quarry lurks in a tree above.

Although the book does not fulfil its declared aim, the studies of railroad history may be of interest to economists and historians. Stylistically, the book is often heavy with detail: there are, for example, tables giving United States steel production yearly from 1871 to 1890, the proportion devoted to railways, etc. But there are also illuminating insights. For example, R. W. Fogel challenges the conventional view that the improvements in transportation brought about by railroads were the key to American industrialization. He prefers to emphasize that the diversion of resources into railroad construction delayed the advent of motor transport by several decades. Is there a lesson here for the space explorers? It is difficult to tell, because the analogy between rail and space travel is so imperfect: both often leave behind a plume of steam, it is true, but rail travel merely improved transportation between known areas, while space exploration opens up new areas. This fundamental difference sabotages the book's few real attempts at pursuing the analogy. D. G. KING-HELE

HYDROLOGY—CLASSICAL AND MODERN

Modern Hydrology

By Raphael G. Kazmann. (Harper's Geoscience Series.) Pp. xiv+301. (New York: Harper and Row, 1965.) 79*s*.

THE inception of the International Hydrological Decade in 1965 and the water shortages of the same year have helped to stimulate an interest in one branch of the geosciences—hydrology. In his introduction to *Modern Hydrology*, the editor quite rightly states that an up-to-date, authoritative but readable work is needed by newly interested administrators, lawyers, legislators and planners as well as by academics and professional hydrologists. The comments that follow will help indicate whether the book under review fulfils the undoubted need.

The dust cover claims the book to be "a succinct but thorough discussion of the hydrologic cycle, the development of water resources, and the effects of this development on future projects". Its organization of the material is refreshingly simple; after an introductory chapter, the basic components of the hydrological cycle are examined in turn, the two concluding chapters being an account of water resources development, and final summation. Within the terms of reference given, the contents of the chapters on "Precipitation" (22 pages), "Evaporation" (14 pages), "Surface Water" (70 pages) and "Ground Water" (80 pages) are no more than adequate. One must deplore the absence of material in both text and illustrations from sources outside the United States in a work dealing with the principles, methodology and practical application of hydrology, and presumably aimed at a world-wide market. The meat of the book is contained in the chapters on "Water Resources Development" (38 pages) and "Summation and Outlook" (26 pages). The remarks of the author on the organization and financing of large-scale water development works are forthright and thought-provoking. They are directly applicable to the present British scene where belated enthusiasm for barrage schemes and large-scale redirection of river water must be tempered by the high costs of such projects.

The purport of the title is emphasized many times throughout the book. Prof. Kazmann's thesis is that the concept of 'classical hydrology' is dependent on the assumption that the data are 'clean', that is, the result of natural circumstances alone. Such conditions are becoming increasingly less common because the numerous side-effects resulting from man's activities exert a modifying influence on the hydrological data, which are the foundations of modern hydrology. He goes further; given a continuation of the process, the data would become so 'dirty' that it would be impossible to distinguish between natural hydrological events and those induced by man in the form of dams and diversions, surface- and groundwater abstraction, and sewage disposal. This point of view seems over-pessimistic. Man's activities have been complicating hydrological data for centuries past, and indeed only rarely can water development projects be undertaken without incurring some form of hydrological side-effect. One might go so far as to say that most data have been of the dirty variety since scientific hydrological measurement first began.

Prof. Kazmann has attempted to cover too wide a field in too little space, and at the same time has tried to satisfy too many diverse interests. His central theme is the effect of man's activities on the hydrological cycle, and the significance of modern versus classical hydrology. The book would have been improved had it been more specifically directed to those ends. While *Modern Hydrology* will make a stimulating and worth-while addition to library shelves as a work of reference, it is unlikely to supersede any of the accepted hydrological text-books.

G. P. JONES

SOIL BIOLOGY

Bodenbiologie

Von Georg Müller. Pp. 889. (Jena: Veb Gustav Fischer Verlag, 1965.) 153*s*. 5*d*.

BODENBIOLOGIE, which was intended to fill a gap in the German literature as well as to supplement the more general literature of soil science, has certainly achieved its purpose. The author is to be congratulated on covering the extensive field of soil biology so thoroughly. Soil biology is the newest and perhaps most important branch of the soil sciences; it is developing rapidly and any attempt to integrate the separate studies of soil bacteriology, mycology and zoology into a unified discipline must be welcomed.

Prof. Müller divides his book into five main sections: soil organisms; methods, considerations of numbers and occurrence of soil organisms with reference to site conditions; activities of soil organisms; and influence of cultivation practices on the life in the soil. In the first section the morphology, systematics, ecology and physiology of the soil microflora (bacteria, fungi, algae and lichens) are discussed in much detail followed by a similar treatment of the soil fauna (from protozoa to mammals).

The section on methods concentrates rather on procedures for counting and isolating organisms, but also deals with all the usual laboratory techniques for studying the organisms in culture and refers also to soil sampling and to statistics. The effects of a variety of soil factors and conditions on different organisms and their populations in soil are treated in the third section. The fourth large section is an account in detail of the biochemical activities of organisms with more emphasis on the microflora (of which more is known) than the fauna, and attention is paid to the part played by different organisms in mineralization, humification and weathering processes. An important fifth section describes the effects of various treatments such as irrigation, cultivation, fertilizing

plant protection and soil inoculation measures on the different kinds of soil organisms. Finally some reference is made to soil sickness. Literature references take up about eighty pages; there is a useful index and also a list of all the genera and species of organisms mentioned.

Although not the only recent book on this subject, this volume is probably the most comprehensive at present. The book is well produced and bound and not expensive in view of its size. Misprints and errors are very rare (Beijerinck, of course, was a Dutchman, not a Dane). The text is reasonably up to date and moreover contains a fair number of references to Russian and Eastern European work as may be expected of an East German book. That it is written in German may unfortunately limit its usefulness, but it can be recommended to all advanced students and research workers, biologists and non-biologists alike, in the field of soil science.

N. WALKER

STEROIDS IN THE POLARIMETER

Selected Constants

Optical Rotatory Power. 1*a*. Steroids. By J. Jacques, H. Kagan and G. Ourisson. Edited by S. Allard. (Tables of Constants and Numerical Data, 14. Associated Organization of the International Union of Pure and Applied Chemistry.) Pp. 1031. (London, Paris and New York: Pergamon Press, Ltd., 1965.) 258 F.

THE steroids form a closely-knit group of organic compounds which have been in the forefront of natural product chemistry for more than thirty years. The reasons for this lie in their biological and economic importance (particularly in the pharmaceutical industry), and in the peculiar appropriateness of their rigid structure for investigations of reaction mechanisms, and of many physical properties. Steroid chemists have been well provided with text-books, with forums for discussion, and with specialized collections of data and materials.

Among the most valuable of these collections has been the catalogue of optical rotations of steroids, published in 1956. *Selected Constants: Optical Rotatory Power* is the second edition of this collection of data on optical rotation, to which have been added the melting-points of most of the compounds listed. Optical rotations are important as criteria of purity and also as characteristic constants for structural and stereochemical problems.

Although expensive, this work is essential for all laboratories working in the steroid field—and highly desirable for other laboratories which are interested in the general relations between optical rotation and structure. The literature is covered up to 1961, structures being corrected up to 1964 where necessary. About twenty-one thousand compounds are listed, in contrast to eight thousand compounds in the previous edition.

The introduction, in both French and English, deals with the nomenclature of steroids. The compounds are catalogued under their molecular formulae with full references (6,300 in all); the book includes extremely thorough indexes to authors and substances.

References to the important new technique of optical rotatory dispersion are given briefly. These items and data on circular dichroism will need to be dealt with more fully in the next edition.

Since optical rotation values are measured for nearly all new steroids, this book really constitutes a one-volume catalogue of steroids; it is therefore the easiest place in which to begin a literature search. The French authors are to be congratulated sincerely on carrying forward the good work of the first edition with their prolonged and meticulous labours.

The book is so valuable, and the method of indexing so simple, that the authors and editor might well ask all colleagues working in the steroid field to assist in the preparation of future editions in the following way. Authors of original papers could readily provide details of new compounds on a standard form, which would present the data on optical rotation ready for the preparation of a third edition or of a supplement. It would be the work of a few minutes to provide the data for each compound in this way, and we should all know that in doing this we were speeding up (and perhaps making a little cheaper) the next edition of this invaluable index and reference book.

W. KLYNE

VARIATION AND GENETICS OF BACTERIA

Bacterial Genetics

By Werner Braun. Second edition. Pp. xiii+380. (Philadelphia and London: W. B. Saunders Company, 1965.) 70*s*.

THE first edition of *Bacterial Genetics* was published in 1953 when text-books in this field were almost non-existent. To-day, however, the reader is confronted with a choice of good texts each covering much the same material. It is against this background that Prof. Braun's revised book has to be evaluated. Both editions of *Bacterial Genetics* have had as an explicit aim the presentation of ". . . the more important findings and principles of bacterial genetics to those primarily trained, or being trained, in bacteriology . . . ". Much of bacterial genetics is complex and too frequently communicated in a confusing manner. Furthermore, data tend to be submerged in a bewildering jargon with the result that the subject becomes largely unintelligible to the non-specialist. Prof. Braun is to be congratulated on making his book clear and palatable to those not primarily trained in genetics and in attempting to relate genetic discoveries to other aspects of bacteriology such as pathology and physiology.

The recent progress of bacterial genetics has been enormous and this second edition of *Bacterial Genetics* is, in large measure, a new book although the layout of the first edition is retained. Part 1 is devoted to introductory considerations, cytology and certain molecular features including mutation and mutagenesis. Part 3 deals with genetic transfer systems and "gene action" and its regulation. The middle section discusses "Representative Mutant Types" and "Population Changes" and, although the approach here is necessarily itinerative, the material is offered interestingly and will make particularly apposite reading for the bacteriologist. Several features of this book appealed to me, notably the careful definition of terms, the cross-referencing within the text, the inclusion of technical details and the insistent distinction made between working hypotheses and established facts. The book is comprehensive but several topics have received but brief consideration. Thus, although the reader is directed to other sources for additional details, this brevity can be misleading; for example, the statement that the life-time of messenger RNA is only a few minutes requires qualification. Also unsatisfactory is the abrupt termination of the book; we are suddenly halted during a discussion of feedback inhibition and allosterism. A more satisfying conclusion might have pursued the theme of regulatory mechanisms and cellular differentiation. Occasionally terms are used rather inconsistently (for example, nucleus and nucleoid), quoted data are at variance (for example, proportion of RNA that is ribosomal) and cited references incorrect. Little mathematical treatment is included. However, these are minor criticisms of an otherwise admirable book. Prof. Braun has accomplished his stated aims and his book deserves to be read by both geneticists and bacteriologists. *Bacterial Genetics* will be especially useful to those bacteriologists and other microbiologists who are not aware of the immense impact and relevance of genetics in their own fields.

ALAN T. BULL

Joseph Priestley

Adventurer in Science and Champion of Truth. By F. W. Gibbs. (British Men of Science.) Pp. xii + 258 + 20 plates. (London and Edinburgh: Thomas Nelson and Sons, Ltd., 1965.) 42*s*. net.

JOSEPH PRIESTLEY is a scholarly and readable account of this remarkable Englishman, the dissenting minister and teacher whose experimental discoveries immediately speeded up the progress of science, but whose advanced political views were widely accepted only a generation after his death.

Priestley did not contribute to science until 1765, when at thirty-two he began to compile his history of electricity. He soon turned to chemistry and started to work on gases in the winter of 1767–68, five years before the publication of his first great paper on "Different Kinds of Air". The important chemical work of the 1770's and early 1780's is well described by Dr. Gibbs, who clearly shows how Priestley was repeatedly forced to grapple with unfamiliar and difficult problems arising from his discovery and examination of a dozen new gases. Priestley quickly contrived methods for saturating mineral waters with carbon dioxide, and for generating hydrogen on a large scale in order to fill balloons.

Not only was he a great chemist but Priestley was also an accomplished linguist and biblical scholar. The book throws new light on his persecution for supporting the French revolution and his subsequent exile in America.

Dr. Gibbs has not only given an account of Priestley's life and work based on a very thorough study of printed and manuscript sources, but he has also described the political, religious, social and scientific background in both England and America. The many illustrations, including a number of political cartoons of the period, add to the value of a book which supersedes the earlier biographies of Priestley and can be recommended to all scientists interested in their intellectual ancestor.

W. A. SMEATON

The Evolution of the Nuclear Atom

By G. K. T. Conn and H. D. Turner. Pp. 266 + 13 plates. (London: Iliffe Books, Ltd.; New York: American Elsevier Publishing Company, Inc., 1965.) 55*s*. net.

THIS is the first of four volumes attempting to show the development of modern ideas on molecular, atomic and nuclear structure. It ranges from Faraday's first studies on electrical discharges in gases up to the Rutherford–Bohr theory of 1913–14. About 90–95 per cent of the material consists of original papers or excerpts from original papers by the principal figures of the time. Most of the quoted passages are from the decisive work of such people as Crookes, Thomson, Rydberg, Geiger, Marsden, Rutherford, Moseley, Chadwick and Bohr, but there are also a number of excerpts on some of the less successful ideas, such as Hertz's view that the cathode rays were a form of radiation, and there is a chapter on the more abortive theories of atomic structure proposed by Jeans, Thomson, Nagaoka, Rayleigh and Schott. These various passages are linked by a sketchy narrative in which the authors have made little attempt at commentary. Their intention has been to let the original authors speak for themselves.

The stated aim of the book is to "provide a stimulus to young research workers", but it is difficult to imagine this being its effect. Young research workers are not likely to read it. It cannot be denied that the momentous papers of Thomson, Rutherford, Bohr and the others make powerful reading even half a century later, yet their collective effect in this presentation is just not inspiring. This sort of material requires much more in the way of historiography to make it interesting.

W. M. CURRIE

Atomic Handbook

Vol. 1: Europe. Edited by John W. Shortall. Pp. xvi + 845. (London: Morgan Brothers (Publishers), Ltd., 1965.) 140*s*.; 20 dollars.

THIS publication represents the fruitful result of several years discussion both within and without the Nuclear Public Relations Contact Group. Information on what is going on in atomic physics is invariably the most difficult to obtain, and Mr. Shortall, as editor, and Morgan Brothers (Publishers), Ltd., have done signal service in providing all concerned with atomic physics with *Atomic Handbook Volume 1: Europe*.

The directory has been designed to give answer to who is doing what and where in atomic energy. It is claimed that it has been written "to serve as a management tool to locate collaborators, follow trends, prevent waste of resources and to facilitate interchange and contact". Essentially, then, it is a guide to people and their work. It provides an invaluable source of names, positions, addresses and telephone numbers of key people concerned with the day-to-day business of atomic energy. This first volume includes details of some 4,000 people in twenty-six countries, eighteen international organizations and almost a thousand industrial firms.

It is pleasing to note that the *Atomic Handbook* will be revised at least every 2 years and also that it is intended shortly to produce successive volumes covering other areas of the world. We all wish the enterprise well, and humbly thank all concerned for taking on the herculean task of making European atomic physics accessible.

Plant and Machinery for the Separation of Air by Low Temperature Methods

Design Atlas. By I. P. Usyukin, I. G. Aver'yanov, S. Gorokhov, A. M. Gorshkov, A. V. Zakharov and N. K. Yelukhin. Edited by I. P. Usyukin. Translated by S. S. Akerib and A. D. Norris. Translation edited by M. Ruhemann. Pp. viii + 185 + 164 plates. (London and New York: Pergamon Press, 1965.) 250*s*. net.

IN this *Design Atlas*, 171 of the 185 pages (each 18·5 × 12·5 in. in size) are devoted to flow diagrams of air separation plants, plant layouts or detailed drawings of equipment for use in such plants. Although mainly concerned with designs of Russian plants and equipment, some information about plants designed in western Europe and the United States is included.

The *Atlas* is attractively produced and the drawings are clearly presented. The publishers have ensured the technical accuracy of the work by securing the services of Dr. M. Ruhemann as editor. While the price seems high it is understandably so in view of the work involved in preparation and reproduction.

The foreword to the Russian edition says that the *Atlas* is designed as a text-book for higher technical institutions and will also be used by staff working in establishments which use low-temperature air separation plants. While this may be true in Russia, one doubts whether either of these groups will find the book useful in western countries. To start with, while in Russia air separation experts are trained as such at undergraduate level, in the West we tend to train men in broader fields and let them specialize later. Furthermore, any leading cryogenic engineering company tends to tailor its plants to suit customer requirements and to incorporate new ideas and items of equipment as they mature. Since this is probably also true of the Russian Oxygen Design Bureau, it is unlikely that the *Atlas* contains the very latest Russian designs. Certainly the non-Russian designs given are far from being "the most important now existing" as claimed in the foreword; they are inevitably far from comprehensive or up to date.

The cost of producing a gas from the atmosphere is dependent almost entirely on power consumption and capital outlay. Frequently the potential customer has to

balance a higher power cost against lower capital outlay. The *Atlas*, which quotes power consumptions but makes no reference to initial plant cost, does not help him in this respect.

Established experts in the design of air separation plants will find the Russian designs of considerable interest, despite the absence of information as to the reasons for the selection of particular cycles, techniques or items of equipment. They may well conclude that there is little to choose between the states of knowledge in this field in Russia and in other countries. N. BOOTH

Luminescence

l'Électron et la Lumière Matière et Photoluminescence. Par G. Monod-Herzen. Pp. viii+278. (Paris: Dunod, 1965.) 39 francs.

THIS volume is divided into two distinct sections. The first deals with the relationship between electromagnetic radiation and the electron, and the second with the general phenomena of photo-luminescence.

In the first section, a chapter is devoted to a description of the electron and its properties while at rest, while moving with linear velocity and while being accelerated. A second chapter deals with the emission of radiation as a result of electron impact on matter, distinguishing between phenomena resulting from primary and secondary processes. Here weight is given to the emission of X-radiations. This naturally leads on to a discussion of the behaviour of electrons in atoms and a brief survey of atomic spectroscopy. This section is brought to a close by a short, but comprehensive, reminder of the main features of molecular spectroscopy.

The second section of the book, which is the larger one, commences with a chapter which explains simply the processes which lead to luminescence and phosphorescence. A brief mention is made of excitation leading to ionization and incandescence.

The remainder of this section deals with luminescence phenomena exhibited by atoms and by molecules in the gas, liquid, glassy and crystalline phases. There is some mention of experimental methods for studying these phenomena but the principal emphasis is on the descriptive understanding of the underlying mechanisms. There is a particularly good account of luminescence in the crystalline phase, and the effect of impurities and imperfections.

This volume can be recommended as a good readable work, splendidly illustrated with well-chosen diagrams and with the necessary mathematical treatments, which have been kept to a minimum. There are very few references so that the book, while a very good introduction to the field, would not be appropriate to the advanced reader who wished to follow up specific points in more detail.

J. C. ROBB

Vision in Vertebrates

By Katharine Tansley. Pp. vii+132+16 plates. (London: Science Paperbacks and Chapman and Hall, Ltd., 1965.) 12*s*. 6*d*. net.

SO many books on vision have been published recently that the need for a further one may be questioned. This small book on *Vision in Vertebrates* fills a gap left by other authors who have concentrated on the vision of the human being, although paradoxically much of our knowledge about the physiology of human vision has been derived from investigations on other vertebrates.

Many interesting contrasts and comparisons of anatomical features between a wide variety of vertebrate eyes are given, along with a full list of sources. Sufficient description of the function of each part of the eye is given to enable the non-specialized reader to understand the possible significances of these anatomical differences. Some excellent photomicrographs are included to illustrate the histological structure, although detailed labelling of the structures would help the reader unfamiliar with microscopic sections.

In a work of this nature it is almost inevitable that teleological arguments will be used to reason from structural differences to function. While this approach does help to add interest and coherence to the assembly of species differences, it may lead in many cases to misleading and improbable conclusions. For example, it is a well-established principle of physical optics that the maximum resolving power of an optical system is determined only by the absolute size of the pupil and not by the focal length of the eye.

This lucid book provides a useful and stimulating introduction to the startling variations of adaptation which the vertebrate eye has undergone in order to match each animal to its visual environment. F. W. CAMPBELL

Recent Progress in Hormone Research

Edited by Gregory Pincus. (Proceedings of the 1964 Laurentian Hormone Conference.) Pp. viii+679. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 192*s*.

THIS is the most recent volume of an annual publication which has come to play an important part in the literature of endocrinology. The value of the series lies in fulfilment of two major functions. First, it contains texts of the papers delivered at the Laurentian Hormone Conference by international authorities invited to review recent progress and present-day thinking in their particular fields. Secondly, discussions at the conference are edited and presented in detail, complete with references. These often bring new ideas introduced in the papers into interesting perspective, and sometimes include explanations of difficulties concerning those ideas which colleagues have found puzzling. In some cases such presentation may one day prove invaluable to the historian.

The topics on which papers were invited at this conference, held in September 1964, were: (1) recent advances in thyroid chemistry and physiology; (2) hormones in normal and pathological physiology; (3) pituitary hormones; (4) steroid sex hormones; (5) comparative endocrinology; and (6) neurohumors.

The standard set by papers at these conferences is high, and it is somewhat invidious to select any for special mention; but among those in this volume are several which were found particularly memorable, either on account of exceptional lucidity of presentation or because of the thought-stimulating nature of their subject-matter. W. S. Peart reviews the functions of renin and angiotensin, and although a later review by this author has since appeared, this paper contains material not duplicated elsewhere and was followed by a valuable discussion of the interaction of the renal hormone system with aldosterone secretion and sodium balance in man. C. Gemzell gives an account of his experience with the use of human gonadotrophins to induce ovulation, and K. J. Ryan and O. W. Smith discuss the biogenesis of steroid hormones in the human ovary. J. J. Christian, J. A. Lloyd and D. E. Davis review experimental work, and observations on animals in the wild, concerning the role of endocrines in the self-regulation of mammalian populations. This has fascinating implications in the field of human social history and seems certain to provoke a great deal of further work. J. Axelrod reviews the metabolism, storage and release of catecholamines, and finally E. W. Sutherland, I. Øye and R. W. Butcher discuss the role of cyclic adenosine monophosphate as a secondary hormone 'messenger' in the action of adrenaline, suggesting that it may also be involved in the action of other hormones.

These and the many other worth-while papers included (a total of fourteen) make the volume, which is handsomely produced, worth its price to almost any biological library. It is a pity that it will probably prove too expensive for most private buyers. J. A. PARSONS

EVOLUTION OF PRIMATE SOCIETIES

By DR. J. H. CROOK and J. S. GARTLAN
Department of Psychology, University of Bristol

RESEARCH on primate behaviour has tended to concentrate on similarities rather than differences between taxa, thereby allowing authors to make generalizations concerning the evolution of primate and human societies based on the characteristics of single species[1]. Recent developments in field investigation[2], however, now provide a range of information clearly demonstrating the contrasts that exist even between species the behaviour and ecology of which appeared superficially alike previously. The number of species sampled remains small but enough is known to permit a preliminary examination of the range of social systems uncovered and their functional significance in the habitats concerned. Analysis of function provides some understanding of the selection pressures responsible for adaptive change in social structure, and, given information regarding relevant ecological change in past time, allows the construction of evolutionary hypotheses.

The present approach is based first on the ethological and ecological results of recent field investigations[3]; secondly, on a methodology of evolutionary analysis of social systems used in recent ornithological work[4,5]; and, thirdly, on recent research in the palaeoecology and palaeontology of African primates[6]. Our purpose is to direct attention to patterns of relationships inherent in the data now available and to begin the task of ordering it. The hypothesis put forward gains strength from two aspects not treated here, namely cases of parallel adaptive radiation among African, Malagasy and Asian primates and intra-specific adaptations to local differences within habitats of single species. Detailed field investigations will, in due course, test the ideas suggested.

Grades of Social Organization

Ornithological investigations have shown that patterns of social organization determining population dispersion are intimately linked to species ecology—the whole interrelationship of behavioural features being co-adapted to certain aspects of the environment forming major selection pressures. In Table 1 we attempt to allocate species recently investigated to a series of 'Grades'[7] representing 'levels' of adaptation in forest, tree savannah, grassland and arid environments respectively. Anatomical investigations of fossil and living material reveal a progressive adaptive radiation from forest-dwelling insectivorous primates to larger open country animals predominantly vegetarian. It is not surprising, therefore, to find correlated trends in the behavioural data[8]. Table 1 reveals a shift from insectivorous, nocturnal forest animals with markedly solitary habits and a population dispersion based on aggressive contacts through a range of fruit- or leaf-eating forms (diurnal; very small family groups or larger parties showing defensive behaviour of a variety of types in 'territorial' encounters with neighbours but, otherwise, little intra-group aggression, sexuality or inter-male competition) to vegetarian browsers of open country normally living in well-structured troops or herds, usually in home ranges and showing much sexuality (often seasonal) and inter-male competition.

The aboreal grades contain several species while fewer are allocated to those of open country. In Table 1 this reflects a large species contingent from Petter's investigations on the lemurs[9]; however, in general, the numbers of forest species do exceed those of open country forms. This is because of the availability of numerous niches in forest where primate populations have specialized in terms of diet, vertical zonation, daily rhythms, etc. The limited ranges of the population units and their confinement to forests means that geographical barriers impose a more extensive speciation than in open country where species show great adaptability in exploiting a considerable range of habitats.

In common with their insectivorous ancestors, the co-adaptations of Grade I primates are clearly related to their nocturnal insect-hunting habits. Two leaf-eating-

Table 1. ADAPTIVE GRADES OF PRIMATES (SEE TEXT)

Species, ecological and behavioural characteristics	Grade I	Grade II	Grade III	Grade IV	Grade V
Species	*Microcebus* sp. *Chierogaleus* sp. *Phaner* sp. *Daubentonia* sp. *Lepilemur* *Galago* *Aotus trivirgatus*	*Hapelemur griseus* *Indri* *Propithecus* sp. *Avahi* *Lemur* sp. *Callicebus moloch* *Hylobates* sp.	*Lemur macaca* *Alouatta palliata* *Saimiri sciureus* *Colobus* sp. *Cercopithecus ascanius* *Gorilla*	*Macaca mulatta*, etc. *Presbytis entellus* *Cercopithecus aethiops* *Papio cynocephalus* *Pan satyrus*	*Erythrocebus patas* *Papio hamadryas* *Theropithecus gelada*
Habitat	Forest	Forest	Forest–Forest fringe	Forest fringe, tree savannah	Grassland or arid savannah
Diet	Mostly insects	Fruit or leaves	Fruit or fruit and leaves. Stems, etc.	Vegetarian-omnivore Occasionally carnivorous in *Papio* and *Pan*	Vegetarian-omnivore *P. hamadryas* occasionally also carnivorous
Diurnal activity	Nocturnal	Crepuscular or diurnal	Diurnal	Diurnal	Diurnal
Size of groups	Usually solitary	Very small groups	Small to occasionally large parties	Medium to large groups. *Pan* groups inconstant in size	Medium to large groups, variable size in *T. gelada* and probably *P. hamadryas*
Reproductive units	Pairs where known	Small family parties based on single male	Multi-male groups	Multi-male groups	One-male groups
Male motility between groups	—	Probably slight	Yes—where known	Yes in *M. fuscata* and *C. aethiops*, otherwise not observed	Not observed
Sex dimorphism and social role differentiation	Slight	Slight	Slight—Size and behavioural dimorphism marked in *Gorilla*. Colour contrasts in *Lemur*	Marked dimorphism and role differentiation in *Papio* and *Macaca*	Marked dimorphism. Social role differentiation
Population dispersion	Limited information suggests territories	Territories with display, marking, etc.	Territories known in *Alouatta*, *Lemur*. Home ranges in *Gorilla* with some group avoidance probable	Territories with display in *C. aethiops*. Home ranges with avoidance or group combat in others. Extensive group mixing in *Pan*	Home ranges in *E. patas*, *P. hamadryas* and *T. gelada* show much congregation in feeding and sleeping. *T. gelada* in poor feeding conditions shows group dispersal

forms are exceptions requiring further explanation. The switch to frugivorous or leaf-eating habits in Grades II and III is linked with diurnal activity and the formation of larger social groups. As with many birds, this development is linked to the change from a diet requiring individual hunting to food sources often locally distributed and at which social responses allow congregation for exploitation in common. 'Family bands' of very small size and larger multi-male social units in forest are often markedly 'territorial', in that defensive behaviour involving displays and/or marking in relation to neighbouring groups is shown. While the behaviour may defend a discrete area, this has not often been demonstrated; nevertheless, it does ensure an over-dispersion of population units.

The small size of social units in many forest frugivores is probably related to limiting conditions of food supply occasioned by the relatively stable conditions of tropical rain forest. A non-seasonal climate with a moderately constant availability of various fruits presumably allows increase in numbers to a ceiling imposed by periodic food shortages due to local food crop failures. In this situation the addition of young to the population may be difficult—recruitment necessarily balancing mortality. Breeding appears to be non-seasonal and this may explain the low frequency of copulations observed in some of these species[10,11]. The 'territorial' behaviour of forest groups may be interpreted as ensuring an adequate provisioning area for the individuals comprising them. It remains difficult, however, to apply this argument to all leaf-eaters.

In the dry forest, savannah and steppe conditions of Grades IV and V marked climatic seasonality with a harsh period of aridity, and food shortage probably imposes high seasonal mortality rates especially on old or infirm animals. In the rainy season, food for the remainder is superabundant and vigorous seasonal breeding[12] can replenish the population without risks of failures from food shortage in rearing young. It is as yet unclear whether the timing of the breeding seasons confers advantages during pregnancy, lactation or in terms of food supply for young animals; however, in principle, the effects with regard to survival may be the same.

Outside the forest the social units are generally larger and this appears to result from open country conditions of predation and food supply affecting ground dwelling populations. Savannah primates face a number of predators and scattering undoubtedly decreases the chances of individual survival. Groups of *Papio* baboons and *Rhesus* monkeys show a marked cohesion permitted ecologically by local food abundance allowing congregation without risk of over-exploitation.

One of the effects of increased group size in open country terrestrial primates is marked competition between males for females and the consequent intra-sexual selection of male characteristics. The open nature of the terrain allows every troop member to be aware of its companion's activities, and the cohesion of most troops makes this doubly sure. The seasonality of mating activities further means that many males are particularly active sexually at the same time, when, in the absence of structural equilibration in the troop, fierce competition and fighting would result. Again some Japanese observations[13] suggest that with increased numbers the socionomic sex ratio of *Macaca fuscata* troops increases so that there are fewer females to be shared among the males. This, they observe, may be a factor occasioning the splitting off of small groups from a troop and the exclusion of 'all male' parties. Finally there is a possibility that female 'open-country' primates may be sexually attractive for longer periods per oestrus cycle than is the case for forest animals[14]. All these factors enhance intra-sexual selection producing sexual dimorphism in size, appearance, and also in behaviour. The marked aggressiveness of male baboons and rhesus monkeys results in differential access to females, and is correlated with the promiscuous behaviour of oestrus females prior to their mating exclusively with the troop despot at about the time of greatest receptivity.

The increased size and aggressive nature of these males are considered to have been pre-adaptive to their role in troop defence. Males disperse around the periphery of moving troops and co-operate against common danger (see, for example, refs. 15 and 16). We do not think size and aggressiveness originated directly as a response to predation (compare with refs. 17 and 18), but the organization of the troop and male co-operative tendencies in defence undoubtedly did so.

Within Grade IV we have included not only typical forest fringe and savannah woodland species such as *Papio cynocephalus* and *Macaca* sp. but also a number of forest forms, which, in secondary habitats provided by human destruction of woodlands, show social organization in some degree similar to these. Characteristic of all the members of this Grade is a marked adaptability revealed in investigations of the species in contrasting habitats. The *Cercopithecus aethiops* population on the rich but small Lolui Island has 'territorial' behaviour not apparent in unlimited but impoverished conditions where the animals have much larger home ranges[19]. Similar, though often less investigated, accounts are available for the langur (*Presbytis entellus*), chimpanzee and baboon. These variations in social systems appear owing to the plasticity of intra-group relations possible in these forms—a plasticity of undoubted survival value in forest-fringe environments.

Grade IV systems seem therefore to be the result of (i) open country conditions of food supply and predation favouring increase in group size, and (ii) intra-sex selection increasing size and aggressiveness of males, thereby producing (iii) marked group structuring and, in some forms, the protective functions of males acting in unison against predators. Changes from Grade IV to Grade V are related to the occupation of habitats in which food supplies are less abundant, and, at least seasonally, more sparsely and infrequently distributed in the environment. In such areas it would be advantageous for groups of Grade IV animals to fragment into smaller, more widely ranging parties to avoid local over-exploitation of food. Indeed there is evidence from *Papio cynocephalus* populations in arid African areas and from *Macaca fuscata* in northern Japan that group size decreases at the limit of the species geographical range. This is probably in part the result of a low population density, their group organization remaining typical of Grade IV. Small groups of this kind are, however, not very efficient population units. The presence of several large males, only functional in mating and playing no part in rearing young, results in the consumption of much food not used in maintaining the species. Furthermore, the role of the male in protection is less efficient in small groups. In these habitats the 'one-male groups'[20] of *Papio hamadryas*, *Erythrocebus patas* and *Theropithecus gelada* are more adaptive in that less food per reproductive unit goes to individuals not involved in rearing young. The exclusive possession of a 'harem' probably increases inter-male competition for females still further and the occurrence of 'all male' population units indicates a considerable degree of exclusion of potential reproductives from breeding. The intense intra-sexual selection is again doubtless the main factor increasing the dramatic appearance of *P. hamadryas* and *T. gelada* males through the growth of large capes on the backs of these animals[21]—an apparent increase in size not requiring much utilization of energy for its maintenance and providing the animals with a distinctly ferocious appearance enhanced by demeanour and facial expressions.

The differently co-adapted characteristics of the three Group V species suggest clearly the interaction of selection pressures from food shortage, predation and habitat

topography in slightly different environments. Thus *T. gelada* in the Ethiopian mountains forms herds in good feeding conditions that split into separately foraging harem groups as conditions deteriorate[16]. Sleeping sites on ever-present cliffs are super-abundant. *P. hamadryas*, although forming 'one-male groups', apparently shows less dispersal because of the limited number of sleeping sites available (rock cliffs, outcrops, etc.) in the single area so far investigated in detail[20]. The patas monkey of open savannah grasslands never forms herds, individual 'one-male groups' keeping apart[22]. There are no rocky sleeping sites and plenty of predators. At night the animals disperse into separate trees and re-assemble in the morning. The male does not adopt the aggressive defence tactics of *Papio* and *Theropithecus;* rather he plays the part of watchdog, showing alert and diversionary behaviour in relation to predators. He does not exert dominance over the group in the same way as the other two species.

The behavioural features of the Grade V species are thus maintained by three main environmental selection pressures the characteristics and range of lability of which are relatively constant within the three habitats. They contrast markedly with the differing values of these same pressures, maintaining the Grade IV organizations in a richer habitat. Signal flow diagrams relating the environmental input of information and the adaptive response of the population in terms of numerical size, population dispersion and social structure are prepared for each of these types. A generalized diagram to which the characteristics of any one of these systems may be fitted is shown in Fig. 1.

The Great Apes and Man

Clearly in Table 1 the Pongidae do not fit easily into categories imposed primarily by investigations of cercopithecid primates. Nevertheless, *Hylobates*, in spite of its adoption of brachiation, has much in common with other tree-top frugivores. Similarities between *Gorilla* and *Pan* to other animals in their Grades are much less clear—a function in part doubtless of their pongid status. Reynolds[23] has clarified the adaptive significance of contrasts in social systems between these two genera.

The development by *Pan* of a simple tool-using culture[24,25] suggests a social condition close to that of early hominids, but we do not accept the suggestion[26] that this necessarily implies a regression from a more human condition. Palaeontological investigations suggest a radiation of early hominids from dryopithecine stocks in circumstances similar to those controlling the transitions from Grade IV to V in the cercopithecids. While *Ramapithicus* and *Paranthropus* were herbivores[27], *Australopithecus* shows evidence from dentition of a more omnivorous food habit including meat eating. Early hominids faced with seasonal food shortage in savannahs probably had initially a social organization not unlike that of the chimpanzee and perhaps formed later either groups guarded by weapon-bearing males or moved in one-male family units—the males playing a part of guardian and watchdog. Possession of weapons would have substituted for gross sexual dimorphism in size. The creatures doubtless retained the ability to congregate in conditions of plenty and in sparsely distributed rocks or tree shelters. These would soon have become bases for hunting raids. Shortage of vegetable food would have accelerated the adoption of weapons for killing animal prey while the trend towards bipedalism, already providing speed in escape from danger, allowed the use of arms in wielding weapons and speed in the chase. The fact that with *Pan* 'all-male groups' occur suggests a source for the loyalty and co-operation necessary in the development of group hunting expeditions. Certainly the biomass of animals suitable for hunting was abundantly present in the grassland savannah of Pleistocene Africa[28], but probably only in *Australopithecus* did an increased reliance on meat lead to major changes in social structure[29].

Sexual Selection

The form of a primate social system is a function not only of selection pressures of the environment. As we have seen, sexual selection, especially in terrestrial societies, plays an important part. Wickler[30] has recently stressed this factor as an ultimate determinant of morphological signals functional in the sexual and agonistic behaviour of certain primates. It would seem that the structures concerned have been derived from skin colour changes occurring in certain phases of the oestrus cycle and for which no signal function is known[31]. Wickler suggests that the coloured buttocks normally present in certain species function in protecting the less dominant males from the despots during quarrels in the troops. Weaker or junior males 'present' to larger animals thereby stimulating a mounting gesture rather than aggression. He considers this to be a case of 'intra-specific mimicry', the male

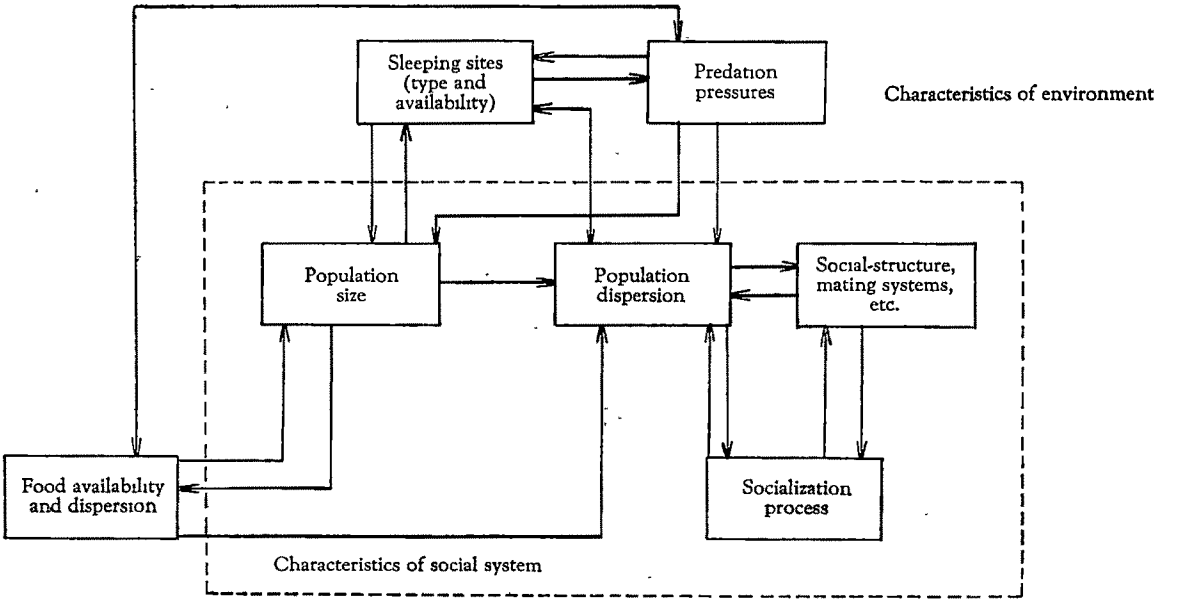

Fig. 1. Diagram showing the role of habitat factors maintaining a specific social system through time in a given environment

buttocks being copies of the feminine original. Again the curiously shaped patch of bare skin on the chest of *Theropithecus gelada* in both sexes, which undergoes cyclical changes including peripheral vesicle formation in the female[32], has a resemblance in pattern and colour to the perineal skin of the female at oestrus. Wickler considers the chest patches to be substitutes for signals given posteriorly in presentation for mating and he implies, though he does not state, that the chest patches of the males function in a similar way as the coloured buttocks of other male baboons.

Recent investigations (by J. H. C.) in Ethiopia have shown that males do indeed examine the chests of females in oestrus prior to certain copulations, probably those occurring early in an oestrus cycle. Quantitative data show, however, that the colour changes on chest and ischial areas are not in phase. Lactating mothers and non-oestrus females have the reddest behinds. It seems odd that if the red chest colour is attractive to males the perineal areas should be most red at precisely the time when mating would be inappropriate. Long nipples in the mid-line of the chest, assumed by Wickler to be signal imitations of the vulva, appear to arise in the course of suckling. Preparous females have small nipples spaced apart, but, when in oestrus, are nevertheless frequently mated. The role of nipple shape and position in sexual signalling prior to copulation is thus in doubt.

The gelada spends a considerably greater time sitting down than does *Papio doguera* in the same area. A chest signal as an indicator of female sexual condition would therefore be more appropriate than an ischial one. It does not appear essential, however, for the signal to be an exact copy of the ischial design—and indeed we find that it is not. In view of the baby and juvenile geladas' prolonged interest in the nipples—with which they play as well as from which they obtain nourishment—adult concern with this area is readily understandable and any colour changes are likely to develop a significance. The extent to which chest patches really copy the behind remains largely subjective. There is no evidence that the chest patch of the male gelada functions in a manner analogous to Wickler's suggestions for the buttocks in males of other species.

Wickler's hypothesis deserves critical scrutiny as it could have considerable significance in the investigation of human sexual aesthetics. The shape of the human mammary glands is not apparently 'essential' for it is not found in the great apes. Possibly they have acquired their function as a sexual releaser in a manner analogous to the evolutionary process suggested for the female gelada's chest. The development could have arisen in co-adaptation with the adoption of the upright bipedal stance in the early Hominidae and the use of the frontal position in mating. However, it is not so much the shape of the human breasts that is the critical sexual releaser as the visual stimulus provided by the nipple and the areolar zone around it[33]. While "intraspecific mimicry" might account for the shape of these organs it seems that normal Darwinian sexual selection (that is, inter-sexual selection) could account for the enhancement of structural features around the nipples. Further research into the significance and evolution of such signals in both non-human primates and man will be of considerable interest.

DRUG ADDICTION* IN BRITAIN NOW

By Prof. D. R. LAURENCE

Department of Pharmacology, University College,
and Medical Unit, University College Hospital Medical School, London

An Interdepartmental Committee on Drug Addiction was set up in 1958 by the Minister of Health and the Secretary of State for Scotland to review the advice on morphine and heroin addiction† that had been given to the Ministers in 1926 and to consider whether any further steps should be taken.

In its report, published in 1961[1], the Committee concluded that addiction should be regarded as an expression of mental disorder and not as criminal behaviour, that satisfactory treatment demanded suitable institutions, but that, as the problem was small, the establishment of specialized institutions was not practicable. It also concluded that a system of registration of addicts would be neither desirable nor helpful as "the incidence of addiction to dangerous drugs was very small and there seemed no reason to think that any real increase was occurring", and that the supply of drugs to addicts through "irregularities in prescribing" by doctors was infrequent and not such as to justify further statutory controls.

In 1964, the Committee was reconvened to consider whether "in the light of recent experience" the advice given in relation to the prescribing of addictive drugs by doctors three years earlier needed revising. Thus, the

* The World Health Organization Expert Committee on Addiction-producing Drugs (ref. 5) now recommends the substitution of the term "drug dependence" for both "drug addiction" and "drug habituation" for it is not proved possible to formulate satisfactory definitions of the two older terms and the component in common is a dependence, psychic or physical or both.

† An addict is defined in the 1965 report as "a person who, as a result of repeated administration, has become dependent upon a drug controlled under the Dangerous Drugs Act and has an overpowering desire for its continuance, but who does not require it for the relief of organic disease".

Committee confined its attentions to the part played by medical practitioners in the supply of "dangerous drugs"—that is, drugs controlled under the Dangerous Drugs Act, such as morphine, heroin, pethidine and cocaine. It did not concern itself with the abuse of amphetamines, barbiturates and similar drugs, which is probably growing apace, so that, although the report is titled "Drug Addiction"[2], it deals with probably less than 1,000 people, 753 known addicts plus a few who get their supplies from illicit sources, whose number "cannot be precisely estimated", though it is very unlikely to exceed the number of those known.

Despite the restricted nature of the enquiry, disquieting facts were revealed. Between 1959 and 1964 the total number of known addicts to "dangerous drugs" rose from 454 to 753; the rise was chiefly due to increased use of heroin (68 in 1959, 342 in 1964) and of cocaine (30 in 1959, 211 in 1964). The age distribution of addicts had also altered; in 1959, 11 per cent, and in 1964, 40 per cent were less than 35 years old. The increase in addiction was largely in London, but there was suspicion of a similar trend in one or two other large cities.

Smuggled and stolen drugs did not, the Committee decided, provide a significant source. The major source of supply for these addicts was "not more than six doctors" (heroin can be prescribed legally in medicine in Britain, unlike many other countries in which it is banned). The problem can be defined thus: there is a substantial increase in addiction to heroin and cocaine, chiefly in London, supported by up to six doctors acting "within the law and according to their professional judgement" and "out of a sense of duty—because they felt that the treatment facilities elsewhere were inadequate". Whatever the six doctors may think, it is hard to resist the conclusion that they are, innocently, if naïvely, providing addicts with enough drugs for them to give away or sell to others, and the *British Medical Journal*[3] accepted that this is not improbable. The Interdepartmental Committee was quite clear on this when it stated that the facility for legally prescribing these drugs for addicts "has now been abused with the result that addiction has increased". If this is so, the question arises whether the long-held and still cherished right of doctors to prescribe whatever they think fit for any patient should be maintained inviolate. The Committee faced this problem and also the question of whether, if doctors were prohibited from prescribing drugs to addicts, for their addiction, this might lead to an "organized illicit traffic", such as does not at present exist in Britain, and the absence of which is attributed to the fact that addicts could be legitimately supplied by the medical profession.

The Committee decided that the existing problem of heroin and cocaine addiction justified the following measures:

(1) Addicts should be formally "notified" to a central authority as with certain infectious diseases.

(2) Special treatment centres should be set up, at least in the London area, and in other areas Regional Hospital Boards should make provision for treatment of addicts in selected hospitals in their regions.

(3) Statutory powers of the staff of treatment centres to detain addicts should be confined to the period of short-lived discomfort of drug withdrawal when the addict feels a specially strong incentive to terminate treatment. It is recognized that, beyond this, compulsory treatment "seems to meet with little success".

(4) Withdrawal of the drug from the addict is only the first step in treatment. Relapse is common "on returning to their old haunts". Therefore, facilities for long-term rehabilitation to prevent relapse are essential.

(5) The right of any doctor to prescribe heroin and cocaine to an addict for his addiction should be withdrawn and such prescribing should only be permissible by the medical staff of a treatment centre. Indeed, even in an emergency such as, for example, when an addict cannot get to a treatment centre or becomes ill, the Committee considers that the doctor in charge should seek authorization from the centre before he orders or administers such drugs.

(6) The Committee emphasizes that its recommendations apply to heroin and cocaine alone, at present, and only to supply to addicts.

(7) These recommendations, if implemented, would create two statutory offences: failure to notify an addict, and supply of a "restricted" drug to an addict by a doctor who is not a member of the staff of a treatment centre. It is considered that where "the central authority" alleges improper prescribing by a doctor, this should be investigated by "a tribunal of his professional colleagues" (the Disciplinary Committee of the General Medical Council) and not by a court of law "as the issues involved are primarily those of professional judgement and conduct".

The first reaction of the medical profession[3,4] was that it should not be necessary to restrict all doctors because of abuse by only six, and this is understandable. However, it has become plain that drug addicts are a group of patients who are peculiarly difficult to handle, that they spread their addiction among their associates and that "therapy by non-specialists is virtually impossible"[4].

As a result of this report, the medical profession is likely to find that refusal to consider even this slight restriction of its freedom to prescribe will fail to carry conviction. Some central control of prescribing for addicts is probably both inevitable and desirable. A reasonable solution might be to extend the right of such prescribing to doctors who accept the guidance of a specialist at a treatment centre which the addict should visit from time to time. In any case, geographical considerations will probably render it impossible to confine prescribing to doctors on the staff of only a few treatment centres.

Presumably any law that was framed in the light of the Committee's recommendations would allow for other drugs to be put on the restricted list by the Ministers if evidence accumulated that addicts had turned to, say, pethidine or methadone, and evidence of prescribing abuse was found.

The Committee interpreted its terms of reference "as meaning that we were not being invited to survey the subject of drug addiction as a whole", and they have probably done as much as could be expected of eight people meeting eight times. It is to be hoped that the Ministers who convened the Committee and gave them, whether deliberately or not, such a restricted brief will now set up a study group of much wider membership and with much wider terms of reference to investigate the whole problem of drug abuse in society. The Interdepartmental Committee was concerned about the wider problem sufficiently to exceed its terms of reference for a moment and to write of drug abuse generally that "this feature of contemporary life deserves thorough study so that remedial action on all relevant fronts may be planned with full knowledge and understanding". This somewhat ponderous phraseology obscures the urgency of the matter. But the Committee evidently felt a sense of urgency, even though it has not given cogent expression to it.

The problem of drug abuse is growing particularly among the young, and it will not be a short or easy task to get the knowledge of its "complex variety of social, medical and psychological factors" that is essential to deal with this destructive force in our society. The sooner a comprehensive study is put under way, the better.

Complex Carbohydrates

edited by **E. F. NEUFELD** and **V. GINSBURG**
National Institutes of Health, Bethesda, Maryland
VOLUME 8 OF METHODS IN ENZYMOLOGY

Contains detailed directions for the preparation and assay of the enzymes and substrates involved in the biosynthesis of complex carbohydrates. Included are 119 individual articles on the subjects of analytical methods, preparation of substrates, enzymes of sugar activation, enzymes of complex saccharide synthesis and enzymes of complex saccharide utilization.

September 1966, about 725 pp., 208s.

Cryobiology

edited by **H. T. MERYMAN**
National Naval Medical Center, Bethesda, Maryland

An integrated and comprehensive presentation of biological freezing, which discusses heat transfer, freezing injury, measurement of freezing parameters, and freezing in clinical medicine. The fascinating concept of suspended animation is detailed by data covering the freezing process in physical and biological systems and effects of freezing on enzymes and enzyme systems, animal tissues, mammalian blood, intertidal animals, plants, bacteria, and viruses.

August 1966, 775 pp., 168s.

Comparative Phytochemistry

edited by **T. SWAIN**
Univ. of Cambridge, England

Based on papers presented at a 1965 NATO sponsored meeting of the Phytochemical Group in Cambridge, this volume deals with the distribution and biogenesis of chemical substances in plants. By indicating interesting taxa and biosynthetic sequences, it will prove of interest to natural product chemists as well as taxonomists.

March 1966, 360 pp., 93s.

METHODS IN COMPUTATIONAL PHYSICS: Advances in Research and Applications

Nuclear Particle Kinematics

edited by **Berni Alder, Sidney Fernbach**
Lawrence Radiation Laboratory, Livermore, California
and **Manuel Rotenberg**
University of California, La Jolla, California

May 1966, 246 pp., 92s.

The Chlorophylls:

PHYSICAL, CHEMICAL, AND BIOLOGICAL PROPERTIES

edited by **L. P. VERNON** and **G. R. SEELY**
C. F. Kettering Research Lab, Yellow Springs, Ohio

Reviews recent developments in the study of physical, chemical, and biological properties of chlorophylls. This treatise is divided into four sections; the chlorophylls as chemical entities; the chlorophylls in real and colloidal solution, and in the solid state *in vitro;* the biosynthesis, organization, and properties of chlorophylls in plant and bacterial cells; and the photochemical and photophysical behavior of chlorophylls *in vitro* and *in vivo*.

August 1966, 679 pp., 200s.

Fiber Optics

PRINCIPLES AND APPLICATIONS

by **N. S. KAPANY**
Optics Technology, Inc., Palo Alto, California

This volume presents a complete discussion of the field of fiber optics. The subject material ranges from basic principles to geometrical and physical optics of fibers, from waveguide effects to fiber optics technology, and from fiber drawing to assembly and testing.

Late 1966, about 375 pp., approx. 100s.

Electron Radiation Damage in Semiconductors and Metals

by **J. W. CORBETT**
G. E. Research Lab, New York

Provides a comprehensive and critical review of damage in semiconductors and metals as produced by all types of radiation (e.g., electron, proton, neutron, gamma, etc.). Detailed consideration is given to identification of lattice defects effecting specific physical properties, experimental determination of the cause of radiation damage effects, and the theory of electron radiation damage.

September 1966, 410 pp., 132s.

Volume 4

Magnetism

A TREATISE ON MODERN THEORY AND MATERIALS

edited by **George T. Rado**
U.S. Naval Research Laboratory, Washington, D.C.
Harry Suhl
Department of Physics, University of California, La Jolla, California

VOLUME IV: EXCHANGE INTERACTION AMONG ITINERANT ELECTRONS

by **Conyers Herring**
Bell Telephone Laboratories, Murray Hill, New Jersey

Broad in scope, this treatise discusses the most diverse aspects of ferromagnetism, ferrimagnetism, and antiferromagnetism in insulators as well as in metals.

September 1966, about 425 pp., 116s.

Academic Press 111 Fifth Avenue, New York 10003

DECOMPOSITION OF SOLIDS

D. A. YOUNG, Imperial College of Science and Technology, London

Kinetic studies of the thermal and photolytic decomposition of solids have imposed powerful geometric factors which tend in practice to dominate interpretation. Many chemically dissimilar substances decompose with similar if not identical kinetics, whereas the azides, most of which decompose simply to give a metal and nitrogen gas, encompass a wide range of kinetic forms. Solid state chemists are driven to deduce the nature of the imperfections from the kinetics of the decomposition. It is the purpose of this book to chart the development of reaction topochemistry and, by highlighting unsolved problems, to indicate fields for further research.

Contents: Introduction; Formal theory; Endothermic decompositions; The photolysis of solids; Exothermic decompositions; Author index; Subject index.

The International Encyclopedia of Physical Chemistry and Chemical Physics: Topic 21: Solid and Surface Kinetics, Volume 1.

224 pages **55s./$8.50**

THEORY OF ELEMENTARY GAS REACTION RATES

D. L. BUNKER, University of California

Gas kinetics is one of the most interesting fields of physical chemistry, having several different modes of scientific research intersecting its study. This book is concerned primarily with the middle part of the research spectrum, and uses both quantum and classical mechanics, concentrating on elementary gas reactions.

Contents: Introduction to the Theory of Gas Reaction Rates; Bimolecular Exchange Reactions; Unimolecular Reactions; Recombination and Bimolecular Dissociation; Résumé and Prognosis.

The International Encyclopedia of Physical Chemistry and Chemical Physics: Topic 19: Gas Kinetics, Volume 1.

128 pages **35s./$5.50**

NEW PERGAMON PUBLICATIONS

TABLES OF LAGUERRE POLYNOMIALS AND FUNCTIONS

V. S. AIZENSHTADT, V. I. KRYLOV and A. S. METEL'SKII, Mathematics Institute, Academy of Sciences of B.S.S.R.

Laguerre polynomials and functions are widely used in many problems of mathematical physics and quantum mechanics, for example, in the integration of Helmholtz's equation in paraboloidal coordinates, in the theory of the propagation of electromagnetic oscillations along long lines, in the solution of Schrodinger's equations for hydrogen-like atoms, etc. as well as in the expansion in series of an arbitrary function in the interval $(0, \infty)$. The tables contain the values of Laguerre polynomials and Laguerre functions for $n=2,3,\ldots,7$; $s=0(0.1)1$; $x=0(0.1)10(0.2)30$ and the zeros and coefficients of the polynomials for $n=2(1)10$ and $s=0(0.05)1$.

168 pages **50s./$8.00**

THE MECHANICAL PROPERTIES OF ORDERED ALLOYS

N. S. STOLOFF and R. G. DAVIES, Scientific Laboratory, Ford Motor Company

A full account of the research and trends to date in this important field is given in this volume.

Contents: Introduction; Formation of order; Elastic constants; Dislocation structure in superlattices; The strength of ordered alloys; Strain hardening and strain; Aging; Fracture; Fatigue; Creep; Plastic deformation and physical properties; Summary.

Progress in Materials Science, Volume 13, Part 1.

92 pages **flexi-cover 25s./$4.00**

JUST PUBLISHED

THE MECHANICAL AND PHYSICAL PROPERTIES OF THE BRITISH STANDARD EN STEELS Vol. 2

J. WOOLMAN and R. A. MOTTRAM, British Iron and Steel Research Association

The main object of this three-volume work is to have available in one source of reference data on the most commonly used range of steels in the United Kingdom—B.S. 970 En Steels. Some of the information has been published previously, some properties have been determined but not published, whilst the remaining data had not, until this work started, been investigated. Volume 1 includes the most important properties of En 1 to En 20 inclusive and the present volume and volume 3 are concerned with En 21 to En 39 and En 40 to En 363 respectively.

508 pages **£7 7s./$20.00**

BIOCHEMICAL PHARMACOLOGY

Executive Editor: P. ALEXANDER, Chester Beatty Research Institute, Institute of Cancer Research, The Royal Cancer Hospital

This journal provides a forum for the publication of all phases of pure and applied cellular pharmacology including organochemical, physiochemical, biochemical and cytological studies. By including all aspects of research involved in the development of biologically active material (Chemotherapeutic agents as well as insecticides, fungicides, plant growth regulators, etc.) it is hoped that a better appreciation of the problems involved will be attained.

Published Monthly.

OBITUARIES

Sir Neil Hamilton Fairley

THROUGH the death of Sir Neil Hamilton Fairley, who died at the age of seventy-five on April 19, tropical medicine lost one of its greatest scientists and physicians. He carried out a series of brilliant pieces of research on a wide variety of subjects, was responsible for establishing the academic Department of Tropical Medicine in the University of London, played a large part in re-establishing the Hospital for Tropical Diseases, London, after the Second World War, and was president of the Royal Society of Tropical Medicine and Hygiene from 1951 until 1953. He was a valuable member of committees and sat on many connected with tropical medicine, where he was the undoubted leader of his field for many years.

Fairley was born in 1891 in Australia, and graduated with first-class honours from the University of Melbourne in 1915, when he joined the Army and immediately made his mark as a research worker by investigating cerebro-spinal meningitis, which was then creating a great problem among Australian troops. In 1916 he was posted to Egypt and there appreciated the enormous problem which schistosomiasis caused and the difficulties which it presents in diagnosis. He set to work to devise immunological methods of detecting it, and the complement-fixation test and skin-testing antigens which he brought into being are still extensively used and have provided the basis for much further work on the subject. Tests based on his work are used in epidemiological surveys, and much of modern schistosomal control work results from his findings. At this time he also carried out a series of classical investigations on the evolution of schistosomal lesions in animals.

After the First World War, Fairley studied tropical medicine at the London School of Hygiene and Tropical Medicine and worked at the Lister Institute before returning in 1920 to Australia as first assistant at the Walter and Eliza Hall Institute, Melbourne. In 1921 he went as Tata professor of tropical medicine to Bombay and there pioneered investigations on tropical sprue. He carried out detailed clinical and pathological studies of this disease and reached the then novel conclusion that high protein and low fat diets should be used for its therapy. Their introduction enormously improved the prognosis of the disease which until that time had been serious and not uncommonly fatal. Illness interrupted his work, and after a period of convalescence in Britain he returned to the Walter and Eliza Hall Institute. Fairley undertook research on the important problem of snake bite, for which treatment was then largely empirical and very unsatisfactory. He measured venom yields of Australian snakes and carried out detailed studies in animals of the effects of venom. His work enabled anti-venines to Australian snakes to be produced and their use standardized and rationalized.

In 1928 he became physician to the Hospital for Tropical Diseases, London. The pathogenesis of black-water fever was poorly understood at that time and his work on it was of outstanding importance, He demonstrated that when erythrocytes haemolysed, a hitherto unknown pigment, methaemalbumin, was produced. He carried out other investigations of haemolytic anaemia associated with malaria and malnutrition in Macedonia, and this phase of his research culminated in his election to fellowship of the Royal Society in 1942.

At the outbreak of the Second World War, Fairley was invited to become consultant to the Australian Forces. In the Middle East he was responsible for the introduction of sulphaguanidine for the treatment of bacillary dysentery and thus ushered in a new era in the management of this disease. At this time malaria was causing enormous casualties in the Far East and as much as anything else had defeated operations in Burma and New Guinea. The Land Headquarters Medical Research Unit, Cairns, Queensland, was set up to investigate it, its control and prevention, and Fairley was appointed director. He built up a very strong research team and again carried out classical work, perfecting the use of sub-inoculation techniques and not only demonstrating that malaria could be effectively controlled with mepacrine but also pointing the way to a later demonstration of the pre-erythrocytic phase of the malaria parasite—a discovery in which he participated. These investigations were detailed and complex; throughout Fairley was meticulous in carrying them out and brilliant in his use of deductive reasoning. Without his findings, it seems certain, the war in the Far East could not have been won. This work crowned his career and together with earlier achievements won for him international acclaim, a knighthood and many honours. Among the latter were the award of the Buchanan Medal of the Royal Society, the Manson Medal of the Royal Society of Tropical Medicine and Hygiene and the Moxon Medal of the Royal College of Physicians of London.

Few have done more in the field of scientific medicine than Fairley and certainly none has been kinder or more considerate than he was. His generosity and gentleness of nature were almost as internationally known as was his scientific work. Through his research, teaching and his association with large numbers of young men in his investigations and hospital work he had a tremendous influence for good on tropical medicine, an influence which will long continue. A. W. WOODRUFF

NEWS AND VIEWS

Dragon Resurgent

AFTER many ups and downs, the *Dragon* project to develop a high-temperature gas-cooled reactor is within sight of success. Hopes are high that the construction of a commercially viable reactor could begin within two or three years. At a recent symposium, Mr. C. A. Rennie, executive of the *Dragon* project, raised the prospect of competition between the *Dragon* and two other reactor systems now being developed in Britain—the advanced gas-cooled reactor and the fast breeder reactor—by saying that high-temperature reactors could generate electricity economically and could use only slightly enriched fuel as well. The first 20 MW (thermal) high-temperature reactor is now operating at Winfrith Heath, Dorset, and the development programme is financed jointly by Britain and eleven other countries.

When it was first planned in 1958, the *Dragon* reactor was intended to work with low fuel enrichment, but further work suggested that a highly enriched mixture of uranium and thorium would be necessary. But now the pendulum has swung back again and low enrichment is thought feasible. This has the attraction that the output of European thermal diffusion plants for enriching

uranium could be used. Another development of which the *Dragon* people are proud is the development of coated particle fuels which retain a large proportion of the fission products. This has made it possible to dispense with or to simplify the arrangements for preventing the escape of fission products into the reactor cooling cycle.

The *Dragon* programme is at present intended to end in March 1967 and will by then have cost £25 million. An extension of three years at a cost of £6 million is at present being considered. About a third of the total cost has gone on the construction of the reactor experiment, a third on running the reactor, and a third on research and development. Mr. Rennie claims that in its present state of development the high-temperature reactor will need less research and development to bring it to a commercial viable state than will the obvious competitors of this system.

Physics Teaching in Britain

THE Institute of Physics and the Physical Society has set out to give physics teachers in British schools and technical colleges a greater sense of community with professional physicists. One manifestation of this is the appearance of a new journal *Physics Education* intended to provide a certain amount of practical help for the classroom teacher but primarily to inform him (or her) of innovations in teaching technique. Pleased though the physicists were last week with their new venture, there were chemists to be heard saying that the new journal follows some years after the appearance of *Education in Chemistry*, designed to cater for the needs of chemistry teachers in schools and similar institutions.

Prof. K. W. Keohane, professor of physics in the Chelsea College of Advanced Technology and consultative editor of the new journal, says in his introduction that he intends to cater for the interests of teachers of physics "at all levels, from the upper forms in schools to the universities, colleges of education, technical colleges and indeed industry". Prof. Keohane is about to become the co-ordinator of the Nuffield Foundation Science Teaching Project and he says, in his introduction, that the atmosphere created by curriculum development projects like that of the Physical Sciences Study Committee in the United States and the Nuffield Foundation in Britain have made timely the launching of the new journal. He argues that there will be a need for "regular and continuous servicing" of the new curricula and effort by educational authorities to ensure that teachers are enabled to keep up not only with rapid advances in knowledge but also with developments in the curriculum and teaching method. Universities, the argument goes, should watch out for the influx of students from the schools brought up on a refreshing curriculum.

The new journal is only a part of the plans of the Institute and Society for fostering interest in physics education. A joint committee with the Royal Society, called the Committee on Physics Education, with Sir Nevill Mott as chairman, is plotting other schemes. One of these is an attempt to create regional centres to which physics teachers in schools may look for help, advice and continuing opportunities for training. The first of these centres is likely to emerge around the Department of Physics of the Manchester Institute of Science and Technology.

Nuffield Science Teaching

THE Nuffield Foundation has announced that Prof. Kevin Keohane, head of the Department of Physics at the Chelsea College of Science and Technology, is to become co-ordinator of the Nuffield Foundation Science Teaching Project from August 1, 1966. The work of the Project is at a particularly interesting stage, partly because the developments of the past four years are about to culminate in the publication of the books which embody O-level courses in physics, chemistry and biology, and partly because systematic trials of sixth form and combined science courses are about to begin. Prof. Keohane will combine responsibility for the Science Teaching Project with some of his present duties at Chelsea. From the point of view of the College, the appointment serves to emphasize the interest which has been taken at Chelsea in the past two years in fostering links between academic institutions and the schools. The College has, for example, been concerned to find ways of helping with the training of science teachers and has at various times considered the possibility of starting a unit for this purpose.

Atomic Energy Commission

THE E. O. Lawrence memorial awards of the Atomic Energy Commission have been presented to the following for contributions to nuclear science: Harold M. Agnew, Los Alamos Scientific Laboratory, for development of nuclear weapons; Ernest C. Anderson, also of Los Alamos, for research in nuclear medicine and biology and for development of liquid scintillation counting; John R. Huizenga, Argonne National Laboratory, for work in nuclear fission processes; Murray Gell-Mann, professor of physics at California Institute of Technology, for contributions to the theory of elementary particles; and Paul R. Vanstrum, Oak Ridge Gaseous Diffusion Plant, for technical administration and leadership in developing isotopic separation for uranium.

Canadian Science Council

THE Canadian Government has established a council to advise on science policy, called the Science Council of Canada, under the chairmanship of Dr. O. M. Solandt, vice-president for research and development of de Havilland Aircraft of Canada, Ltd. Dr. Solandt is well qualified for his new post by his previous experience as the first chairman of the Defence Research Board of Canada, which he helped to plan and which was formed in 1947. Since then, he has been in charge of research and development at the Canadian National Railway, and was elected chancellor of the University of Toronto for two years beginning in July 1965. The vice-chairman of the Science Council of Canada will be Dr. Roger Gaudry, at present rector of the University of Montreal, but with previous industrial experience in pharmaceuticals.

Rockefeller Animal Behaviour

THE Rockefeller University and the New York Zoological Society have jointly established an Institute for Research in Animal Behavior at New York. The Institute will not be a building but rather a group of scientists attached to one or other of the sponsoring institutions which will collaborate in research and teaching in animal behaviour. One of the facilities available to the new Institute will be the New York Zoological Society's collection of living animals.

They also plan to make a number of joint appointments to the faculties of the two institutions. Prof. Donald R. Griffin has been appointed director of the Institute. He will be joined later this summer by Prof. Peter Marler, from the University of California at Berkeley, and by Drs. Fernando Nottebohm, Richard Penney and Roger Payne. The Rockefeller University hopes that the work of the new Institute will form part of the overall development of teaching and research in the behavioural sciences which have been organized in recent years by Dr. Carl Pfaffmann, and that this part of the University's interest will be helped by the appointment of Prof. Neal E. Miller, a psychologist, to the faculty.

Effect of Dietary Lipids on Blood

A SYMPOSIUM was held in Cambridge on March 17 and 18, 1966, under the chairmanship of Prof. A. C.

Frazer (Britain) and Prof. M. J. L. Dols (The Netherlands), to discuss the present position with regard to the effect of dietary lipids on blood. The meeting was sponsored by the International Federation of Margarine Associations. In the first session Dr. H. J. Thomasson (Netherlands) presented investigations of blood lipids in a Trappist community under different dietary regimens. Dr. E. H. Ahrens, jun. (United States), discussed the possible mechanism of long-term blood lipid changes and described the investigations of his group into sterol balance. The second session was concerned with short-term changes and papers were given by Dr. D. S. Fredrickson (United States), who described changes in blood lipid pattern resulting from alterations in the diet, with particular reference to lipoproteins, and by Dr. D. S. Robinson (Britain), who discussed the lipid transport function of lipoproteins and the possible role of lipolytic enzymes. The third session was devoted to a discussion on the effects of lipids on white blood cells and erythrocytes. Dr. P. Elsbach (United States) described the differences between the behaviour of granulocytes and macrophages towards lipids, and Dr. J. de Gier (The Netherlands) described some effects of fats on red blood cells.

In the final session, the possible effects of dietary lipids on blood platelets and blood coagulation were the subjects of discussion. Prof. G. V. Born (Britain) described the possible relationships between lipids and blood platelet behaviour and Prof. R. G. Macfarlane (Britain) discussed the blood-clotting mechanism and the possible points at which lipids might be expected to have some significant effect.

In all, there were thirty-eight participants in the symposium, representing fifteen different countries. Original material presented at this meeting will be published independently by the respective authors in appropriate scientific journals.

Pig Trypanosomiasis in Africa

PIG trypanosomiasis, a possible source of human trypanosomiasis or 'sleeping sickness', is the subject of a monograph by Dr. L. E. Stephan, of the School of Public Health and Medicine of the American University, Beirut, Lebanon (*Pig Trypanosomiasis in Africa*. Commonwealth Bureau of Animal Health, Review Series No. 8. Farnham House, Farnham Royal, Buckinghamshire. 15*s*.). The review includes the geographical distribution of pig trypanosomiasis, the characteristics of the five species which infect the pig, and their mode of transmission, the chemotherapy and chemoprophylaxis of these infections, and an especially valuable chapter on the pig as a reservoir of human trypanosomiasis. Dr. Stephan concludes that further investigation is needed before any decision can be made on this point.

South African Museum

THE Minister of Education, Arts and Sciences decided that as from April 1, 1964, the South African Museum should consist of two sections: the South African Museum (Natural History) and the South African Museum (Cultural History). The Cultural History Section has moved into the old Supreme Court building. Two new galleries have been built for natural history, and extensions to the Marine Biology Department and a new palaeontological laboratory are in progress. Notable additions to the collection of photographs include prints of the Bushmen of Tsumkwe Pan, S.W. Africa, and a set of negatives of tribal studies taken *c*. 1900.

Technology and the U.S.S.R.

IN a written answer to the House of Commons on May 24, Mr. Frank Cousins, the Minister of Technology, outlined his visit to the U.S.S.R. earlier that month and commented on his discussions with Mr. Kosygin on the value of exchange in science and technology between Britain and the U.S.S.R. He had visited the U.S.S.R. at the invitation of Academician V. A. Kirillin, chairman of the State Committee for Science and Technology, to discuss with representatives of the Soviet Government their methods for managing and deploying technological resources and for introducing new technology into industry. He had been able to see some of the advanced technological work being carried out in research institutes and discussed methods of training technologists. During his visit, Mr. Cousins and Mr. Kirillin had discussed the organization and operation of the State Committee and its working relations with the Academy of Sciences, the Ministry of Higher Education and with Gosplan. Mr. Kirillin had described the methods used by the Soviet Government for allocating priorities to technological projects and for estimating their value, and for exploiting technological resources. He had also outlined the role of Soviet technology in economic planning, the training of qualified technologists and the dissemination of scientific and technological information.

Surveying Sand and Gravel Resources

IN a written answer in the House of Commons on May 26, the Minister of Land and Natural Resources, Mr. F. Willey, stated that he was giving priority to a survey of sand and gravel resources to the extent needed to supplement existing deposits potentially capable of economic exploitation. The Chelmsford and Ipswich areas were being studied first, and the aim was to establish potentially workable reserves, a category between possible resources as shown on geological maps and resources proved by detailed exploration by the industry. The first year's work would provide an opportunity to develop appropriate techniques and the field work would be done on an agency basis by the Institute of Geological Science.

Grants for Research

ON May 25 the Minister of State, Mr. G. Roberts, stated that of 1,078 applications for research grants to the Science Research Council in the fiscal year 1965–66, 832 were granted in whole or in part. For the Medical Research Council the corresponding figures were 516 and 377; for the Agricultural Research Council, 73 and 56; and for the Natural Environment Research Council, 101 and 75.

Dipeptide Sequences

MR. BEN BLOOM, of the National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Maryland, is seeking help in collecting information about amino-acid sequences in portions of polyamino-acid molecules. He is constructing a digital computer programme to evaluate the frequency of the occurrence of dipeptides and undertakes that information sent to him at Building 10, Room 9*B*-09, National Institutes of Health, Bethesda, Maryland 20014, will be fully acknowledged in any publication that may eventually be made. Bloom's work is in part inspired by that of H. B. Bull (*Arch. Biochem. Biophys.*, **112**, 208; 1965), who found in an analysis of 1,304 dipeptides in eight protein molecules that, of the 400 possibilities, ten were favoured and eight occurred less frequently than would have been expected.

University News: Belfast

DR. CHARLES DOW has been appointed to the chair of comparative pathology, and Dr. H. B. Gilbody to a second chair of physics.

Liverpool

THE University of Liverpool has just announced that Dr. K. McCarthy, senior lecturer in bacteriology, has been

appointed to the chair of bacteriology. He will take up his appointment on October 1, 1966, when Prof. A. W. Downie retires.

Massachusetts Institute of Technology

WILLIAM B. KEHL has been appointed associate professor of electrical engineering at the Massachusetts Institute of Technology and associate director of the M.I.T. Computation Center. Dr. John Ross has been appointed a professor of chemistry and, for five years, head of the Department of Chemistry.

Appointments

THE trustees of the British Museum (Natural History) have appointed Dr. H. W. Ball to be keeper of the Department of Palaeontology in succession to Dr. E. I. White, who retires on June 30; and Mr. R. Ross to be keeper of the Department of Botany in succession to Mr. J. E. Dandy, who relinquishes his post on September 30 to devote more time to research.

Announcements

DR. A. R. SANDAGE, of Mount Wilson and Palomar Observatories, has been awarded the Gold Medal of the Pontifical Academy of Sciences. This award was instituted by Pope John XXVIII to honour a young scientist who has made distinguished contributions to science.

DR. ALAN T. WATERMAN has received an award created by the National Academy of Sciences in the name of the late Edwin Bidwell Wilson to honour a civil servant especially distinguished in the field of science and public affairs. The award was presented during the Vicennial Convocation of the Office of Naval Research in Washington.

THE American Geophysical Union has made the following awards: the *William Bowie Medal*, to Dr. L. R. Slichter; the *John A. Fleming Medal*, to S. E. Forbush; the *James B. Macelwane Award*, to Dr. D. L. Anderson.

A SYMPOSIUM on "Aromaticity", sponsored by the Chemical Society, will be held in the University of Sheffield during July 6–8. Further information can be obtained from the General Secretary, The Chemical Society, Burlington House, London, W.1.

THE second conference of the Institute of Information Scientists will be held at Jesus College, Oxford, during July 11–13. Further information can be obtained from Dr. D. J. Campbell, 54 Hurst Rise Road, Cumnor Hill, Oxford.

THE seventh general assembly of the International Union of Crystallography will be held in Moscow during July 12–19. Further information can be obtained from the General Secretary of the Union, Rekencentrum der Rijksuniversiteit, Grote Appelstraat 11, Groningen.

A symposium on "Statistical Mechanics and Thermodynamics", arranged by the International Union of Pure and Applied Physics, will be held in Copenhagen during July 11–16. Further information can be obtained from Prof. T. A. Bak. H. C. Ørsted Institute, Universitetsparken 5, Copenhagen Ø.

AN international symposium on "Naturally Occurring Phosphoric Esters", arranged by the Chemical Society, will be held in Newcastle upon Tyne during July 10–12. Further information can be obtained from the General Secretary of the Chemical Society, Burlington House, London, W.1.

AN international summer school on "The Autonomic Nervous System" will be held by the Netherlands Central Institute for Brain Research, Amsterdam, during July 10–23. Further information can be obtained from Dr. J. P. Schadé, Central Institute for Brain Research, IJdijk 28, Amsterdam.

AN international symposium on "Reaction Mechanisms of Inorganic Solids", arranged by the Chemical Society, will be held in the University of Aberdeen during July 11–16. Further information can be obtained from the General Secretary of the Chemical Society, Burlington House, London, W.1.

A CONFERENCE on "Chemically-grown Surface Films", arranged by the Electron Microscopy and Analysis Group of the Institute of Physics and the Physical Society, will be held in the University of Strathclyde during July 7–8. Further information can be obtained from the Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

THE first international conference on "Haemorheology" will be held in the University of Iceland, Reykjavik, during July 10–16. Further information can be obtained from the Scientific Organizing Committee of the conference, Hemorrhage and Thrombosis Research Laboratories, Veterans Administration Hospital, East Orange, New Jersey.

ERRATUM. Sir Harry Melville points out that the U.K. Science Research Council postgraduate awards are already tenable at universities outside Britain, contrary to the implication on June 4 (*Nature*, 210, 977; 1966).

A MECHANISM FOR THE GENERATION OF ACOUSTIC-GRAVITY WAVES DURING THUNDERSTORM FORMATION

By A. D. PIERCE and S. C. CORONITI

AVCO Corporation, Research and Advanced Development Division, Wilmington, Massachusetts

DURING the past three decades, a number[1-7] of investigators have reported experimental evidence which would seem to indicate that thunderstorm activity may be related to ionospheric disturbances and, in particular, to sporadic *E*. Roberts *et al.* have provided more recent evidence in their data of path losses of 21·6 Mc/s radio waves transmitted from Panama and received at Stockbridge, New York[8]. They report a noontime disturbance which was detected on various days of August and September, 1964. This noontime disturbance represented a marked decrease in absorption below normal levels. Onset tended to occur between 1115 and 1215 E.S.T. The disturbance duration was about 1 h. We find this evidence particularly suggestive as the path passed over a portion of Florida especially noted for intense thunderstorm activity. One of our colleagues, W. J. Breitling, has checked on thunderstorm activity on August 19 (which was one of the two dates explicitly cited by Roberts *et al.* for which the noontime disturbance was observed) and found that a thunderstorm did exist in a region near the propagation path. Furthermore, the fact that thunderstorms tend to occur during the summer months and during the early afternoon[9] would seem to corroborate the reported times of the noontime disturbance occurrence. Although this evidence is highly circumstantial (as is also that of the previous investigators), it does tend to reinforce our belief that further investigation should be devoted to possible mechanisms by which thunderstorms can exert an influence on the ionosphere and that additional experiments should be carried out that would provide more conclusive evidence.

In this article we shall suggest a mechanism by which energy can be propagated from a thunderstorm during its early stages to the ionosphere and by which an ionospheric disturbance can be created The mechanism involves the generation of acoustic-gravity waves by air movements in the thunderstorm and the propagation of these waves to ionospheric levels.

The belief that acoustic-gravity waves propagating upwards from the troposphere may be responsible for a number of types of ionospheric disturbances has become increasingly widespread in recent years. Hines[10] has shown that many or most of the observational data pertaining to irregularities and irregular motions in the upper atmosphere can be interpreted on the basis of atmospheric gravity waves (that is, acoustic-gravity waves) and has discussed the possibility that these waves may originate in the troposphere. Gossard[11] has investigated the propagation of these waves from the troposphere and has found that a window can exist for wave periods between 10 min and 2 h through which fairly large amounts of energy can sometimes flow out of the troposphere. Although Gossard discussed several mechanisms by which such waves could be generated, he did not suggest any mechanism by which a thunderstorm could generate acoustic-gravity waves.

In describing our suggested mechanism, it is convenient first to review certain known features of thunderstorm formation. During the initial stage of the thunderstorm cell[9] (that is, the cumulus stage) an updraught extends throughout most of the cell. These updraughts are generally of the order of 10 ft./sec, but may locally (particularly at times early in the mature stage) exceed 100 ft./sec. The driving force for the updraught would seem to be an instability of the lower atmosphere. If this instability occurs in a region near the ground where locally the potential temperature decreases with height, then the air in the lower layer rises, causing the updraft, until a level is reached where the potential temperature (which will not change in an adiabatic expansion) is equal to that of the ambient air at the same altitude. The cooling of the air as it rises may cause condensation of water vapour and this condensation gives up energy to the air which in turn tends to increase the potential temperature and cause the driving force of the updraught to be more intense. The equilibrium height of the unstable air then increases due to the fact that the potential temperature in a stable atmosphere increases with height.

As the unstable air rises to its equilibrium height, it will overshoot this and then be pulled back. The net result will be an oscillation of the air at an altitude approximately the same as that of the cloud tops. The period of the oscillation should be about the same as the local Brunt period[12] (that is, that predicted for free vertical oscillations of the atmosphere).

Such an oscillation has been observed by C. E. Anderson[13], who gives an example of a curve of the vertical velocity of a cumulus cloud top versus time derived from measurements on photographs of developing clouds. The particular example given by Anderson shows an oscillation with a velocity amplitude of 330 ft./min and a period of 11·8 min superimposed on a steady rise of the air. Anderson's measurements are particularly suggestive as an 11·8-min period is of the correct order of magnitude for Brunt's period in any realistic atmosphere at an altitude below the tropopause.

The total energy associated with the oscillation observed by Anderson can be readily estimated. Taking $\frac{1}{2}\rho_0 V^2$ as the order of magnitude of the energy per unit volume, where ρ_0 is the ambient density and V is the peak oscillation velocity, we find the energy per unit volume to be of the order of 1 erg/cm^3. (The value of ρ_0 used in this estimate was 5×10^{-4} g/cm^3.) If we next assume the oscillation to extend over an area roughly 10 km by 10 km and over a height interval of 3 km, we can estimate the total energy of the oscillation to be 3×10^{17} ergs. Even if this estimate were too large by a factor of 10^3, an energy of 10^{14} ergs would still be considerable.

Because viscosity has negligible effect on oscillations of such a long period, the principal mechanism for the dissipation of this energy should be in its transport by wave motion (that is, by acoustic-gravity waves). These waves should have a period roughly equal to the local value of the Brunt period at source altitude.

The attainment of realistic estimates of the amplitudes of the resulting disturbance at distances removed from the source altitude is difficult because of the complicated manner in which atmosphere temperature gradients affect the propagation. Although we are at present considering this problem, some very rough estimates can be made which indicate that the effects on the ionosphere may be considerable. To make these estimates we consider the oscillation of the air at cloud top heights as producing waves which propagate according to the laws of ordinary acoustics. In the example reported by Anderson, the fluctuations in pressure at cloud top heights would be

estimated as being of the order of 7 per cent ambient. If we ignore gravitational dispersion, reflexions, refraction, etc., the ratio of the fluctuations in pressure to the ambient pressure of a travelling wave will vary inversely to the square root of the ambient pressure. Thus the ratio should increase by roughly a factor of ten as the wave travels upwards by 40 km. Even at ground level, the oscillation should be significant, as an oscillation of much less than 0·1 per cent can be detected by microbarographs. (However, the wave oscillations at ground-level may be obscured by the pressure fluctuations due to turbulence created by the thunderstorm formation.)

If these simple estimates were valid, then the wave would be a shock by the time it reached the ionosphere. We do not expect this to be the actual case for reasons which will be discussed later. However, even a pressure fluctuation of 1 per cent ambient at ionospheric levels would have a significant effect on radio wave propagation as the relative fluctuations in electron density will tend to equal those of the pressure—especially in the lower ionosphere where the collision frequency is much greater than the wave frequency.

A more careful analysis of this mechanism will have to take into account the propagation characteristics of acoustic-gravity waves—which are considerably different from those of ordinary acoustic waves. It is possible that considerable reflexion can occur at intermediate altitudes. This reflexion is particularly large at wave periods close to the local value of the Brunt period. Because the wave period at the source altitude is virtually identical to the local Brunt period, the reflexion process will be particularly strong there. However, because at frequencies near the Brunt frequency propagation is more favourable in the direction of increasing Brunt frequency and as, near tropopause altitudes, the Brunt frequency is increasing with height, the propagation should be predominantly upward. The group velocity of the wave near the source altitude may be expected to be very small and also to be nearly horizontal. Considerable geometrical spreading should be expected at ionospheric heights which would tend to reduce the magnitude of the effect from that expected for a wave propagating vertically upwards. It is possible also that some ducting may occur at intermediate altitudes. All these considerations make it difficult to say with any certainty that the mechanism we suggest will cause appreciable ionospheric perturbations. Nevertheless, it does show considerable promise and merits further investigation.

We thank Dr. R. M. Cunningham of AFCRL for several helpful discussions in relation to this problem.

REMOVAL OF MAGNESIUM FROM UNDERGROUND WATERS USING LIME

By DR. R. J. W. McLAUGHLIN
Department of Geology
AND
DR W. T. AGAR
Department of Physiology, University of Melbourne, Australia

THE problem of the production of sufficient fresh water for the needs of mankind is one which has steadily become more pressing, and considerable effort is now expended in research aimed at desalination. In Australia, generally acknowledged as the driest continental land-mass, this difficulty has always been acute, especially for the watering of domestic animals, and much marginal land is always in a state of hazard. The position is sometimes so critical that large areas may be dependent on waters whose concentration of salts lies close to the toxic level, and certainly well in excess of tolerated maxima of city supplies anywhere in the world. It is hardly surprising that authorities have hesitated to give decisions on maximum tolerable levels, but it is interesting to note that the better-watered areas have much lower 'suggested tolerable levels' than the semi-arid regions[1]. Such waters, in the dry regions, nearly always have their source in underground aquifers. These waters contain variable quantities of soluble salts, depending on the nature of the aquifer, and the rate of fill and movement in this porous layer. The most common ions in solution are sodium and chloride, but there are others also. One of these, magnesium, is especially harmful to animals. For this reason it is unfortunate that many hydrological authorities report their chemical analyses merely as chloride. From this they calculate the percentage of sodium chloride present, assuming quite arbitrarily that all the chloride is balanced by sodium. Using this type of calculation, many waters which appear safe are in fact highly dangerous to stock, especially to young animals.

It is surprising that so little attention appears to have been given to the magnesium content of underground waters. We have on several occasions found underground waters, from bores in Western Victoria, Australia, which have contents of from 400 to 1,000 parts per million magnesium after a long period of dry weather. This is within the range toxic for farm animals on dry summer pastures[2,3] and harmful effects were noted in stock drinking these waters, cattle and young sheep being more susceptible than older sheep.

A high concentration of magnesium in drinking-water may have a deleterious effect on animals in a number of ways. Initially, the presence of magnesium salts in water may make the animal disinclined to drink. Peirce[3] found that sheep suddenly presented with water of high salinity showed loss of weight and a marked decrease in food intake, whereas, if the salinity was increased gradually over 3 to 6 weeks, the same levels of salinity could be tolerated without nutritional disturbance. Field observations in Western Victoria confirm that animals moved to waters containing a high concentration of magnesium show at first a marked disinclination to drink.

These waters certainly have a most unpleasant taste to human beings. The most important harmful effect of the magnesium ion appears to be its local action in the alimentary canal after ingestion. Sheep and cattle drinking water of high magnesium content frequently contract diarrhoea. This is not surprising, as Peirce[3] found that sheep drinking water containing 0·20 per cent magnesium chloride (510 parts per million magnesium) had an average daily intake of 2·2 g magnesium, whereas a cathartic dose of magnesium sulphate for man contains about 1·5 g magnesium. The loss of fluids and nutrients from diarrhoea is likely to be a major cause of the nutritional disturbances caused by an excessive intake of magnesium. In addition, a direct depressing effect of the magnesium ion on the absorptive epithelium of the intestine cannot be excluded. Magnesium toxicity is unlikely to be due to excessive absorption leading to a blood plasma level in the toxic range. Magnesium is poorly absorbed from the alimentary canal and is rapidly excreted by normal kidneys. The highest plasma levels observed by Peirce[3] in sheep drinking water containing 0·50 per cent magnesium chloride (1,280 parts per million magnesium) were about 4 m.equiv./l. compared to the normal for sheep of about 2·5 m.equiv./l. General toxic effects in man (loss of reflexes, cardiac and respiratory failure) are not seen until a plasma level of 6 to 12 m.equiv./l. is reached[4] compared to the normal for man of about 2 m.equiv./l.

The source of the magnesium content of underground water is two-fold. Normally, rain-water contains proportions of salts with sodium : magnesium ratios generally similar to that of the ocean, from which they are derived by various mechanisms, such as spray, bursting bubbles, etc.[5]. Such solutions are then believed to become more concentrated by ion-filtration processes involving clay membranes[6–8]. The second source lies within the rocks themselves. Basic rocks such as basalt and also many shales contain large quantities of magnesium and, taken together, these two probably make up the predominant rock type over large areas of the Earth. A proportion of this magnesium is taken into solution during leaching, especially if the *p*H is low. The adage of Plinius, "*Tales sunt aquae, qualis terra per quam fluunt*" (waters take their nature from the rocks through which they flow), is certainly true of waters which have percolated through such rocks. The sum total of the various hydrological processes is to give a certain degree of stratification in aquifers, with fresher water overlying more saline liquids. When the subterranean water is overdrawn, the more saline bottom layers rise to give pollution. This is a common occurrence in dry spells, but even in winter it has been observed to take place if large amounts of water are withdrawn at any one time.

The removal of salts from water may be carried out by various methods such as distillation, dialysis and ion-exchange. All these are still comparatively expensive, especially for small-scale production. Many of the waters at present unsuitable for stock would become tolerable if the magnesium content could be lowered. Such a process does already exist and a considerable technological industry is, in fact, founded on the removal of magnesium from sea water by lime. The principle is simple. The solubility of magnesium hydroxide is several orders of magnitude lower than that of calcium hydroxide, or calcium carbonate in the presence of carbon dioxide. Exchange of calcium for magnesium is rapid at the interface between solid and liquid, and because of the low solubility of calcium hydroxide in water, little excess calcium is added to the water, even on long standing. In any case, excess solution of calcium hydroxide raises the *p*H, and subsequent absorption of carbon dioxide from the atmosphere gives a scum and finally a precipitate of calcium carbonate, while the *p*H falls to tolerable levels.

Experiments were conducted on a series of synthetic solutions and finally on bore waters, from basaltic terrain, containing toxic levels of magnesium. The addition of various quantities of lime to such systems gave efficient removal of magnesium in quite short periods of time (30 min), provided sufficient lime was added to give replacement on a 1 : 1 basis. The greater the amount of lime added, the more rapid the replacement. The replacement is understandably more rapid with stirring and takes longer in quiescent solutions. Another technique which has been used is the use of a filtration medium. After a large number of additives had been tried, a mixture of lime and coarse sawdust was found to act as an excellent filtration bed, and it allowed a constant passage of water. Depending on filter size, flow speed, etc., varying amounts of magnesium are removed. In filtration experiments it is important to have an inert but porous extending additive, or else clogging of the filter by fine-grained magnesium hydroxide rapidly occurs. The results of a series of experiments on one bore water have been tabulated in Table 1.

Table 1 EXTRACTION OF MAGNESIUM FROM AN UNDERGROUND WATER BY TREATMENT WITH LIME

	1	2	3	4	5	6	7	8
Calcium	6·2	5·7	7·2	11 0	10 4	8·8	18·3	37·4
Magnesium	21·3	20·8	18·4	14·3	15·4	17·3	5·9	0·3
Calcium + magnesium	27·5	27·5	25·6	25·3	25 8	26·1	24·2	37·7
*p*H	8·7	10 0	10·2	10·3	10 0	10·5	10 7	12·3

Values are given in molar parts per million to facilitate comparison.

(1) Bore water from Penshurst, Victoria, Australia, aquifer under basalt (2–5) Water after treatment with calcium oxide, 0 5 g/l , stirred 10 min, 30 min, 100 min, 270 min respectively. (6, 7) 1 g/l., stirred 10 min and 30 min respectively. (8) 2 5 g/l., 30 min stirring.

The replacement of magnesium by calcium does not present any problem, for both Heller[9] and Peirce[10] have shown that animals do not suffer any ill effects on waters high in calcium. In fact, such waters may provide an excellent source of calcium for animals the diets of which are deficient in this element. One additional advantage which may frequently arise is the precipitation of a portion of the calcium as the mineral gypsum, for waters containing high contents of magnesium are often also high in sulphate. Although the solubility of calcium sulphate is higher in sodium chloride solution than in pure water, precipitation of gypsum does occur when there is excess sulphate. In technology, use is made of the reduction in solubility of gypsum in sulphate solutions by adding 0·5 per cent of sodium sulphate to concentrated brine solutions to precipitate gypsum[11].

It may be argued that waters high in soluble matter should not be used. Such advice is of small assistance to the pastoralist whose livelihood is threatened, because owing to drought or other causes the water on which he depends has become more saline. It is believed that a fuller appreciation of the chemical nature of waters in the drier parts of the world would reveal many sources, at present thought valueless, to be capable of use after treatment with lime. A survey of the literature on Australian water sources has shown that waters rejected as unsuitable by pastoralists are nearly always high in magnesium and often sulphate as well. It should be pointed out that this rejection is based not on theory but on practical experiment.

Because of the ready availability of lime in any agricultural or settled community, the cost of treating water by this method is small and no complicated equipment is necessary.

DATING GEOMAGNETIC POLARITY EPOCHS IN RÉUNION

By DR. F. H. CHAMALAUN and DR. IAN McDOUGALL
Department of Geophysics and Geochemistry, Australian National University, Canberra

IN most palaeomagnetic investigations of Tertiary rocks the directions of natural remanent magnetization (NRM) are found to be approximately parallel or antiparallel to the direction of the present geomagnetic field. The rocks are said to possess normal or reversed polarity respectively. This bimodal distribution of polarities may be caused either by reversals in polarity of the geomagnetic field or by the rocks possessing the property of self-reversal.

Theoretical considerations indicate that rocks containing certain magnetic minerals may spontaneously acquire a direction of magnetization opposite to that of the ambient field. There are no laboratory tests at present available which can establish whether a rock had the property of self-reversal at the time it became magnetized. Other tests have to be used to distinguish between the two possible explanations of the observations.

If it can be shown that rocks of the same age have the same polarity throughout the world then this would constitute strong support for the hypothesis of geomagnetic field reversal. By contrast, if self-reversal were of importance in producing the bimodal distribution of polarities, then no consistent pattern of age versus polarity would be expected. Hence, a combination of isotopic dating and palaeomagnetic studies should provide a means of distinguishing between the two hypotheses.

Recently, by using these two techniques, a surprisingly consistent pattern of age versus polarity has emerged[1–5]; this is strong evidence in favour of the hypothesis of geomagnetic field reversal. The investigations have been directed mainly at establishing the relations during the past 4 m.y., and for this period four polarity epochs have been named[4,5]. In addition, at least two events have been recognized[4,5], an event being a short-period change in polarity during an otherwise normal or reversed epoch. The duration of an event may be of the order of 0·1 m.y.[5].

These investigations are important for a proper understanding of the origin and behaviour of the geomagnetic field; they should also form the basis for using polarity measurements as a means of correlating rocks that cannot be dated by isotopic or palaeontological methods.

Most of the available data have been obtained on rocks from the northern hemisphere; it is of some importance to make similar investigations on rocks from the southern hemisphere. This article presents palaeomagnetic and age results on rocks from the island of Réunion in the Indian Ocean. We are concerned here mainly with geomagnetic polarity epochs; full discussion of other aspects of this work will be given elsewhere.

Réunion is situated at 55° 30′ E., 21° S. at the south-west extremity of the Mauritius–Seychelles Ridge. The island is built of two volcanoes. Piton des Neiges, an extinct volcano, forms the north-western two-thirds of the island, and Piton de la Fournaise, which is still active, occupies the south-eastern part. Various aspects of the geology of Réunion have been described previously[6–9]. Both volcanoes are built predominantly of basaltic lavas which have tholeiitic affinities. The main basaltic shield of Piton des Neiges is covered by an extensive veneer of feldsparphyric basalt, hawaiite and mugearite, termed the "differentiated series" by Upton and Wadsworth[8].

More than one hundred samples were collected from unweathered, well-exposed outcrops on both volcanoes. Specimens were oriented by means of a Brunton compass. Isotopic dating was carried out on more than thirty-five of the samples used in the palaeomagnetic investigations.

The whole-rock technique of potassium-[illegible] was used as previously described[10,11]. Argo[illegible] med by isotope dilution and potassium by f[illegible] tometry. The experimental uncertainty in the measured ages generally is less than ±5 per cent at the 95 per cent confidence level, except in those cases where the air argon correction exceeds 85 per cent, when the error may increase to more than ±10 per cent. Estimates of the experimental error are given in the list of results, based on the quality of the mass spectrometer runs, the air correction, and the reproducibility of both argon and potassium determinations, as most results were measured in duplicate. Only essentially holocrystalline, unaltered rocks were used in the dating to minimize the possibility of loss of radiogenic argon. The consistency of dates determined on rocks the relative stratigraphic positions of which are known provides good evidence that the measured ages are correct within the limits of experimental error.

Palaeomagnetic measurements were made with a short-period astatic magnetometer. A series of fifteen test specimens were thermally demagnetized in steps up to 600° C, and by alternating fields up to 700 oersted (peak). These tests showed that the rocks generally are magnetically somewhat unstable. The thermal decay curves are variable, and commonly show low blocking temperatures. In many cases the intensity of NRM was reduced to less than one-half at 150 oersted (peak) during alternating current demagnetization. Furthermore, when left in the laboratory, the direction changed by as much as 15° over a period of 6 weeks. Most samples had a substantial component of temporary viscous magnetization which, however, could be removed after alternating current treatment to 150 oersted (peak). After alternating current demagnetization, the directions fall into two reasonably well-grouped clusters of normal and reversed polarity which approximate closely to the magnetic dipole field direction, when sign is disregarded. There are two exceptions: the magnetic direction of *RU*13 moves towards the reversed group on alternating current demagnetization, but does not quite reach it. Sample *RU*80 has an anomalous direction of magnetization, but would fall within the normal group if it is assumed that there was a misorientation of 180° in the strike line. This appears to be confirmed by the fact that another sample from the same lava flow has normal polarity.

The results are listed in Table 1, and plotted in Fig. 1 together with previously published data. The nomenclature of the polarity epochs follows that of Cox *et al.*[4,5]. Only those results are given for which the magnetic and age measurements were made on the same sample. Those samples measured palaeomagnetically, but not dated, can readily be correlated with the dated samples from the stratigraphy and polarity.

All the samples from Piton de la Fournaise have normal polarity. The indicated ages on seven samples from this volcano range from 0·04 to 0·35 m.y. Owing to the low proportion of radiogenic argon in the runs the dates have uncertainties of between ±10 and ±80 per cent (Table 1), the larger error relating to the younger samples. Similarly all specimens from the differentiated series of Piton d[illegible] Neiges possess normal polarity, and the measured dat[illegible] which are generally of good precision, lie in the range 0·10–0·35 m.y. The age data confirm that Piton de la Fournaise was erupting before Piton des Neiges became extinct.

as of the main dome building phase of Piton des ...es, termed the "oceanite series"[8], can be divided into three distinct groups on the basis of the age measurements. It is not known whether this indicates three major periods of eruption or whether it is the result of biased sampling because of the restricted accessibility of the outcrop of the oceanite series.

The youngest group of lavas of the oceanite series are dated at between 0·43 and 0·58 m.y. (six samples), and indicate that the hiatus between this series and the differentiated series was of short duration. Lavas of this group consistently have normal polarity.

The results from the lavas of Piton de la Fournaise, the differentiated series and the younger lavas of the oceanite series of Piton des Neiges provide a large body of data that show that in the age range 0·04–0·58 m.y. the polarity was normal. Fig. 1 emphasizes that, prior to the present work, very few results were available for this part of the time scale. These rocks clearly belong to the Brunhes normal polarity epoch.

A second group of lavas from the oceanite series have measured ages lying between 0·97 and 1·18 m.y., based on samples from seven flows. Five of the specimens yield dates in the range 1·07–1·18 m.y., and have reversed polarity. These results are consistent with previously published data; the rocks can confidently be assigned to the Matuyama reversed epoch. Sample *RU*13 (*GA* 1255), dated at 1·02 ± 0·03 m.y., was magnetically somewhat unstable, but also appears to belong to the reversed polarity group. The remaining lava of this age group is a distinctive columnar olivine basalt that crops out on the road to Takamaka. Field observations suggest that the lava occurs adjacent to the edge of a valley eroded in the oceanite series; the valley was afterwards filled by lavas of the differentiated series. The directions of magnetization measured on three different samples from this particular olivine basalt agree to within a few degrees and indicate normal polarity. Two of the specimens were collected by one of us, and the third was obtained at a later time by Dr. M. W. McElhinny. All three samples were dated (Table 1), and the results agree closely at 1·01 ± 0·05 m.y. The rocks are holocrystalline; *RU*93 and *RU*182 are quite free of alteration, but *RU*92 showed incipient alteration which may account for the poor reproducibility of the age measurements on this sample. Because of the consistency of the results we are very confident of both the polarity and age measurements.

Table 1. Potassium–Argon Dates and Palaeomagnetic Polarity Results on Rocks from Réunion (*N*–Normal Polarity; *R*–Reversed Polarity) (Errors quoted for Dates are Estimates only, Equivalent to about the 95 per cent Confidence Level)

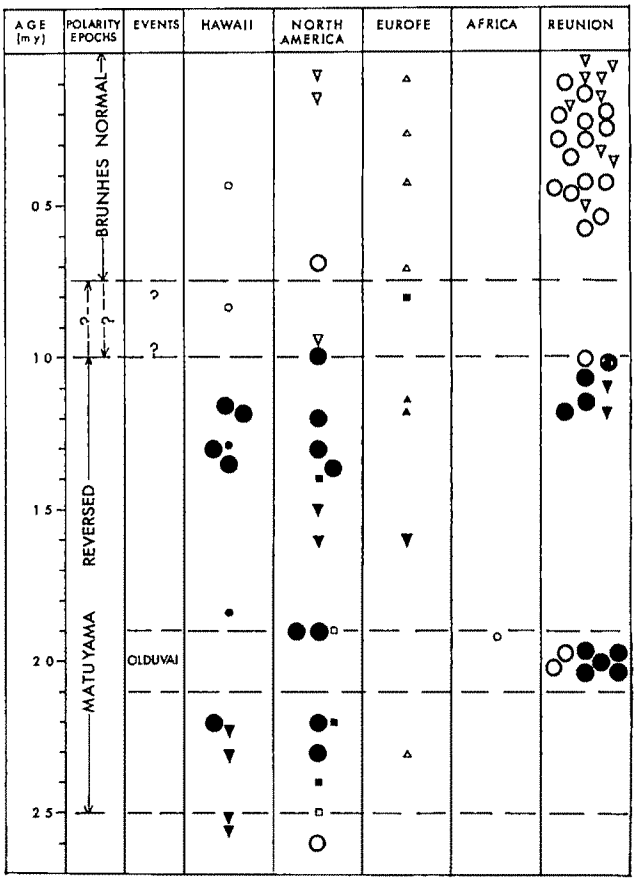

Fig. 1 Plot of potassium–argon dates versus magnetic polarity for rocks from Réunion, together with previously published data from elsewhere within the age range 0 to 2·6 m.y. See refs. 1, 3, 4, 5, 15 for sources of data. Open symbols, normal polarity, closed symbols, reversed polarity. Large circle, data appear to be satisfactory. Small circle, date determined on different sample from that on which palaeomagnetic measurement was made, although generally from the same formation. Triangle, polarity determined using a hand compass. Inverted triangle, uncertainty in age determination greater than 10 per cent. Small square, detailed information not published

These results suggest that a change from normal to reversed polarity occurred at about 1·0 m.y. The data available are too few to decide whether this is the boundary between the Brunhes normal and Matuyama reversed epochs. The results from Réunion and elsewhere indicate that normal polarity prevailed from the present back to about 0·7 m.y. ago, and that the polarity was reversed from about 1·0 m.y. to at least 1·9 m.y. ago (Fig. 1). The boundary between the two epochs must lie between 0·7 and 1·0 m.y., but because of somewhat conflicting evidence the relationships are not clear in this time range. The relevant data may be briefly reviewed. The normally magnetized Bishop Tuff, California, is dated at about 0·71 m.y.[12], and basalts with reversed polarity from Victoria and France are dated at 0·81 ± 0·03 m.y.[13], suggesting that a change from normal to reversed polarity occurred at 0·75 ± 0·07 m.y. A date of 0·84 ± 0·04 m.y. was recorded on a rock from East Maui, Hawaii[10]; it was inferred that this rock had normal polarity because other samples from the same volcano had this polarity[14]. Basalt of the Devils Postpile, California, has normal polarity and was dated at 0·94 ± 0·16 m.y.[3], and the Big Pine

obsidian is reversely magnetized and has a measured age of 0·99 ± 0·04 m.y.[15].

These data suggest that either the boundary between the Brunhes normal and Matuyama reversed epochs occurred at 0·75 ± 0·07 m.y., with a short interval of normal polarity (that is, an event) at close to 1·0 m.y., or that the boundary lies at 1·01 ± 0·03 m.y. and the reversed polarity of rocks dated at 0·81 m.y. records an event in an otherwise normal epoch. Another possibility is that self-reversal is partly responsible for the somewhat confused picture. Clearly many additional data are needed in the age range 0·7–1·0 m.y. to distinguish between the alternative explanations.

One of the most important findings from our work in Réunion concerns the third and oldest group of lavas from the oceanite series of Piton des Neiges. The eight samples which were used for the age determinations all give dates agreeing closely at 2·0 ± 0·1 m.y. Of these rocks three have normal polarity and five show reversed polarity. Two of the rocks of normal polarity were from the same lava flow about 30 m apart. However, several other samples from the same sequence also have normal polarity, and although they were not dated it is obvious that they must have essentially the same age. The age data are not precise enough to distinguish between the two groups, but at one locality it appears that rocks with reversed polarity conformably overlie rocks with normal polarity. According to the dates these samples belong to the Matuyama reversed epoch, which extends from 1·0 m.y. or younger to 2·5 ± 0·1 m.y.[1,2,4,5]. Hence, from Réunion we have evidence for normal polarity within the Matuyama reversed epoch, apparently indicating a normal event of short, but uncertain, duration. This can be correlated with the Olduvai event[4,5], which was first suggested from palaeomagnetic studies[16] on a basalt from Olduvai Gorge, Tanganyika, dated at 1·9 m.y.[17]. Our data provide strong confirmatory evidence for the reality of the Olduvai event, which we confidently date at 2·0 ± 0·1 m.y. Its existence also seems to be confirmed by work in the Pribiloff Islands, Alaska[5], but the data have not been published, so that no accurate comparison with the present investigation can be made.

The combined palaeomagnetic and age data from Réunion generally are in good agreement with results from other parts of the world. The results lend a[illegible] strong support for the hypothesis that geomagnetic [illegible] reversals are the main cause of the bimodal distribution of polarity. Our investigations emphasize the need for detailed work on rocks the ages of which lie between 0·7 and 1·0 m.y.

Although the main purpose of this article is to discuss polarity epochs a brief summary of some of the conclusions from the dating seems desirable. Piton des Neiges was active at least 2·0 m.y. ago and eruptions continued until as recently as 0·1 m.y. ago. The marked change in composition of the lavas of Piton des Neiges from basalts of tholeiitic affinities to alkali lavas occurred over a short interval of time of the order of 0·1 m.y. or less. This suggests a close genetic association between the two lava series, in agreement with conclusions reached from strontium isotope studies[9,18]. The data also indicate that Piton de la Fournaise was active at least during the period when the lavas of the differentiated series of Piton des Neiges were being erupted.

We thank R. Fanucci and E. Hugot for assistance while one of us (I. McD.) was in Réunion. Dr. M. W. McElhinny kindly collected some additional samples for us. J. A. Cooper, I. H. Ingram and J. Wasik provided technical assistance with the age determinations.

RADIO EMISSION OF GASES IN A HIGH-VOLTAGE DISCHARGE

By Dr. G. V. MCGARL and Prof. J. M. MARCHELLO
University of Maryland, College Park, Maryland

IT is well known that electric sparks are excellent sources of high-frequency radio noise. In the present experiments, radio emission from sparks in helium, argon, hydrogen, nitrogen, ammonia and air were measured to determine whether any characteristic emission spectra exist in the radio range for these gases when in the presence of a strong electric field and accompanying discharge.

The spark was drawn between two nickel electrodes in a 250-ml. spherical glass vessel. The entering gas continually flowed upward between the electrodes and left through an exit port in the top of the vessel. The electrodes were 3/8-in. cold-rolled nickel rods tapered to an 18° solid angle. The electrodes were threaded through nuts in the sidearms of the vessel. The sidearms were detachable so that the gap between the electrodes could be easily adjusted. The nuts in the sidearms were connected to the outside through tungsten rods which passed through the glass.

The power supply for the greatest number of runs was a 60-cycle high-voltage transformer having a 115 V input and 7,500 V output at a root mean square current of 0·089 amp. The power to this transformer was supplied by a 20-amp 'Variac' to control the voltage. A few runs were made with a high-frequency spark to determine if the characteristic radiations existed with a high-frequency power source. The power source for these experiments was a 27·132 Mc/s diathermy machine.

The glass reaction vessel was surrounded by a radio shield consisting of a grounded copper-screen wire box. The antenna was a combination dipole and wire loop antenna for the range from 0·19 to 1·65 Mc/s and a wire loop antenna for the range of 1·65 to 30 Mc/s. The antennae were mounted inside the radio shield close to the react[illegible] vessel and parallel to the electrodes. The radio r[illegible] was a five-band 'Hallicrafter' model *S*-118 equip[illegible] a standard 'Hallicrafter' *S*-meter kit to me[illegible] strength. The radio ground was common[illegible] wire shield and the transformer.

The gases used were as supplied b[illegible] and no attempt was made to purif[illegible] cases the gases contained less than

Table 1

Gas	Peak emission frequencies: Peak frequency Mc/s	Ratio of peak strength to base signal strength: Mean	Range	Comment
Argon	0 32	1 2	1·1–1 3	Possible
	0·70	1·2	1 1–3 0	Possible
	1·3	1 6	1 1–2 0	Definite
	2·8	1·2	1·1–2 5	Possible
	7·0	1·6	1·2–3 0	Definite
	9 0	1·6	1 2–3 0	Definite
	13 0	2 1	1 2–4 0	Definite
	17·0	15 0	1·1–2 0	Definite
	21·0	2·2	2 0–3·0	Definite
Helium	1·1	1·8	1 2–4 0	Definite
	2 0	1·5	1·2–5·0	Definite
	2·6	1·3	1·0–4·0	Possible
	9·0	1·8	1·5–3 0	Definite
	13 0	1 9	1 5–2 0	Definite
Hydrogen	None			
Nitrogen	0·25	3·3	2 0–9 0	Definite
Ammonia	0 25	2·5	2 0–10,000	Definite
Air	0 25	6 0	5 5–3,000	Definite

The *S*-meter was set at zero by removing both the antenna and the ground wires and shorting out these terminals. The entire five bands were then scanned for background without either spark or antenna and the frequency which gave the lowest signal was determined. Using the variable potentiometer in the kit, this quietest point was then set to zero on the *S*-meter. From time to time this procedure was undertaken to adjust for shifts in the zero of the *S*-meter.

Before each run 4 or 5 l of the gas to be investigated were passed through the reaction vessel to ensure that the gas within the vessel was essentially the same as that in the supply tank. Sufficient voltage was then placed across the electrodes to initiate a discharge. If the 7,500 V available was insufficient to initiate a discharge, a 'Tesla' coil-leak detector was used.

After initiation, the power was set at the desired level by adjusting the input voltage. The apparatus was then run for at least 1 h to allow for stabilization. After the period of stabilization, the signal power, as indicated by the *S*-meter, was recorded as a function of frequency over the range from 0·19 to 30 Mc/s. This measurement was then repeated several times during the next hour to check for drift. The power to the discharge was then shut off. Immediately following this, the reading was repeated in order to determine the background intensity.

The characteristic frequency of each observed peak and its signal strength relative to the adjacent radio noise level are presented in Table 1 for each of the gases investigated. Figs. 1, 2 and 3 are typical curves of the observed radio emission for the gases. The discontinuities in the curves are caused by band changes in the radio receiver. The dipole antenna was designed for use in the first two bands, and consequently the signal strength in these bands appears higher than in the other bands. In general, the sensitivity of the antenna receiver combination decreased with increasing frequency, as is shown by the decline in the base line evident in the figures.

Figs. 1 and 2 show some characteristic emission curves for argon. Table 1 shows that argon exhibits six definite emission frequencies. These are at 1·3, 7·0, 9·0, 13·0, 17 0 and 21·0 Mc/s. There are also three possible peaks at 0·32, 0·7 and 2·8 Mc/s. In general, these peaks are weak and did not appear as definite on some occasions as the other peaks.

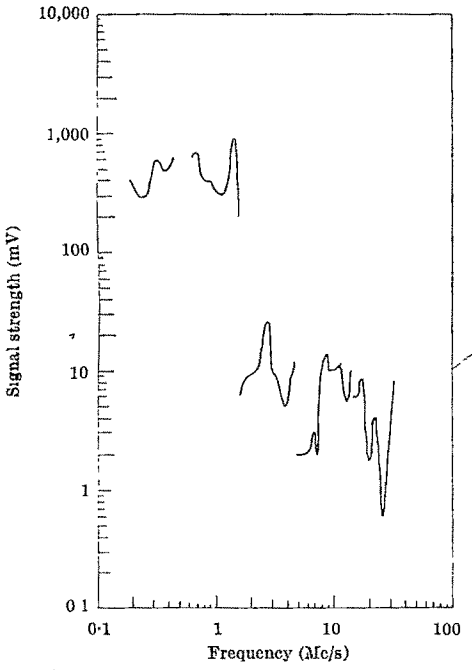

Fig 1. Radio emission spectrum of argon

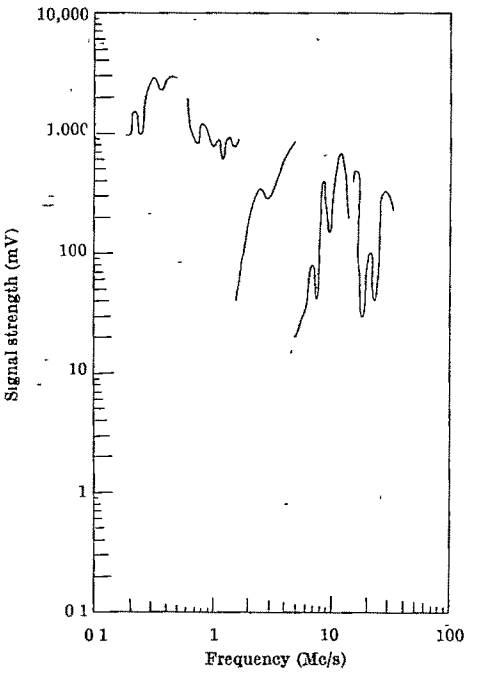

Fig. 2. Radio emission spectrum of argon, wet, short electrode gap

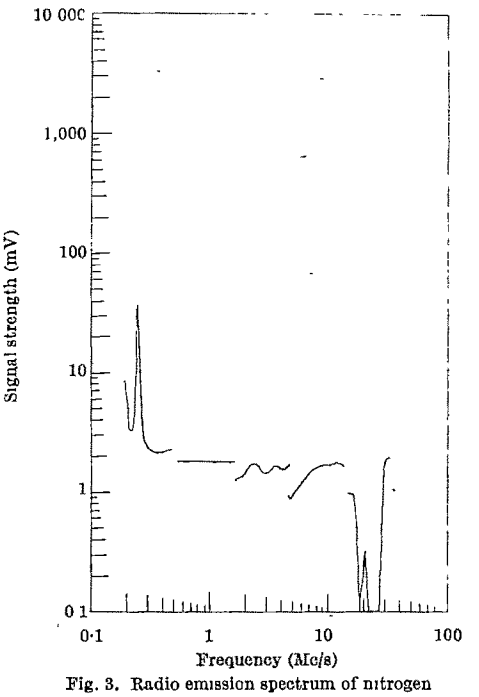

Fig. 3. Radio emission spectrum of nitrogen

Helium exhibits four definite characteristic emission frequencies. These are at 1·1, 2·0, 9·0 and 13 Mc/s. There is also a possible peak at 2·7 Mc/s; however, it is somewhat weaker than the others and could not be detected on several occasions.

As indicated in Table 1, hydrogen shows no characteristic peak frequency. A uniform radio noise was observed across all five bands. The signal strength decreased with increased frequency, due to the antenna, similar to the levels of base noise in Figs. 1 and 3.

For air, ammonia and nitrogen, only one characteristic frequency was observed. This occurs at 0 25 Mc/s. Since ammonia decomposes in the discharge to nitrogen and hydrogen, and air is four-fifths nitrogen, it seems that the 0·25 peak is characteristic of nitrogen. On occasion a peak near 0·25 Mc/s appeared in the argon discharge. This may have been due to a trace amount of nitrogen in the argon. This argument is supported by the relatively strong signals obtained at 0·25 Mc/s as shown in Table 1.

In the majority of runs the cold electrode gap was 2·5 mm and the power input was 290 W. This corresponded to an average field strength of about 6,400 V/cm. In several cases the gap distance was reduced to 1·5 mm and the corresponding field strength was about 8,500 V/cm. The effect of changing the electrode gap is illustrated in Figs 1 and 2. The general conclusion is that changing the gap changes the noise level, but does not affect the position of the peaks.

Figs. 1 and 2 also indicate the general drift in signal strength, since they represent two runs that were made several months apart. The base level varies with the physical conditions of the electrodes. Large changes in the base level can be effected by the simple expedient of cleaning the electrodes with a wire buffing wheel. Fig. 2 also shows that there is little, if any, effect of a small amount of moisture on the emission of the radio signals.

The effects of changing pressure and power level were also investigated. Increasing the power supply simply increases the noise level, but does not shift the characteristic frequencies. Reducing the pressure reduces the signal strength and does not change the peak emission frequencies.

In several runs the diathermy was used as a power source for the spark discharge in helium at one atmosphere. Over the first four bands, the diathermy discharge gave a low noise level and no peaks. In the fifth band, which contains the diathermy's rated signal frequency of 27·132 Mc/s, the signal increased uniformly and went off scale on the *S*-meter as the diathermy frequency was reached. The radio emissions observed for the 60-cycle discharge are apparently not excited by the high-frequency discharge. This may be because the frequency of the discharge is higher than any frequency of the emission peaks presented in Table 1. In addition, the mean field strength is in the order of one-half that of the 60-cycle discharge. The mean electron energies may be considerably less because the field reverses much more frequently.

It appears that the observed radio emission frequencies are a submacroscopic phenomenon. This hypothesis is based on the failure of the observed frequencies to shift with changing pressure or with changing electric field strength and power. If the frequencies were a plasma resonance effect, they would be expected to shift with pressure. If this were a system resonance effect, different characteristic frequencies for the different gases would not be expected, and a shift with changing field strength would be expected.

The various mechanisms by which plasmas are known to emit radiation are[1,2]: radiative recombination, bound electronic transitions, radiation in free-free transition bremsstrahlung, and possibly from magnetofluid-mechanical waves. It seems quite unlikely that recombination and bound transitions would involve energies as low as those corresponding to the observed radio frequencies.

The radiations studied by radio astronomers at present contain only one singular wavelength, the 21-cm line (1,420 Mc/s) emitted by hydrogen in the neutral state[3]. This line corresponds to hyperfine transitions of the neutral atom between its two possible spin states. The 21-cm line for hydrogen and the corresponding hyperfine lines for other substances ordinarily lie considerably above the radio frequencies observed in the present experiments.

Macroscopic phenomena in plasmas that involve electromagnetic radiation are electron and ion resonance and magnetic waves. Substituting the root mean square current and voltage in equations for the electric conductivity of slightly ionized plasmas indicates that the degree of ionization is 10^{-4} (ref. 1). For the gases at atmospheric pressure used, this corresponds to electron and ion concentrations of 10^{-15}/c.c. Thus the electron and ion concentrations vary from near zero when the field reverses to slightly more than 10^{15} at peak field strength.

The fact that 60-cycle current gives the radio signals while 27·132 Mc/s current does not may indicate that the heavy ions rather than the electrons are responsible for the signals. For the average concentrations mentioned above, the corresponding plasma electron frequency is 10^{-12}/sec (1), and the plasma frequency for argon is 10^{-9}/sec. Both these values are well above the observed frequencies. In addition, it is difficult to see how macroscopic plasma resonance frequencies which are usually determined for radio and microwave transmission and absorption can be expected to be responsible for discrete radio emission.

Since the gas collision frequency is in the order of 10^{-10}/sec whatever process is emitting, the radio signals must withstand several thousand collisions. In addition, the build-up and reversal of the electric field every 1/120 of a second is so slow that it seems impossible for resonance coupling to take place between the slowly varying field and the radio emission process.

Alfvén waves have been observed in gas discharges when strong magnetic fields are used[4]. It seems unlikely that they have any connexion with the observed signals, as they are restricted to frequencies which are small compared with the ion cyclotron frequencies in the magnetic field. Since no magnetic field was applied, the only field present is that which arises from the flow of current. There is little reason to believe that these magnetofluid-mechanical waves could account for the observed radio signals.

During the build-up and decay of the electric field, the electrons will receive varying amounts of energy from the field. For argon some of the electron velocities will pass through the critical value required in the Ramsauer effect[2]. At one atmosphere, an electron, on the average, will gain 0·30 eV between collisions from the field in the case of the 290 W. For argon[2] the minimum cross-section of 1 Å^2 occurs for electron energies of 0·55 eV and the maximum cross-section of 26 Å^2 occurs at 13 eV for the bombarding electron energy. As the field strength changes some electrons should pass through the region of almost complete transparency corresponding to the minimum in the collision cross-section. The Ramsauer effect does not occur in helium because the strength of the potential well is insufficient to produce a phase difference of 180° for the partial reflexion.

If the electron collision cross-sections pass through a minimum and a maximum, as they would for argon, the electric conductivity, which is inversely related to the cross-section, would also show considerable variation during the build-up and decay of the electric field. Such a change in cross-section could also permit an apparent emission peak in the otherwise continuous bremsstrahlung which arises from free-free transitions between electrons and heavy particles[2]. While this somewhat involved argument might be applied to argon, it will not, apparently, suffice for helium and nitrogen. Thus the radio strength

bremsstrahlung interactions can hardly be expected to provide an explanation for the observations.

The Stark effect[5] offers a potential explanation of the data. The splitting of the spectral lines in an electric field is not symmetrical about the original line, and the energy shift is given by the product of the field strength and the dipole moment. However, available data on hydrogen, helium and sodium indicate that the energy levels between the split spectral lines are considerably larger than the energy of the observed radio signals.

Cathode sputter arising from the collisions of ions and atoms with the electrode surface may be the cause of at least some of the radio signals. There is little information available from theory or experiment to allow a decision on the contribution that cathode sputter may make. Previous investigations have reported sputter rates in the order of the collision frequency of the particles with the surface[2]. If this is the case, sputtering rates at one atmosphere are several thousand times above the observed frequencies.

The particle-surface energy levels are very closely spaced near the top of the potential well, and it is possible that radio frequency transitions may occur between bound states near the top of the well for particle-surface interaction[2]. It seems unlikely that these will be sufficiently discrete to explain the observed signals. On the contrary, it appears that the transitions, if they occur, will give nearly continuous signals much like the bremsstrahlung emission.

Some support for the cathode sputtering argument is found in the fact that polishing the electrodes increased the background radio emission level. Since polishing did not influence the location of the emission peak frequencies, it is difficult to see how this particle-surface interaction can provide an explanation for the observations.

Since radio signal strength readings were taken over long periods of time, and a given frequency was often observed for many minutes, the results reported are average values which represent a great number of occurrences of the emission phenomena. None of the aforementioned radiation emission processes offers a satisfactory means of explaining these observations and it appears that the observed emission process arises by some mechanism not previously considered or reported.

LASER INTERFEROMETRY OF A DROPPING MERCURY ELECTRODE

By PROF. J. LEJA

Department of Mineral Engineering, University of British Columbia, Vancouver, British Columbia

AND

PROF. R. N. O'BRIEN

Department of Chemistry, University of Alberta, Edmonton, Alberta

SINCE the advent of the uniphase output, low wattage C. W. gas laser, the long path-length interferometer has become practical for the study of phenomena in the liquid phase. The study of concentration polarization around working electrodes has already received attention in thin cells, but the laser light source with its high degree of spacial and temporal coherence now permits the use of a thick enough cell to contain a dropping mercury electrode. Using such a long-path interferometer (identical to short-path models described previously[1,2], but substituting a laser for a sodium vapour lamp) the first qualitative results on transport mechanisms around the dropping mercury electrode are described here.

The original Ilkovic equation (where $i_d = 607\, n\, D^{\frac{1}{2}}\, C\, m^{\frac{2}{3}}\, t^{\frac{1}{6}}$, i_d is the average diffusion current, n is the number of faradays per mole, D is the diffusion coefficient of the electroactive substance, C is its concentration, m is the rate of mercury flow, and t the drop time), represented by curve 1, falls far short of describing the experimental current-time relationship[3], curve 2, plotted in Fig. 1 (taken from Markowitz and Elving[4]).

The main deficiencies of the equation are the assumptions that (1) during the initiation of drop formation a constant concentration is always encountered; (2) the rate of flow of mercury is constant; (3) mass transfer is by diffusion and migration only (and not by convection). The mathematical treatment of Matsuda[5] (curve 3 on Fig. 1) has shown that the discrepancies are not due to lack of mathematical rigor but to inadequate assumptions regarding the physical situation.

Without the knowledge of precise physical data, Markowitz and Elving made logical corrections to two of the aforementioned assumptions (assuming depletion of electroactive material around the capillary tip, and following the Lingane and Loveridge[6] method to account for the effect of convection on the current) and derived expressions plotted as curves 4 and 5, Fig. 1, which approximated the experimental data much better than either the Ilkovic or Matsuda formulae. Curve 4 differs from curve 5 in that in curve 4 a planar rather than spherical spacial distribution of a parabolic concentration gradient is used.

Curve 2 represents the experimental data of Taylor, Smith and Cooter[3]. The solution was $3{\cdot}018 \times 10^{-3}$ M Cd^{2+}, the diffusion constant assumed was $7{\cdot}2 \times 10^{-6}$ cm²/sec and the mercury flow was 2·305 g/sec, giving a drop life time of 3·392 sec.

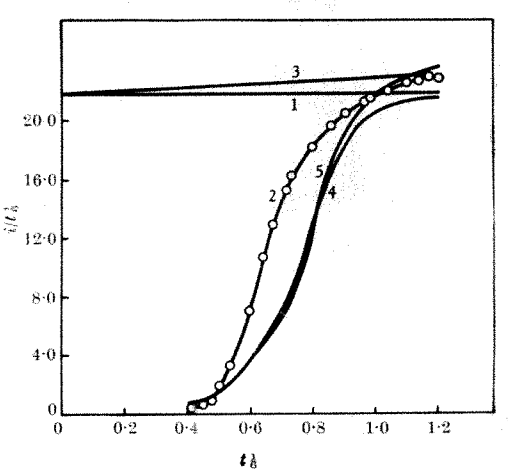

Fig. 1. Theoretical and experimental current-time dependence at the dropping mercury electrode taken from Markowitz and Elving (ref. 4). Curve 1 is the simple Ilkovic equation. Curve 2 shows the experimental results of Taylor, Smith and Cooter (ref. 3). Curve 3 is Matsuda's equation (ref. 5). Curves 4 and 5 are those of Markowitz and Elving using a plane and spherical approximation of an initial parabolic concentration gradient, respectively

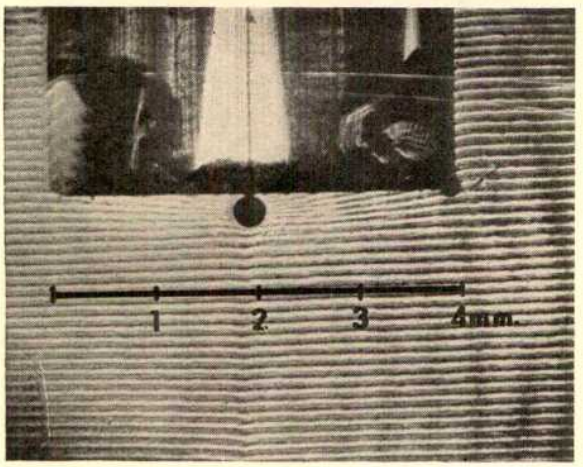

Fig. 2. Maximum concentration observed around a mercury drop. The solution is 0·1 N lead nitrate, 1 N potassium chloride at −1·40 V. The concentration of lead nitrate is about zero at the mercury-solution interface at the top of the drop

Elving (to whom we are indebted for the suggestion of the form of this work) and Markowitz assumed the concentration encountered by an emerging drop was always 2/3 C_0, where C_0 is the bulk concentration of the electroactive species. Fig. 2 is an interferogram taken with a motion picture camera in 0·1 N lead nitrate with 1 N potassium chloride supporting electrolyte at −1·4 V. The spacial distribution is far from spherical or planar but does have the shape which would be expected if a convective upward flow of electrolyte around the capillary was occurring, and this is what has been observed by following the movement of suspended rosin particles.

Fig. 3 is an interferogram taken when an attempt was made to start the camera, mercury flow and current simultaneously. The salt bridge is shown at the right. Potassium chloride is diffusing out of it into the less concentrated cell solution (0·1 N lead nitrate, 1 N potassium chloride, electrolysed at −0·45 V, drop time 1¼ sec) and convection upward is occurring, distorting the diffusion perturbation to the fringes to the right at the bottom of the frame and carrying some of the lower refractive index solution up between the salt bridge and the capillary. It should be noted that the concentration change at this unfavourable voltage (just within the range of the normal polarographic wave for lead ion) is very small compared to that in Fig. 2 at −1·45 V, the top of the polarographic wave.

Fig. 4 is a series of interferograms: 4*a* was taken of the same drop as Fig. 3, 1¼ sec later as the drop is about to fall, and 4*b* is $\frac{1}{16}$ of a sec after this. The drop has fallen and its 'ghost' is just visible. A very small concentration gradient over the whole bottom area of the capillary is just visible (breaks in the first and second double fringes, and the ninth, tenth, eleventh, twelfth and thirteenth below the capillary are optical defects in the cell) and has the same convection-influenced form as Fig. 2.

Fig. 4*c* was taken, 1¼ sec later, of the next drop as it is about to fall. The general, slight slope in the concentration gradient is now slightly increased, but the gradient immediately around the drop is much more pronounced. Comparing this with Fig. 2 (and assuming that the refractive index of lead nitrate is greater than that of copper sulphate at 6328 Å as it is known to be at 5893 Å), the concentration of lead ion is near zero at the upper part of the drop in Fig. 2 and about 2/3 C_0 in Fig. 4*c*. Fig. 4*d* was taken $\frac{1}{16}$ of a sec after Fig. 4*c* and shows the new drop already forming.

We believe that this is the first interferometric motion picture work done on the dropping mercury electrode, although high-speed motion pictures have been used to correlate drop formation and electrical phenomena[7].

Improvement in photographic techniques and measurement of the refractive index of lead nitrate solutions at the laser wave-length will soon make it possible to obtain quantitative results. Meanwhile, there would seem to be

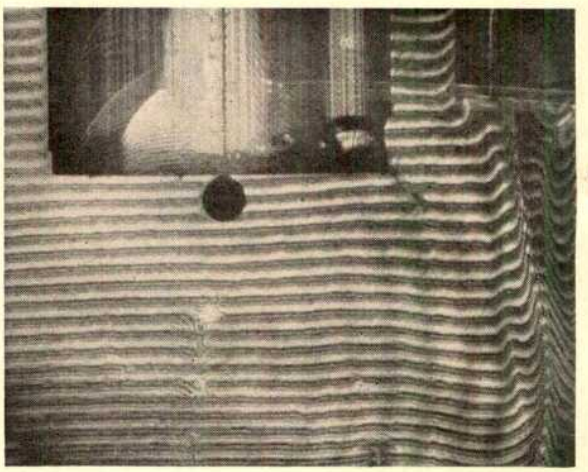

Fig. 3. The first drop of mercury to flow into the cell. The camera and current (voltage −0·45 V) were turned on at the same time as the mercury began to flow. The salt bridge is seen to the right of the capillary. The solution is the same as Fig. 2

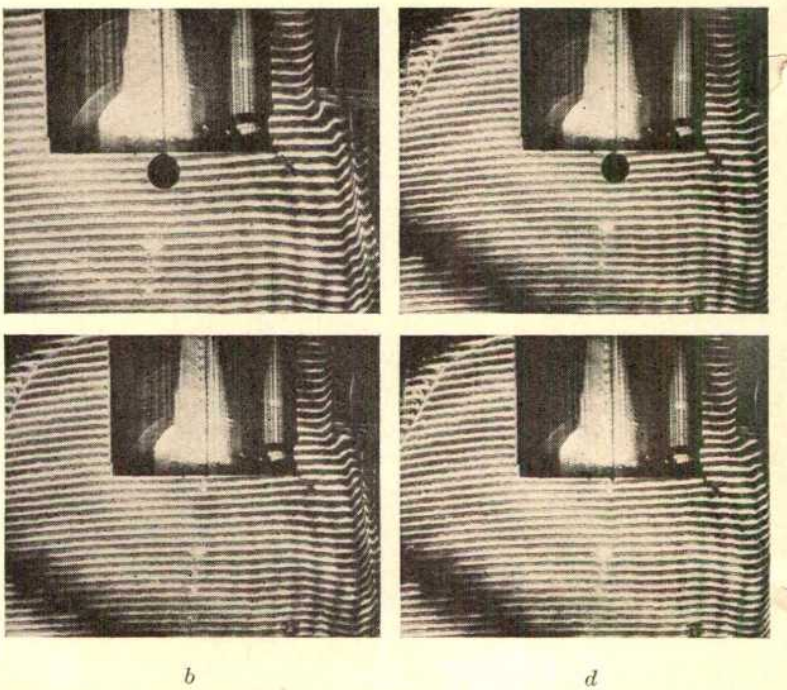

Fig. 4. A series of interferograms taken subsequent to Fig. 3. Frame *a* was taken 1¼ sec after Fig. 3, and frame *b* was taken $\frac{1}{16}$ of a sec later showing the ghost of the drop after it has fallen and very little concentration change. Frames *c* and *d* are photographs taken of the next drop again 1¼ sec and $1\frac{1}{16}$ sec later showing the increase in concentration gradient with successive drops

no doubt that concentration polarization, not spacially spherical or constant with time of electrolysis around the drop, is dependent on applied voltage and natural convection.

The experimental work was done by P. Winkelaar and J. Wojno and supported by the National Research Council of Canada, whom we thank.

ELECTROLUMINESCENCE OF TRANSFORMER OIL AND LIQUID PARAFFIN IN HIGH D.C. FIELDS

By E. JONES and L. ANGERER

Dielectric Liquids Laboratory, Department of Electrical and Control Engineering, Battersea College of Technology, London, S.W.11

RELATIVELY little information is available regarding the electroluminescence of insulating oils. Darveniza and Tropper[1,2] have described electroluminescence phenomena in transformer oil, its constituents and in simple organic liquids containing fluorescent materials, when they are subjected to high d.c. stresses. Emission of light, conduction current and stress relationships were investigated and also the effect of added impurities on the breakdown voltage of the solutions.

The study has been continued, for some time, at this Laboratory and the results presented here give more information about these phenomena. The test liquids used were transformer oil and liquid paraffin. Anthracene and 1,4-*bis*-2-(5-phenyloxazolyl)-benzene (POPOP) were used to study their effect on conduction current and light output.

The test samples were prepared by filtering through a No. 5 sintered glass filter and degassing to a pressure of 10^{-3} mm mercury. The test cell had a capacity of about 10 ml. and two nickel electrodes of 5 mm diameter were used to form the test gap. An eleven-stage photomultiplier was placed adjacent to a synthetic quartz window, perpendicular to the common axis of the spheres, and a microscope with a magnification of 100 was used for visual observation.

All tests were preceded by an electrical prestressing period in an attempt to stabilize the conditions during the tests. The effect of prestressing on the conduction current was similar to that reported by other workers[3–5]—2 h being needed to obtain reproducible measurements. The photomultiplier anode current was much greater at the beginning of the prestressing period and decreased with time in an approximately exponential manner, the mean value of the light output decreasing by several decades. In most cases, reasonable steady values for mean light output could be obtained after a period of 20–30 min of prestressing. Further stressing, for as long as 6 h, resulted in only small further decrease of about 30 per cent in the light output.

The photomultiplier had an *S*13 cathode with the spectral response covering from 1600 to 7000 Å and was connected to a Vibron electrometer by means of a cathode follower. A high-speed oscilloscope was used for a study of the photomultiplier anode current waveshape and a d.c.—10-c/s pen-recorder was used to record the fluctuations of light output.

The photomultiplier anode current consisted of a series of discrete pulses even when the liquid was highly stressed. The number of pulses increased with the applied stress and it was found that the mean value of the anode current was proportional to the pulse count. Fig. 1 shows typical conduction current and light pulses as seen on the oscilloscope screen at different stresses. The shape of the individual pulse appeared to be a function of the detecting circuitry. The use of a soda glass filter gave no appreciable change of the mean value of the photomultiplier current.

From time to time a sudden increase of the anode current of the photomultiplier was observed; this decayed in a generally exponential manner in a few minutes. Furthermore, even under the most stable conditions, a small variation of the anode current, about its mean value, was always present. Fig. 2 shows such an increase of light output with consequent decay and the fluctuation of light output about its mean value.

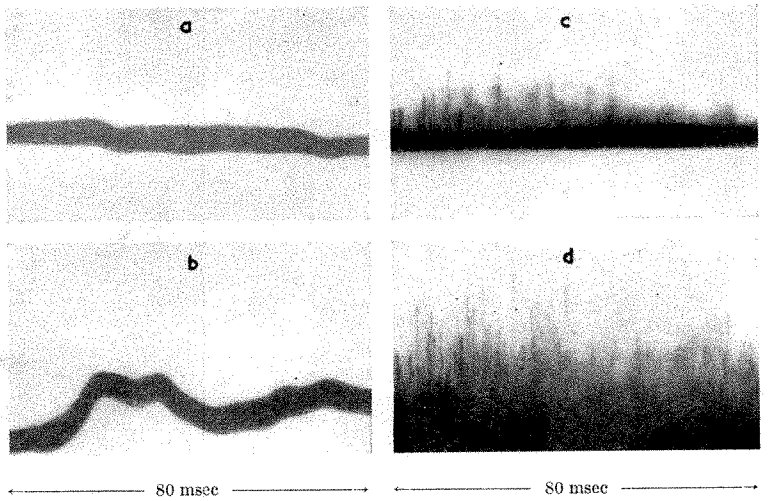

Fig. 1. Fluctuation of conduction current and light output pulses at different constant stresses. *a* and *b*, Fluctuation of conduction current at stresses of 200 kV/cm and 600 kV/cm, respectively. *c* and *d*, Light output pulses at stresses of 200 kV/cm and 600 kV/cm, respectively

From many tests a straight line for $\log_{10} B$ (light output) mean stress characteristics was obtained for several decades, but in some cases a pronounced curvature was also observed. Several minutes of stressing were required, at each value of applied stress, to allow the light output to settle to a stable value before the measurements were taken. The light output was observed to be lower for ascending values of stress than for descending values. Accidental breakdowns were found considerably to affect the light output. The effect was observed to be most marked with the first breakdown—subsequent breakdowns had less effect, providing there was an adequate prestressing period of the sample after a breakdown.

For nearly all the tests plots of $\log_{10} B/\log_{10} I$ (light output versus conduction current) yielded linear relationships

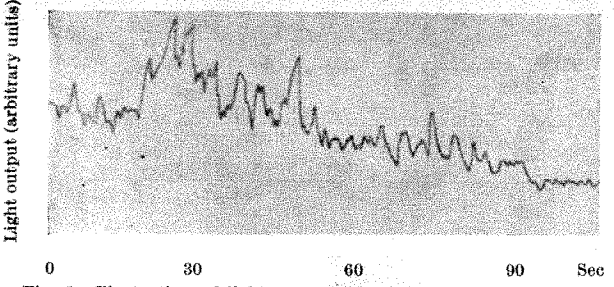

Fig. 2. Fluctuation of light output (photomultiplier anode current) under constant stress of 600 kV/cm. The figure shows a sudden increase in light output which decayed in about 90 sec

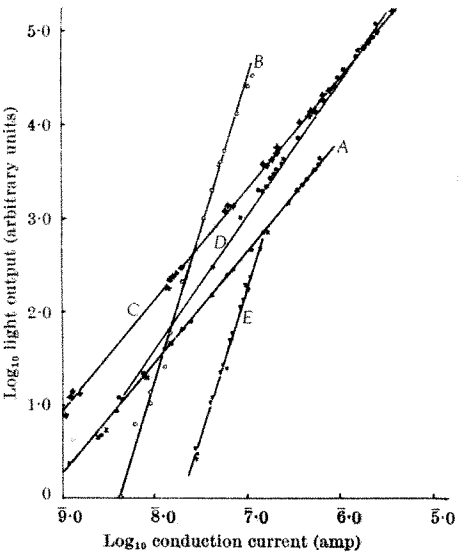

Fig. 3. $\log_{10} B/\log_{10} I$ (light output-conduction current) characteristics. *A*, Liquid paraffin and transformer oil; *B*, liquid paraffin containing POPOP at a concentration of 2×10^{-5} mole/100 g (28μ, 51μ, 81μ and 125μ gaps); *C*, transformer oil containing POPOP at a concentration of 2×10^{-5} mole/100 g (125μ gap); *D*, transformer oil containing POPOP at a concentration of 2×10^{-5} mole/100 g (51μ gap); *E*, liquid paraffin containing POPOP and dissolved nitrogen at atmospheric pressure (125μ gap)

over several decades. This is in agreement with the results reported by Darveniza and Tropper[2] and by Kalinowski and Dera[6]. Hysteresis effects were relatively small with no significant consistency. There was also no significant change of the slope of the characteristics for different gap settings. As can be seen from Fig. 3, pure liquid paraffin and transformer oil gave the same characteristics for all gap settings. Straight line $\log_{10} B/\log_{10} I$ characteristics were also obtained for solutions of liquid paraffin and transformer oil containing POPOP at a concentration of 2×10^{-5} mole/100 g of solvent but the slope of the characteristics was considerably changed. The presence of POPOP in both solutions resulted in an increase of conduction current followed by a considerable increase of light output.

Visual observations of the gap revealed that at very high stresses a visible luminescence could be observed in transformer oil and in solutions containing POPOP. For lower stresses no visible luminescence was noted in either liquid. In the case of pure liquid paraffin and transformer oil at high stresses, occasional transient spots of light have been observed—the light output under these conditions varying appreciably about its mean value.

Luminous spots in insulating oil gaps, subjected to high d.c. stresses, were also observed by Dakin and Berg[7], who attributed them to the luminescence of transformer oil molecules excited by electrons emitted from points of high localized electric stress on the electrodes. Similar phenomena were reported by Eidel'berg[8], who investigated the electroluminescence of castor oil in high a.c. fields. Two types of luminescence were observed: bright spots, at lower stresses, which flashed up and vanished very quickly, and at higher stresses, weak steady luminescent spots the brightness of which increased with applied stress. Both phenomena were also simultaneously observed.

A hysteresis effect was reported by Tumerman and Czajakow[9], who found that this effect can be reduced by increasing prestressing period or increasing the frequency of applied voltage. These authors also reported the difference between light signals as obtained from paraffinic wax and liquid transformer oil induced by uni-directional trapezoidal pulses. In transformer oil a series of short-duration pulses were observed, their frequency depending on the magnitude of applied voltage and the steepness of the trapezoidal wave front.

We thank Prof. W. F. Lowering for providing facilities and advice.

COMMON MODE OF ACTION OF THREE AGENTS THAT DECREASE THE TRANSIENT CHANGE IN SODIUM PERMEABILITY IN NERVES

By BERTIL HILLE
The Rockefeller University, New York

VALUABLE clues to the nature of the ionic permeability changes accompanying the excitation of nervous tissues will come from a detailed analysis of the effects of chemicals applied directly to nerve membranes. For two primary reasons the node of Ranvier of single myelinated frog fibres is a good preparation in which to study the mechanism of action of applied reagents: (1) the cell membrane is exceptionally naked at the node; (2) a complete biophysical description of nodal currents and voltages is possible. Electron micrographs[1] show that the only visible barrier between the bathing medium and the excitable membrane is a basement membrane and a loose collar of pseudopod-like processes of the adjacent Schwann cells. The membranes of these processes are not found to be in contact with the nodal membrane. In nearly every other common nerve preparation a uniform, closely adhering cellular layer bounded in turn by a basement membrane covers the nerve surface. The nakedness means that applied local anaesthetics, for example, have full effect within seconds and can be washed out almost completely[2]. The second advantage of the node follows the availability of a voltage clamping technique[3,4]. The Hodgkin–Huxley[5] equations for ionic currents of the squid giant axon modified by using different values for the

empirical rate constants account for the normal action potentials and other electrical responses of *Rana pipiens* nodes[6,7].

This article reports voltage-clamp analyses of the rapid, reversible effects of a powerful toxin, a local anaesthetic, and a tranquillizer. All three affect the sodium conductance in the Hodgkin–Huxley model. This change can be interpreted in terms of a physical model.

Data from voltage-clamp experiments on large fibres of the sciatic nerve of *Rana pipiens* were recorded and analysed with the aid of a computer. Every 50 μsec two digital samples, one of current and one of voltage, were stored using an on-line analogue-to-digital converter associated with a 'Control Data 160*A*' digital computer. Each voltage-clamp command pulse was applied in duplicate to the nerve, and the data of the duplicate runs were automatically added before being recorded on magnetic tape. The magnetic tape could be analysed immediately or at any later time with a 'Fortran' programme which was designed to separate the sodium, potassium, and leakage currents and to extract the kinetic and amplitude constants of the Hodgkin–Huxley equations. The computer programme could also draw graphs of the intermediate stages of the analysis such as: current-voltage diagrams, residual currents after subtracting leakage current, or sodium current after subtracting potassium current. One of these graphs is shown in Fig. 1. The separation of currents was achieved mathematically by fitting the Hodgkin–Huxley functions, and thus does not imply that the leakage current, for example, is carried only by ions other than sodium and potassium.

The membrane potential was held at −75 mV, approximately the normal resting potential. For the 25 msec preceding the variable command pulse the membrane was hyperpolarized to −120 mV. With this prepulse all steady-state inactivation of the sodium-carrying mechanism was removed. The standard experimental protocol was to measure the currents flowing in response to command pulses at nineteen equally spaced voltages from −67·5 mV to +67·5 mV absolute (each in duplicate) as well as to a pulse at −135 mV that measured the 'leakage' conductance. Successive 5-min periods in increasing concentrations of the experimental agent were alternated with 5-min periods in Ringer's. The preparation was maintained at between 3° and 10° C.

The drugs used were the puffer fish poison tetrodotoxin (gift of Sankyo Company, Ltd.), the local anaesthetic 'Xylocaine' (as the hydrochloride gift of Astra Pharmaceutical Products, Inc.), and the tranquillizer 'Compazine' (prochlorperazine ethane disulphonate), a close relative of 'Chlorpromazine' (gift of Smith, Kline, and French Laboratories). The drugs were applied as solutions in standard frog Ringer's solution buffered with *tris*-(hydroxymethyl) aminomethane at *p*H 7·2. At all concentrations a steady state effect was reached within the few seconds before the first measurements were made.

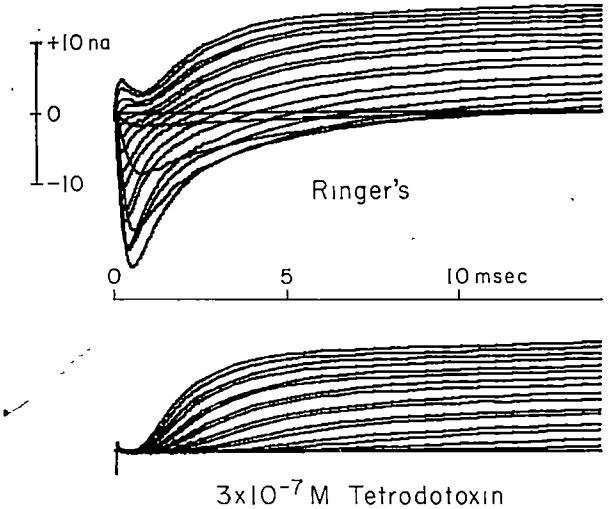

Fig. 1. Voltage-clamp currents plotted against time. The curves are drawn by the computer from raw data after subtracting the leakage current. Outward currents are positive. The nineteen clamp voltages were spaced at 7·5-mV intervals and spanned the range of membrane potentials from −67 5 mV to 67·5 mV. The two families of curves are the responses of the same node in a control solution and in tetrodotoxin

The effect of the agents on the current-clamped node was to raise the threshold, slow the rate of rise, and decrease the amplitude of the action potential without affecting the resting membrane potential. These changes are explained by a specific diminution of the sodium current seen in the voltage-clamp measurements. Fig. 1 is a plot of two families of ionic currents against time at the nineteen clamp voltages. The leakage component of the current has already been subtracted by the computer. In the upper family from an untreated node, the sodium current turns on and off in the first few milliseconds. At most depolarizations it appears as an inward current (negative on the graph) and at the largest depolarizations as an outward current. The outward potassium current turns on gradually as the sodium current wanes. In the lower family of curves from a node in 3×10^{-7} M tetrodotoxin, both the inward and outward sodium components are entirely absent. The same complete loss of sodium currents occurs with 5×10^{-5} M 'Compazine' and 10^{-3} M 'Xylocaine'.

Within the ionic hypothesis there are only three parameters whose variation could lead to a loss of the sodium current. The time constant of the turning on (τ_m) could be increased, the time constant of the turning off (τ_h) could be decreased, or the maximum available sodium conductance ($\bar{g}_{Na}$) could be decreased. To determine which of these changes occurred here we measured these parameters in normal nodes and in the same nodes treated with enough drug to approximately halve the sodium current: 3×10^{-9} M tetrodotoxin, 2×10^{-5} M 'Compazine' or 10^{-4} M 'Xylocaine'. In all cases the time constants were unchanged within the reproducibility of replicate clamp series in the same solution (about ±10 per cent at clamp-voltages that give fairly large currents), and no change was seen in the voltage dependence of steady-state sodium inactivation. Therefore, these three agents act primarily by reducing $\bar{g}_{Na}$.

While the reduction of $\bar{g}_{Na}$ is sufficient to explain the changes in the action potential we also looked for effects on the time constant (τ_n) and steady-state conductance (g_K) of the potassium component and on the conductance of the leakage component ($\bar{g}_L$). No changes were seen with tetrodotoxin up to 3×10^{-7} M, with 'Compazine' up to 5×10^{-5} M, or with 'Xylocaine' up to 5×10^{-4} M. At $3{\cdot}5 \times 10^{-3}$ M 'Xylocaine', $\bar{g}_K$ was reduced to 75 per cent of its original value without noticeable change in τ_n or $\bar{g}_L$. Higher concentrations of these reagents were not tried.

As the agents used here reversibly eliminated conduction in a nerve they may be said to have local anaesthetic action. This action was known before this investigation was started[8–10]. When the ionic basis of the action potentials of squid axons was clarified[5] it became apparent that non-depolarizing anaesthesia could be due to some kind of reduction of the transient inward sodium currents that underlie the rising phase of the spike. Shanes[11–12] reviews many studies that demonstrate (1) a summation of the effects of local anaesthetics and of treatments which decrease sodium currents: low external sodium, refractoriness, and depolarization by elevated external potassium or by applied electrical currents; and (2) an antagonism between local anaesthetics and treatments which enhance sodium currents: high external sodium, veratrine, and hyperpolarization by applied electrical currents. Thus our observations are not surprising. However, neither the specificity nor the precise nature of the sodium current reduction by anaesthetics has been previously described. Only recently, experiments with tetrodotoxin have demon-

strated that agents could be specific inhibitors of sodium currents[14]. Takata *et al.*[13] showed in giant axons from the lobster that tetrodotoxin reduces $\bar{g}_{Na}$ without affecting the sodium current kinetics. The present experiments agree with their observations and extend them to other agents. We expect that most local anaesthetics will be found to act in this way.

We believe that the principle of distinguishing physical components of biological tissues by their different chemical reactivities is a valid one and expect that it can be used to demonstrate the spatial as well as the functional separation of the formal parameters of the Hodgkin–Huxley equations. If this can be done, the formal parameters will seem less like an arbitrarily chosen set of variables of an abstract model and more like the one-to-one representations of physical properties of molecular constituents of the membrane. The specificity of tetrodotoxin has been used to argue that the sodium current channels are spatially separate from the potassium current channels[14]. We can extend this argument to 'Xylocaine' and 'Compazine'. The major effect of another compound, tetraethylammonium ion, is to reduce reversibly the delayed potassium currents of frog nodes[15,16]. A nerve in 6 mM tetraethylammonium chloride has almost no potassium currents, slightly diminished sodium currents, and 95 per cent of the normal leakage current. On the addition of 1·2 mM 'Xylocaine' we find little conductance remaining other than the leakage, which is unchanged. Thus the leakage channels, the sodium channels, and the potassium channels may be regarded as spatially separate, independent structures of the membrane, containing molecular configurations that react selectively with these reagents. Probably the reduction of $\bar{g}_K$ seen in high concentrations of tetraethylammonium ion or of 'Xylocaine' results from reaction with the potassium channel. These two compounds share some structural properties, but are different enough for 'Xylocaine' to favour the sodium channel over the potassium channel by a factor of about 100, while tetraethylammonium ion favours the potassium channel by a factor of more than 50.

The final subject of this article is a hypothesis regarding the mode of action of these compounds. We believe that the sodium channels of the nerve are closed or clogged individually by the binding of the anaesthetic molecule to a complementary structure in the channel. The molecule is active as a cation and approaches the binding site from the extracellular side of the cell membrane.

A binding equilibrium is suggested by the steady increase from no effect to nearly full effect over a ten-fold range of concentration with the steady state achieved rapidly and reversibly. A study of the apparent binding constants of various anaesthetic molecules in the isolated frog node could suggest the structure of a part of the sodium channel. The anaesthetic seems to be active as the cation because the guanidino group (pK about 12·5) of tetrodotoxin and the tertiary amino group of 'Xylocaine' and 'Compazine' (pK 7·9 and about 7·6, respectively) are largely ionized at pH 7·2. Perhaps the sodium channel bears a negative charge that attracts sodium ions, calcium ions, and other cationic molecules including the anaesthetics. The activity of the cationic form would seem to contradict the general clinical rule that local anaesthetics are more powerful in alkaline solution; however, it is recognized that this rule follows from the requirement of the free base for diffusion through layers of tissue to reach the site of action[9,17]. Indeed studies of the pH dependence of local anaesthesia clearly show that anaesthesia of isolated fibres is favoured by the cation while the anaesthesia of whole nerve trunks is favoured by the free base[18,19]. The molecules must be acting from the extracellular side because large extracellular charged molecules could not come to equilibrium with the axoplasm a few seconds after application. Truant[20] found that squid axons loaded with procaine are not blocked so long as the escaping procaine is washed away but are blocked if most of the surrounding fluid is blotted away and the anaesthetic accumulates outside the nerve. This effect can be repeated many times[12]. We have depicted the binding of the molecule as a clogging of the sodium channel because anaesthesia seems to decrease the available number of channels as reflected by the magnitude of $\bar{g}_{Na}$ without affecting the kinetic properties of those remaining.

I thank Dr. Frederick A. Dodge, jun., who designed most of the instrumentation, and Dr. H. K. Hartline, who made his computer available to me.

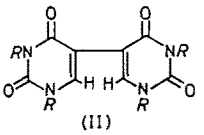
PHOTOCHEMISTRY OF 5-BROMOURACILS: ISOLATION OF 5,5′-DIURACILS

By HIROSHI ISHIHARA* and PROF. SHIH YI WANG

Departments of Radiological Science and Biochemistry, The Johns Hopkins University, School of Hygiene and Public Health, Baltimore, Maryland



ALTHOUGH the increased ultra-violet sensitivity of bacteria[1,2], bacteriophages[3,4] and mammalian cells[5] attendant on the incorporation of 5-bromouracil (BU (I)) or 5-iodouracil into DNA in place of thymine has been widely observed, the mechanism by which this occurs remains uncertain. Previously, it was believed that the photochemical conversion of halogenated pyrimidines to uracil in the DNA might be a lethal event[6], but this hypothesis has been refuted by the work of Rupp and Prusoff[7] and that of Hotz[8].

The ultra-violet sensitization produced by these thymine analogues could be due either to their greater photochemical reactivity[9] or to the inability of existing cellular mechanisms to repair the type of damage (photoproduct) produced[3,4]. In either case, the isolation and identification of the photoproducts of 5-halogenouracils and the

* On leave of absence from Chemical Laboratory, Nagoya City University, Mizuho ku, Nagoya, Japan.

study of their photochemical mechanisms is essential to a complete understanding of the enhanced ultra-violet sensitivity.

From the irradiation of BU and 5-bromo-1,3-dimethyluracil (BDMU) in aqueous solutions with germicidal lamps, many photoproducts were isolated, identified, and quantitatively estimated (*Biochemistry*, in the press). Among these are two coupled products (II): 5,5′-di-1,3-dimethyluracil ($R = CH_3$, DMU-DMU) from BDMU and 5,5′-diuracil ($R = H$, U-U) from BU. (To avoid confusion between the 'single bonded coupled product' and the '*cyclo*butyl dimer', we propose to abbreviate the former as U-U, DMU-DMU, etc., and to change the latter from the present abbreviation (TT, UU, TT) to U=U, T=T, etc.)

(II)

This type of coupled product, with only one single bond between two pyrimidine rings, may be of significance in photobiology. This article briefly describes the isolation and identification of these two coupled products.

Methods and Materials

Chromatographically pure samples of BU and BDMU (I), prepared according to the method of Wang[10], were used. For BU, λ_{max}^{HOH} 276 mμ, $\varepsilon = 7{\cdot}30 \times 10^3$; λ_{min}^{HOH} 241 mμ, $\varepsilon = 1{\cdot}76 \times 10^3$. For BDMU, λ_{max}^{HOH} 283 mμ, $\varepsilon = 8{\cdot}57 \times 10^3$; λ_{min}^{HOH} 246 mμ, $\varepsilon = 1{\cdot}57 \times 10^3$. General Electric 'Germicidal' tubes (*G15T8*) were used as our sources of ultra-violet light: these emit mainly at 253·7 mμ. For spectroscopic investigations, 25 ml. of a 0·1 mM aqueous solution was placed in an 8-cm diameter Petri dish and covered with a quartz-plate (the depth of the solution was 5 mm). One lamp was used for irradiation at proper distances for various dose-rates and the solutions were agitated during irradiation. Dose-rates of ultra-violet light were calibrated according to the method of Latarjet *et al.*[12].

For the synthesis of 5,5′-di-1,3-dimethyluracil (II)[13], 4·38 g of BDMU was dissolved in 25 ml. of dry nitrobenzene under refluxing with stirring. Purified copper powder (4·38 g) was added portion by portion over a 4-h period. The reaction mixture was then allowed to reflux for 2 days with stirring. Afterwards, the reaction mixture was filtered and most of the nitrobenzene was removed under reduced pressure. The remaining few ml. of nitrobenzene were removed by steam distillation. The aqueous solution so obtained was filtered and was concentrated for crystallization to yield 0·4 g of the crude product. Material twice recrystallized from absolute ethanol gave a melting-point at 281°–282° C (subl.). λ_{max}^{HOH} 272 mμ, $\varepsilon = 15{\cdot}1 \times 10^3$; λ_{min}^{HOH} 244 mμ, $\varepsilon = 7{\cdot}2 \times 10^3$. Analysis for $C_{12}H_{14}O_4N_4$ was: calculated, C, 51·79; H, 5·07; N, 20·44; found, C, 51·69; H. 4·97; N, 20·21 (kindly undertaken by Dr. S. M. Nagy, Microchemical Laboratory, Massachusetts Institute of Technology).

Spectroscopic Study

Wacker[6,14] reported that the ultra-violet absorbancy of an aqueous solution of BU remains unchanged during ultra-violet irradiation up to a total dose of 2×10^5 ergs/mm². On the contrary, we observed a continued increase in ultra-violet absorbancy at about 240 mμ when a 0·1 mM aqueous solution of BU was irradiated at a dose-rate of 15, 30, 45, 60 or 90 ergs/mm²/sec with a final total incident light dose of $1{\cdot}5 \times 10^5$ ergs/mm². When BDMU, a model compound, was irradiated in an identical manner, the increase in a shorter wave-length region was also observed in all cases, and was more pronounced with lower dose-rate. In addition, a decrease in absorbancy at the maximum was also observed and, in particular, there was a 5 per cent decrease at high dose-rate (90 ergs/mm²/sec) with a total incident light dose of $1{\cdot}5 \times 10^5$ ergs/mm². These preliminary spectroscopic investigations clearly demonstrated that BU and BDMU do undergo photochemical changes even with a small dose of ultra-violet light. The absence of any appreciable decrease in absorbancy at the maximum suggests that the photoproduct has a similar absorption spectrum in the neighbourhood of 270 mμ. It is indicative that the photoproduct may still possess the pyrimidine ring. The increase in the 240 mμ region implies that the photoproduct must have high absorbancy in this region. U-U or DMU-DMU becomes the most likely candidate because they contain two uracil moieties and have high absorbancy at 240 mμ.

Isolation Study

(1) *Fractionation after irradiation.* 10 l. of a 1 mM solution of BDMU were irradiated in quartz tubes for 1·5 h at room temperature under conditions described previously[11]. During irradiation, the *p*H of the solution changed from about 6·0 to about 3·0 and the absorbancy at 283 mμ decreased about 55 per cent. The solution was titrated to *p*H 9 with sodium hydroxide to release the volatile acids and to prevent the loss of volatile acids during evaporation. The solution (*p*H 9) was concentrated to about 10 ml. in a rotary evaporator at below 40° and subjected to continuous ether extraction for 5 days. In this way three fractions were obtained, namely, the distillate fraction, the ether extract, and the aqueous phase. The present article deals only with the ether extract.

(2) *Separation and identification.* The ether extract was evaporated to dryness and the residue was dissolved in 2 ml. of chloroform. 3 g of alumina (*p*H 10, for chromatography, Merck) were mixed with this solution and the chloroform was evaporated in a gentle stream of nitrogen. The sample was transferred quantitatively to a water-jacketed column packed with 75 g of alumina ($1{\cdot}5 \times 50$ cm) and was treated with various eluents (see Table 1). Eluates were collected in 25 ml. fractions. Quantitative estimations were made after evaporation to dryness. The residue from each fraction was dissolved in water and the ultra-violet spectrum recorded. On the basis of the amount of residue and of the ultra-violet absorbancy, seven large fractions were obtained. Each fraction was evaporated to dryness on a rotary evaporator below 40° C and dried over phosphorus pentoxide. The residue was extracted three times with chloroform and filtered. The combined chloroform solution was evaporated to dryness and the residue dried *in vacuo* and weighed (see Table 1).

These products were crystallized from water or ethanol and identified by comparing their melting-points, mixed melting-points, ultra-violet, and infra-red spectra, with those of authentic samples of the various products and by elementary analyses.

Table 1. Isolation and Identification of Photoproducts of BDMU in Ether Extract by Alumina Column Chromatography*

Fraction No.	Identified as	Tube No of eluates	Eluted with ethanol-ether (v/v)	Amount obtained (mg) By weight	Amount obtained (mg) By E_{270} mμ	Percentage in total ether extract
1	—	1–34	0 100 (ether alone)	<0 1	—	<0·01

† Other products will be described in a subsequent article

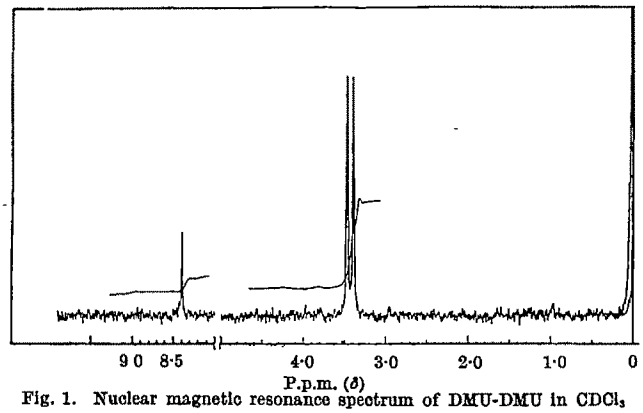

Fig. 1. Nuclear magnetic resonance spectrum of DMU-DMU in $CDCl_3$

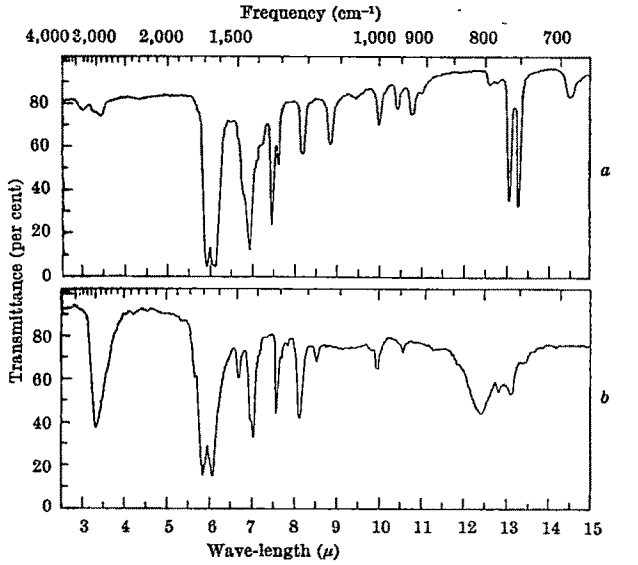

Fig. 2. Infra-red spectra of single-bonded dimers, DMU-DMU (*a*) and U-U (*b*) in potassium bromide pellet

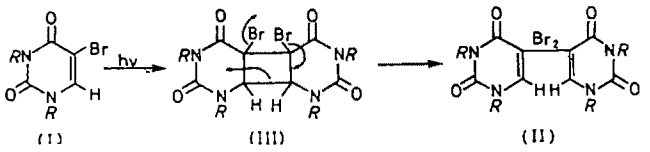
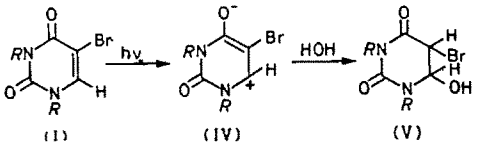


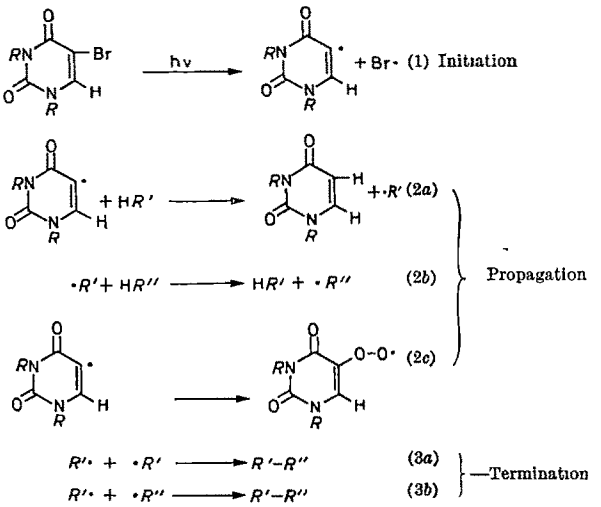
The nuclear magnetic resonance spectrum of DMU-DMU ($CDCl_3$) contains three singlets; one (δ8·42) is attributed to the proton at C (6) and the other two (δ3·40 and δ3·47) are for the methyl groups on N (1) and N (3) (Fig. 1). The singlet rather than a doublet for C (6) and the absence of a signal for a proton at C (5) (δ about 6) indicate that the compound is coupled through C (5) and C′ (5) atoms. This is compatible with the structure of the single-bonded coupled product. The ratio of the peak areas C (6): —N—CH_3 is 1 : 6 which is what would be expected for this compound. (Measurements were made by Mr. Martin Schweizer on a 'Varian *A*-60' spectrometer. Values of δ are given in p.p.m. from tetramethylsilane.)

A similar study on the irradiation of BU in an aqueous solution resulted in the isolation of the crystalline U-U. Its identity was established by comparison with DMU-DMU after exhaustive methylation with diazomethane. Infra-red spectra of these coupled products are shown in Fig. 2.



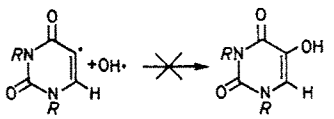
Photochemical Mechanisms

Three conceivable mechanisms for the photolysis of BU will be discussed in the following paragraphs. The first two are well known in the photochemistry of nucleic acids while the third has long been recognized in the action of visible or ultra-violet light on halogenated organic compounds.



(*A*) The formation of *cyclo*butyl derivatives by way of the photodimerization process occurs most frequently in solid films[15–17] and in frozen aqueous solutions[15–19], but seldom in dilute (1 mM–0·1 mM) aqueous solutions. Even if the homodimer (III) of BU is formed, the electronic effect of the bromine atom would be expected to confer instability, with possible decomposition to 5,5′-diuracil derivatives (II) according to the following scheme[13b]:

(*B*) The formation of a water addition product (V) by way of a photo-zwitterion intermediate (IV) occurs in uracil derivatives. Water addition would have to result in a decrease of absorbancy at the maximum due to the saturation of 5,6-double bond[20]. The decrease in ultra-violet absorbancy should be reversed to various extents by acid, alkali or heat, because the water addition products are known to revert to the originals under such treatment[21]. Since heating of the irradiated solution of BDMU in dilute acid (0·1 N hydrochloric acid, for 20 min at 100° C) did not affect its absorbancy, it must be concluded that the water addition compound is not a final product. However, the possibility remains that the water addition compound may exist as a transient intermediate during irradiation. In fact, this situation could be analogous to that of thymine derivatives[22]. Lozeron *et al.*[23] have recently reported the identification of the water addition product from 5-fluorouracil irradiated in aqueous solutions.



(*C*) The formation of radicals by way of the photo-dissociation process frequently occurs with halogenated organic compounds[24]. In this reaction, the homolytic cleavage of the C–Br bond results in the formation of Br· and uracil radicals (VI)—step (1). Uracil molecules may be produced by hydrogen abstraction from other surrounding molecules, and consequently a second radical (·*R*′) is produced—step (2*a*). The propagation sequence might then follow to produce ·*R*″—step (2*b*). Thus, a 'chain-like' reaction might occur and terminate with the reaction between two radicals to form single-bonded coupled products. Two radicals of the same species would give a homocoupled product—step (3*a*); and two different ones would give a heterocoupled product (3*b*).

It must be mentioned that, in the presence of oxygen in the irradiation medium, peroxide radicals could be formed—step (2c). The fate of these *R*-OO· radicals and also Br· from step (1) is a question that should be investigated further.

Another question that arises is whether hydrogen abstraction from the solvent molecules occurs in this chain reaction. If this did occur it would result in the formation of HO· which in turn would couple with uracil radicals to form 5-hydroxyuracil derivatives (VII) as shown. Thus, it is reasonable to assume that the presence of a 5-hydroxy compound would indicate the participation of water molecules in this chain reaction. However, the 5-hydroxy derivatives were neither isolated as photoproducts nor detected from the irradiation mixture of BU or BDMU by the 'Ferric chloride test' (*Biochemistry*, in the press). The results suggest that the 5-hydroxy compound is not a photoproduct and therefore water does not participate in this chain reaction.

(VI) (VII)

The homolytic cleavage of C–Cl, C–Br and C–I bonds requires 79, 66 and 57 kcal/mole, respectively[25], and the 253·7 mμ light would provide about 110 kcal/einstein which is, therefore, ample for initiating the chain reaction. Assuming photo-homolysis occurs with all these analogues in biological systems, the thermodynamical consideration would predict that the least potent sensitizing agent is 5-chlorouracil. The most pronounced one should be 5-iodouracil, the mechanism of which has been discussed by Rupp and Prusoff[26]. It is also interesting to note that 5-fluorouracil demands at least 105 kcal/mole for homolytic cleavage of the C–F bond. The requirement would decrease free radical formation. Indeed, the water addition reaction becomes predominant when 5-fluorouracil is irradiated with ultra-violet light[23].

The foregoing prediction is very similar to that of the findings in biological systems[27,28]. Bacteria pre-incubated with low concentrations of fluorouracil show enhanced resistance to ultra-violet irradiation[29]. This phenomenon may be due to the inability of fluorouracil to form free radicals. If this type of radical reaction should occur in DNA, it is conceivable that the uracil radicals produced by irradiation could attack their neighbouring purines, pyrimidines, or sugar moieties. Thus, different possible homocoupled products and heterocoupled products would result. In the absence of water participation in the radical reaction, the formation of various coupled products in the irradiated DNA may assume an even more important role. Moreover, from a stereochemical point of view, the formation of coupled products is much more favoured than *cyclo*butyl homodimers and heterodimers in DNA molecules. A similar type of intermediate has been proposed for the photo-oxidation of thymine derivatives[30–32]. Both observations could serve as a basis for further photobiological investigations related to thymine and 5-halogenated uracils.

This work was supported in part by a contract from the U.S. Atomic Energy Commission and by a research career development award from the Division of General Medical Science, U.S. Public Health Service.

TRANSPORT OF TRITIUM-LABELLED *l*-HISTIDINE THROUGH THE SCHWANN AND MYELIN SHEATHS INTO THE AXON OF PERIPHERAL NERVES

By PROF MARCUS SINGER and MIRIAM M. SALPETER

Department of Anatomy, Western Reserve University, School of Medicine, Cleveland, Ohio, and Laboratory of Electron Microscopy, Cornell University, Ithaca, New York

THE neurone is unique in a morphological sense in that its axonal processes extend from the cell body for long distances. When these delicate threads of cytoplasm are separated from the cell body, they rapidly waste and disappear. For this reason early workers realized that the cell body in some way maintains the morphological integrity of the entire process; and the cell body was called the "trophic" centre of the neurone, thus implying a nourishing function on the processes, a concept generally accepted to-day. Moreover, the agents of trophic control are believed to perfuse the axon in a continuous stream from the cell body[1,2]. Lapsed time photography supports the view of axoplasmic streaming and shows that the force of movement is provided by pulsations of the axon itself[3]; also, radioactive substances of various sorts have been demonstrated by biochemical and autoradiographic techniques to be incorporated at first in the cell body and to move thence into the axon[4,5]. The rate of movement has been determined in some instances and the possibility of disto-proximal streaming has been explored[6]. Therefore,

the ensemble of evidence at the moment supports the view that the cell body is the source of cytoplasmic constituents of the axon.

The question must now be asked, is it not possible and, indeed, logical that the incorporation of substances into the axon also occurs along its length by way of the sheaths that envelop it and, therefore, that the cell body is not the exclusive source of axonal stuff? Some of the early cytologists raised this question and speculated that the myelin segment is nutritive in function[7]. The question has been examined recently by Geren and Schmitt, who reasoned that the axonal surface must have some access to interstitial fluids and to products of Schwann cell metabolism for its own metabolic activity and to maintain the ionic and water balance required for propagation of the impulse[8,9].

We have evidence to show that the amino-acid, *l*-histidine, can be followed through the sheaths of the axon and thence into the axoplasm itself. Therefore, the cell body, albeit a predominant source, is not an exclusive one for substances in the axon.

Twenty-eight newts, *Triturus viridescens*, were injected intraperitoneally with 40–50 μc. of tritium-labelled *l*-histidine in 0·05 ml. of 0·01 N hydrochloric acid. Then brachial spinal nerves 3 and 4 were removed 1 h to 8 days afterwards, fixed in Carnoy's fluid containing magnesium ion for about 1 h, and sectioned at 5μ. The pieces included proximal segments of nerves 3 and 4 and their ganglia which were cross-sectioned in the case of nerve 3 and cut longitudinally in the case of nerve 4, and a distal piece of nerve extending from the brachial plexus to the elbow which was sectioned longitudinally. In some instances the nerves were transected just distal to the ganglia before the animals were injected with the radioactive substance; and the part distal to the cut was fixed 12 and 24 h after injection. For light microscopy the nerves were coated with the photographic emulsion Kodak '*NTE*-3', and exposed at low temperature for 3 weeks before developing; the sections were then stained with carmalum.

One hour after injection the radioactive label could be detected around and in the nucleus of the sheath of Schwann of the intact and also of the transected nerve. The axon did not contain any label and the myelin sheath was not involved. Ganglion cell bodies were well labelled as were the cells of two other tissues, skin and liver, selected for comparison with nerve. By 2 h some of the *l*-histidine label appeared in the axons. The axons and sheath nuclei of transected nerve were indistinguishably labelled from normal ones. In both normal and transected nerve the label was as heavy in distal as in proximal regions.

In subsequent hours the intensity of the label in the axons increased and the silver grains were often arranged along the axis of the individual nerve fibres. By 24 h the axonal region appeared about as heavily labelled as the Schwann nuclei; and the distribution and intensity of the tritium label in nerves separated from their cell bodies appeared indistinguishable from those of normal nerves. The label in the ganglia and the fibres of intact nerves, including Schwann nuclei, persisted until about the fifth day when it appeared to fade, but an obvious, although sparse, label could still be seen after 8 days when the experiment was terminated

Autoradiographic investigations of nerves 4, 24 and 72 h after injection of tritiated *l*-histidine were also made with the electron microscope. Animals were injected intraperitoneally with 500 μc. of aqueous *l*-histidine. A proximal and distal segment, the former including the spinal ganglion and the latter extending to the elbow, were fixed in osmium tetroxide, embedded in 'Epon 812' and prepared for electron microscope autoradiography[10]. Sections (500–1000 Å) were coated with monolayers of Ilford '*L*4' or Kodak '*NTE*' emulsions. Developed grains were counted and expressed as a density of radioactivity, namely grains per unit area of underlying tissue. The density of radioactivity was compared in sections of equal thickness coated and developed under identical conditions[11].

Four hours after injection of radioactive *l*-histidine, developed grains could be seen over all the components of the nerve fibres. The density of radioactivity in the axis cylinder was the same in the proximal and distal segment of the nerve. The Schwann nucleus and the myelin sheath showed a higher density of label than the axis cylinder. By 24 h the density of developed grains was about equal for the three components along most of the nerve. At this time the radioactivity of the axons in the proximal segment near the ganglion was higher than in the terminal segment, probably reflecting the addition of radioactive material streaming from the neuronal cell body into the axis cylinder. The density of radioactivity was reduced over all the components of the neurone 72 h after injection, but the disparity in intensity of labelling between the proximal and distal axoplasm was even more marked.

Electron microscope autoradiograms of thinner sections (500 Å) coated with monolayers of Kodak '*NTE*' emulsion for optimal resolution showed that the label in the axis cylinder was randomly distributed over the axon and not preferentially associated with a discrete organelle, such as vesicles or mitochondria—although these were sometimes labelled. The technique was, however, inadequate to distinguish the radioactivity of neurofilaments from surrounding axoplasm. The label in the myelin sheath was also scattered throughout the wrappings and was not localized in any part, and thus did not indicate any preferential pathway from the Schwann cell body inwards.

The results support the conclusion that *l*-histidine entered the nerve fibre first by way of the Schwann cell nucleus and perhaps its perikaryon and thence traversed the myelin sheath, and was finally carried into the neuroplasm of the axon. While these investigations were underway, evidence became available that radioactive lysine may also take this route into the axon[12]. Consequently, we wish to assert that the myelin sheath, in addition to its at present recognized function in saltatory conduction, serves to transport substances of metabolic importance into the axon. The mechanism of transport within the myelin is unknown to us. It is possible that the labelled substance moves within the membranes of the myelin sheath or between the interfaces of the wrappings. Robertson has suggested that the clefts of Schmidt-Lantermann represent more obvious waves of cytoplasm of the sheath of Schwann moving between the paired membranes of the myelin wrappings[13]. Perhaps, it is such streams of moving cytoplasm that carry substances inward toward the axon. Or, perhaps, the solid state of the myelin structure provides a mechanism for molecular transport.

Myelin once formed is considered to be metabolically inert since cholesterol, cerebroside, cephalins and sphingomyelin show little metabolic turnover[14]. The presence of incorporated histidine in myelin shows that the substance of myelin does change whether or not some of the incorporated amino-acid is, indeed, part of myelin structure or only a substance in passage.

We have as yet no information about the form in which the *l*-histidine, which eventually reaches the axoplasm, traverses the enveloping membranes of the neurone. The amino-acid may be incorporated into a substance of higher molecular weight within the Schwann nucleus and cytoplasm and be transported in this form through the myelin membranes to the axolemma and thence into the axoplasm. Or, perhaps, only molecularly free histidine penetrates the axon after being transported inward through the membranes that surround the axon. But, whatever the form of histidine before it reaches the axoplasm, it must traverse the myelin sheath, which must now be considered to function as a pathway for metabolic

substances from the extracellular fluid to the axonal cytoplasm. Therefore, the axon is fed by two streams, one originating in the cell body and moving within the axon itself and a second by way of the enveloping sheaths.

PERSISTENCE OF AN ORGAN-SPECIFIC ANTIGEN IN ORGAN AND TISSUE CULTURES OF HYPERPLASTIC HUMAN THYROID GLAND

By A. G. NICOL and Dr. J. SWANSON BECK
Department of Pathology, The University, Aberdeen

THE organ culture system has been used to investigate *in vitro* the thyroid gland of several mammalian species[1–3] including man[4–7]. The persistence of the human thyroid organ-specific antigen in tissue (cell) cultures has been investigated with the immunofluorescence technique using human auto-immune antibodies to an organ-specific microsomal antigen[5,8], but there are no conclusive reports of investigations on this antigen in organ cultures of human thyroid glands.

In this article we report short-term maintenance of hyperplastic human thyroid gland tissue *in vitro* in organ culture. The persistence of the human thyroid organ-specific antigen in organ cultures and disaggregated tissue (cell) cultures of the same glands was compared in a concurrent investigation.

The thyroid glands were obtained at operation for thyrotoxicosis on seven patients (one male and six female, age range 23–50 years). In all patients, pre-operative diagnosis was made on clinical assessment and this was confirmed with studies of iodine-131 uptake in five. Pre-operative medication (methyl-thiouracil or carbimazole, followed by iodine) had been given to all patients. The diagnosis was confirmed by histological examination in all cases. Approximately 12 g of tissue was required for each experiment, 2 g for organ culture and 10 g for tissue culture.

For organ culture, a modification of the method described by Hoorn and Tyrell[9] was used. The base of a sterile 2 in. diameter plastic Petri dish ('Nunclon', Sterilin, Ltd., Richmond, Surrey) was scored by means of a scalpel blade. Ten to twenty explants of thyroid gland, each measuring approximately 4 mm^3, were placed in each dish and 1·2 ml. of chemically defined culture medium ('T.C. 199', Glaxo) was added. The culture fluid was changed every 3 days in the early experiments and daily in the later experiments. Usually ten to twelve Petri dishes were prepared from each thyroid gland. The preparations were incubated at 37° C in a mixture of 5 per cent carbon dioxide in 95 per cent air. The explants were usually investigated as frozen sections, but the contents of occasional Petri dishes were fixed in 4 per cent neutral buffered formaldehyde in saline, and paraffin sections were stained with haematoxylin and eosin. Substantial portions of the explants were considered to have survived, as judged by conventional histological criteria, until about 7 days *in vitro*, as the acinar epithelium appeared intact (Fig. 1)—although necrotic changes were often seen in the stroma of the explants. By 14 days, many explants were necrotic and others exhibited only small foci of survival. The colloid persisted even in necrotic explants.

The sera to be used for immunofluorescence investigation of organ culture explants were selected with an immunofluorescence test using unfixed frozen sections of uncultured human thyroid gland. Five sera containing strong anticytoplasmic antibody (from patients with thyroid disease) and five sera which did not contain antithyroid antibodies (from patients with other diseases) were used in the investigation. Fresh frozen sections were prepared from thyroid organ culture explants frozen on blocks of human or rat liver as the thyroid microsomal antigen is not damaged by this procedure[10,11]. The sections (5μ) were stained with the indirect immunofluorescence method using positive and negative sera with the methods described previously[12]. The appearances of the histologically preserved thyroid tissue in explants stained with anticytoplasmic sera were closely similar to the well-known pattern seen in sections of uncultured thyroid gland[10]. The cytoplasm of surviving thyroid epithelium was brightly stained with some accentuation around the nuclei which were completely unstained (Fig. 2), but there was no specific staining in necrotic epithelium. The stroma was always unstained. The colloid was stained if the

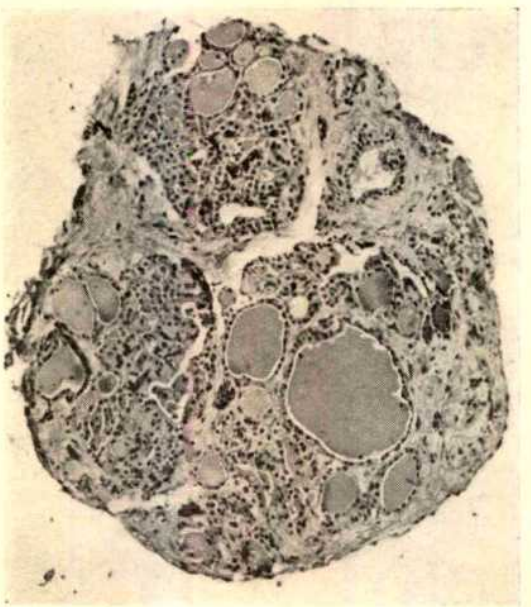

Fig. 1. Human hyperplastic thyroid explant maintained in organ culture for 7 days. (× 100) (stained with haematoxylin and eosin)

serum also contained anticolloid antibody. When sera without anticytoplasmic antibodies were used, faint diffuse non-specific staining was seen throughout the explant (Fig. 3).

The sections were examined independently by both of us, without prior knowledge of the serum used, and the organ-specific antigen was considered to be present when a clear distinction could be made between sections stained by positive and negative sera. The quantities of tissue available did not permit daily sampling of organ cultures, and Table 1 shows the last day on which antigen could be detected and does not represent a negative end-point.

Table 1. PERSISTENCE OF THYROID ORGAN-SPECIFIC ANTIGEN *in vitro*

Experiment No.	Tissue culture: Last day antigen detected	Tissue culture: First day antigen not detected	Organ culture: Last day antigen detected
1	3	4	8
2	2	3	14
3	1	5	7
4	3	5	9
5	3	4	10
6	3	5	8
7	1	3	14

In a few cases, the distribution of immunofluorescence staining in sections of explants maintained *in vitro* for periods of 5, 7, 11 and 14 days was photographed monochromatically and in colour. The appearances were then compared with those seen after haematoxylin and eosin staining of the same or of an adjacent cryostat section. Cells with positive cytoplasmic fluorescence always showed histological survival with preservation of cellular and nuclear detail and no group of cells was identified where convincing histological survival was not accompanied by positive immunofluorescence staining.

The following experiments were undertaken to demonstrate that the immunofluorescence staining was immunologically specific. Anticytoplasmic sera were treated with equal volumes of absorbants—protein solutions or microsomes suspended in an equal volume of saline—for 2 h at 37° C followed by 24 h at 4° C before being used to stain 5-day explants. Absorption with fresh human hyperplastic thyroid gland microsomes prevented staining, whereas absorption with microsomes prepared from other fresh human tissues (gastric mucosa, duodenal mucosa, kidney and prostate) or with purified human thyroglobulin (38 mg/ml.) or serum albumin (50 mg/ml.) did not significantly reduce staining intensity. Two strong anticytoplasmic sera were fractionated by chromatography on 'DEAE Sephadex (*A*50)' and various fractions were used separately as first stage in the immunofluorescence staining of organ-culture sections; bright staining was seen with the IgG (7·0*S* γ-globulin) fractions but not with other serum fractions. The specificity of the second stage of the immunofluorescence reaction was also investigated. An immunoglobulin was involved in this stage as the fluorescein conjugate had been prepared from the IgG fraction of an immune goat anti-human IgG serum. Absorption of the conjugate with human IgG (50 mg/ml.) removed its staining capacity—whereas absorption with rabbit IgG or human serum albumin (50 mg/ml.) did not alter its properties. Fluorescein-conjugated rabbit anti-human serum albumin and fluorescein-conjugated goat anti-rabbit IgG sera gave negative results. On the basis of these findings, and on the reproducibility of the indirect immunofluorescence staining method with anticytoplasmic sera and constant absence of staining with negative sera, we concluded that immunofluorescence staining was immunologically specific for demonstration of the organ-specific thyroid cytoplasmic antigen.

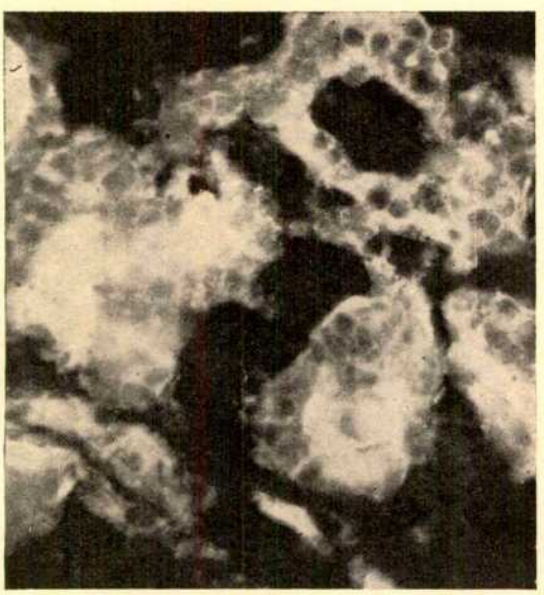

Fig. 2. Immunofluorescent staining of cytoplasm of epithelial cells of explant maintained in organ culture for 4 days. (× 400) (Anti-cytoplasmic antibody)

Fig. 3. Absence of immunofluorescent staining of culture shown in Fig. 2. (× 400) (Normal human serum)

The histological appearances suggested that explants were surviving *in vitro*, while the lack of fluorescence in necrotic areas of explants seemed to indicate that cytoplasmic antigen did not persist after cell death. To investigate the possibility of antigen persistence in necrotic tissue further, 1·0 cm (approximately) cubes of thyroid gland were well moistened with culture medium and incubated in the gas mixture. Histological examination of the tissue masses showed central necrosis from 24 h onwards and autolysis was almost complete by 3 days. Indirect immunofluorescence staining of frozen sections showed that the organ-specific cytoplasmic antigen was lost from this tissue 24 h after removal of the gland from the patient.

Concurrently with the organ culture experiments, tissue (cell) cultures of the thyroid gland were set up, the method differing little from that of Pulvertaft *et al.*[13]. Our haematoxylin and eosin-stained preparations showed partial monolayers of cells identical with those described previously. In previous immunofluorescence investigations on tissue culture preparations, it was found that organ-specific cytoplasmic staining could not be obtained on intact cells[4]. Attempts have been made to disrupt the cell membrane by air-drying the monolayers[5] or by brief fixation with acetone[6], but these methods have serious

theoretical disadvantages in view of the lability of the thyroid organ-specific microsomal antigen[11]. Accordingly, we developed a simple freezing technique to allow penetration of antibodies into the cells; coverslips were washed with gentle agitation in phosphate-buffered saline, dried by blotting the edge on filter paper and snap-frozen by laying the underside of the coverslip on a block of carbon dioxide snow for about 30 sec. Batches of coverslips (usually twelve) were stained after 14, 24, 36, 48, 72, 96 and 120 h in tissue culture with the methods used for organ culture sections.

Immunofluorescence staining was attempted after 7 h in culture, but very few cells remained adherent to the coverslips by the end of the staining process. From 12 to 14 h onwards more cells adhered to the coverslips and immunofluorescence assessment was possible. After 24 h in culture, antigen was seen throughout the cytoplasm in the distribution reported previously[8], but after longer periods in culture (usually about 36 h) it was only seen in a narrow zone around the nucleus. There was no specific staining with normal human sera. The longest duration *in vitro* at which definite cytoplasmic staining was still evident in cells stained by sera containing anticytoplasmic antibody is shown in Table 1. The antigen was considered to have disappeared when we could not detect any difference between technically satisfactory cell preparations stained with anticytoplasmic and normal sera. In experiments 3, 4, 6 and 7 there was an interval between these times because the tissue-culture preparations examined on the intervening days were technically imperfect and could not be assessed.

The times of persistence of the thyroid organ-specific antigen in tissue culture and organ culture systems are compared in Table 1. In the organ cultures, the antigen was demonstrated in all viable cells and was never seen in necrotic cells whereas the antigen was lost from tissue culture cells while they were still apparently viable on histological examination. Furthermore, the antigen was demonstrated after longer periods in organ culture than in tissue culture. There have been no previous reports of investigations of the persistence of the antigen in organ cultures but our findings in tissue cultures confirm the results reported by others[5,8] who used the same method. Slightly longer persistence (less than 1 week) was reported[14] with a different tissue culture technique but even this was shorter than our experience with the organ culture technique. In a biochemical investigation, Hagmuller and Leslie[6] have presented evidence that organ-cultured human thyroid tissue can fulfil the specific metabolic functions of thyroid gland more efficiently than dissociated thyroid cells. Our finding of longer persistence of the organ-specific antigen in organ cultures commends further the use of this technique for metabolic investigations on thyroid tissue *in vitro*.

This investigation was supported by a grant from the British Empire Cancer Campaign to Prof. A. R. Currie.

PROPERTIES AND STABILIZATION OF THE LYSOSOMAL MEMBRANE

By Dr. C. J. DUNCAN

Department of Zoology, University of Durham

ALLISON, Magnus and Young[1] have recently studied the role of lysosomes in the photosensitization of cells, and from these results Allison[2] has presented a unifying hypothesis, implicating lysosomes in carcinogenesis. He suggests that radiation, oncogenic viruses and carcinogenic chemicals have a common action in causing damage to the lysosomal membrane, so releasing the lysosomal enzymes which in turn attack the genetic material of the cell. If the DNase enzymes can operate without impairing the capacity of the cells to divide, they could produce genetic changes (probably deletions) resulting in the somatic mutations which lead to cancerous growth.

If such a hypothesis is correct, the properties and stabilization of the lysosomal membrane are of considerable interest. The available evidence suggests that the membranes bounding lysosomes resemble other lipoprotein unit membranes; many of the agents that disrupt lysosomes also labilize the membranes of erythrocytes and mitochondria[3]. This article emphasizes the similarities between the bounding membrane of lysosomes, the mitochondrial membrane and the plasma membrane of nerves by reference to their specialized properties, and suggests the molecular properties of the lysosomal membrane that are responsible for the maintenance of its integrity.

A hypothesis has been developed elsewhere[4-6], together with supporting evidence[7], that the cation-permeability of the membrane of sense organs and other input components of excitable cells is governed by an ATPase mechano-enzyme system sited in the membrane which is able to change its molecular configuration as a function of ADP–ATP balance. Changes in effective pore diameter and/or position of charged groups would produce a modification of selective cation-permeability. This system corresponds with that shown to be present in the mitochondrial membrane[8], where physical changes (probably of shape or symmetry[9]) are produced reversibly and rapidly by normal reactants of the respiratory chain[10]. It is not the ATPase of the active cation pump. A protein with actomyosin-like properties has been isolated from mitochondria; it underwent conformational changes (as shown by light-scattering and viscosity-change experiments) with ATP and showed ATPase activity[11,12]. Subsequent investigations[13,14] have emphasized the close similarity between this protein and the actomyosin system of muscle. More recently, an actomyosin-like ATPase has been identified in the plasma membrane of the nerve cells from crayfish nerve cord[15] and rat brain[16]. The presence of such a system would then account for the changes in axon length[17] and in the light-scattering properties of the axon membrane[18] which follow nerve activity. Its enzymatic activity would also produce (in part) the changes in liberation of inorganic phosphate which follow nerve activity[19].

Agents that normally sensitize lysosomes (such as anthracene, euchrysine) can produce photodynamic damage to cell membranes[1]. Allison *et al.* describe two

major types of photosensitization. Some dyes (rose bengal) remain at the cell surface; absorption of light of appropriate wave-length causes immediate photo-oxidative damage to the cell membrane with loss of potassium ions. Other substances (neutral red, anthracene) are concentrated in the lysosomes, and light absorption causes escape of lysomal enzymes and cell damage. The presence of oxygen is necessary for photodynamic damage, but photons of these wave-lengths are harmless if no photosensitizers are present. A parallel situation is found when the *Sepia* axon is stained with neutral red; the membrane immediately begins to depolarize (that is, sodium permeability increases) when locally illuminated, again only in the presence of oxygen[20]. During this time, uncoordinated miniature potentials are superimposed which may reveal the quasiquantal recruitment of multiple active foci or patches in the illuminated area of the membrane[20]. As depolarization proceeds, the miniature potentials synchronize into regular oscillations of increasing amplitude, eventually initiating spikes. The maximum amplitude and maximum rate of development of this potential are both dependent on the light intensity. The lysosomal and excitable membranes are therefore both sensitive to this form of photodynamic increase in permeability. Blue-violet light also rapidly immobilizes spermatozoa after the addition of euchrysine. If a 10μ beam of light is directed on the tip of the tail, only that part of the tail is immobilized[1]. The light would presumably be acting on the ATPase of the contractile machinery[21,22].

Although a number of agents labilize the lysosomal membrane, far fewer have been described with a stabilizing action. Antihistaminics (such as benadryl) are an example of a stabilizer[3,23], although at dosages too toxic to be of clinical use at present[2]. Antihistaminics (benadryl, histadyl) also act as stabilizers for nerves[24], that is, they produce little change in membrane potential, but markedly decrease depolarizing changes in the membrane potential brought about by alteration of the potassium ion concentration and other experimental means. These agents are therefore able to resist changes in membrane permeability and to block conduction in frog sciatic nerves[25,26]. Similarly, antihistaminics inhibit the configurational changes in the mitochondrial membrane, producing stabilization[27–29].

There is evidence[6,7] that the ATPase enzyme complex of the excitable membrane is associated with a non-specific cholinesterase component. It is probable that in lysosomes, in mitochondria and in the excitable cell membrane, antihistaminics stabilize and inhibit phosphoprotein turnover[30] by combining with this cholinesterase component; antihistaminics can produce cholinergic block and can correct certain effects of the anticholinesterase DFP, in addition to their action on the mammalian central nervous system[31]. In any event, histamine is a powerful dilator of capillaries; the action is a direct one on the contractile mechanism, the response being independent of innervation. After large doses, the capillaries dilate to such a degree that their permeability is altered. Antihistaminics antagonize this action by straight competition with histamine for the receptor sites[31].

Allison[32] has drawn my attention to other properties of lysosomes. Granules, apparently identical with lysosomes, have been shown to undergo relatively rapid displacements over dimensions that are outside the range of Brownian movement[33], an observation which accords with the presence of a contractile protein.

Metal ions (such as zinc, cadmium and iron) are carcinogenic, again probably operating by way of the lysosomes[32]. These same ions are also potent in accelerating the breakdown of amine granules isolated from the adrenal medulla[34], with a consequent liberation of catecholamines. These amine granules are also dependent on an ATPase system[7,34,35] and it is probable that synaptic transmitter release, catecholamine granules and lysosomes have many features in common[7].

It is therefore suggested that the integrity of the lysosome membrane is governed and maintained by an ATPase mechano-enzyme complex. The effect of many of the labilizing agents on the lysosomal membrane[3] (some with carcinogenic activity) can be explained in terms of a direct or indirect action on an ATPase system[7]. Examples of such agents are phospholipase (destroys ATPase activity[36]), DOC (see refs. 37, 38 and 39), 2,4-dinitrophenol (action on mitochondrial ATPase[40]; modifies membrane permeability[7]), anoxia (depolarizing action on the nerve membrane[24]) and thyrotropin (see refs. 7 and 8).

If the theory implicating lysosomes in carcinogenesis should prove correct, the molecular properties of the lysosome membrane and the means by which it could be stabilized would be of importance. By analogy with the systems present in the mitochondrial and excitable cell membranes, the enzyme activity of the ATPase complex of the lysosomal membrane depends on the integrity of a phospholipid component[36], it is not inhibited by cardiac glycosides, its sensitivity to cations is known and it depends on an active sulphydryl group[41]. Among suitable stabilizing agents (although not necessarily of clinical value), factors influencing ATP supply could have an indirect effect and other possible candidates could be the many stabilizing agents discovered for the excitable cell membrane, such as procaine, calcium ions, physostigmine, sulphanilamide, thiophene-2-sulphonamide and Diamox.

Escherichia coli $B_{s-1}\gamma R$: A STRAIN RESISTANT TO X-RAYS AND SENSITIVE TO ULTRA-VIOLET LIGHT

By V. D. ZHESTJANIKOV

Institute of Cytology, Academy of Sciences of the U.S.S.R., Leningrad, U.S.S.R.

INJURIES caused by X-ray and ultra-violet irradiation are partially reversible. Although the damage caused by the two effects differs in nature (dimers of pyrimidine bases in DNA are induced only by ultra-violet light but never by X-rays)[1,2], dark repair after both forms of injury requires similar conditions[3].

Many examples can be given to demonstrate a parallelism of sensitivity to ultra-violet and X-ray irradiation and recovery after injuries of both kind in bacteria: (1) the cross-resistance to ultra-violet light and X-rays found in various mutants of *E. coli*[4]; in strains of *E. coli* grown, before irradiation, in a glucose media[5], or obtained as a result of treatment with camphor vapour[6]; in various strains of *Bacillus subtilis*[7]; (2) the fact that treatment of radio-resistant bacteria with acriflavine inhibits their recovery and increases their sensitivity to both kinds of irradiation[3]; (3) the displacement of thymine in DNA by 5-bromouracil makes bacteria more sensitive to ultra-violet and X-ray irradiation[8,9]; (4) the transfer of increased X-ray resistance from a radio-resistant donor to a sensitive recipient on conjugation is accompanied by a transfer of ultra-violet resistance[10]; (5) the finding that bacteria cells revive phages irradiated by both ultra-violet and X-rays, although in the latter case this recovery is less strongly pronounced[11,12]; (6) that caffeine, which is a recovery inhibitor, represses a host cell reactivation at both kinds of irradiation[12,13].

Until now, however, there has been no direct evidence as to whether the recovery of ultra-violet and X-ray injuries is produced by identical or different mechanisms. The possibility of obtaining mutants capable of recovering only from one kind of injury seemed to offer an approach to solving this problem. This article discusses our work with the mutant *E. coli* $B_{s-1}\gamma R$, which is resistant to X-ray irradiation yet sensitive to ultra-violet light.

Bacteria of the strain *E. coli* B_{s-1} were cultivated during continuous cobalt-60 irradiation (2,800 r. per 24 h) for 3 months in Petri dishes at 37° C in a nutrient medium containing eosin-methylene blue. The transfer of bacteria was repeated daily (Sunday excluded). The bacteria obtained are designated as *E. coli* $B_{s-1}\gamma R$. The sensitivity of bacteria to ultra-violet light, X- and α-rays was checked periodically and compared with the radiosensitivity of the parent strain B_{s-1} and radio-resistant mutant B/r. Bacteria were grown for 18 h at 37° C on nutrient agar under γ-irradiation and after 10 passages without γ-irradiation. Ultra-violet irradiation of bacteria suspended in water was performed in Petri dishes on mixing. A *BUV*-30 lamp was used as a source of ultra-violet light (2537 Å; dose-rate—120 ergs/mm²/min). The sensitivity to ultra-violet light in a great number of subcultures of *E. coli* $B_{s-1}\gamma R$ was determined according to Greenberg's method[14]. The technique of X- and α-ray irradiation was described by Paribok *et al.*[15]. The host cell reactivation of ultra-violet irradiated phages *T*1 was studied in the following way: the phage *T*1 was irradiated in buffer. The diluted phage was preliminarily adsorbed on bacteria of the strains *B*, B_{s-1} and $B_{s-1}\gamma R$ (multiplicity was less than 1 : 100) and then seeded by the agar layer method. Negative colonies were calculated on the following day.

Fig. 1 shows the change in sensitivity ($L.D._{90}$) to X-rays and ultra-violet light exhibited by the strain $B_{s-1}\gamma R$ when grown under γ-irradiation. Survival curves for ultra-violet, X- and α-irradiation are given in Figs. 2 and 3. The changes in the resistance of *E. coli* $B_{s-1}\gamma R$ to ultra-violet light and X-rays were not identical.

X-ray resistance increases and after 2·5–3 weeks of cultivation under γ-irradiation attains a level of the strain B/r (Figs. 1 and 2), differing from the latter only by the factor 1·14 (factor of differences between the strains B/r and parent B_{s-1}–3·0). The results of two experimental series performed at 20-day intervals proved to be identical. Changes in the ultra-violet sensitivity of *E. coli* $B_{s-1}\gamma R$ cultivated over a period of 3 months under γ-irradiation are insignificant. $L.D._{90}$ was increased from 4 ergs/mm² (parent strain B_{s-1}) to 6 ergs/mm² (*E. coli* $B_{s-1}\gamma R$). The strains B/r and $B_{s-1}\gamma R$ differ by a factor of 52, whereas differences between the strain B/r and parent culture B_{s-1} are characterized by a factor 77 (see Figs. 1 and 2). The properties of *E. coli* $B_{s-1}\gamma R$ are inherited. An increased resistance to X-rays on insignificant changes in ultra-violet sensitivity is retained after ten passages without γ-irradiation. The sensitivity to ultra-violet light has been investigated in 700 substrains of *E. coli* $B_{s-1}\gamma R$ with inherited properties. The technique of double ultra-violet irradiation on nutrient agar[14] applied in this case made it possible to discern radio-resistant (confluent growth) and radiosensitive organisms (which either do or do not form single colonies). It was found that among 700 substrains there was not one which was more resistant to ultra-violet light than a parent culture *E. coli* $B_{s-1}\gamma R$. The strain *E. coli* $B_{s-1}\gamma R$ as well as the initial strain B_{s-1} does not enhance the recovery of ultra-violet irradiated bacteriophage *T*1 (Fig. 4).

The sensitivity of *E. coli* $B_{s-1}\gamma R$ to α-particles is almost identical to that of the strains B_{s-1} and B/r (factor 1·2) (Fig. 3). It has been shown that after α-irradiation (in the presence of oxygen during irradiation) no recovery of irradiation injuries occurs with *E. coli*[15].

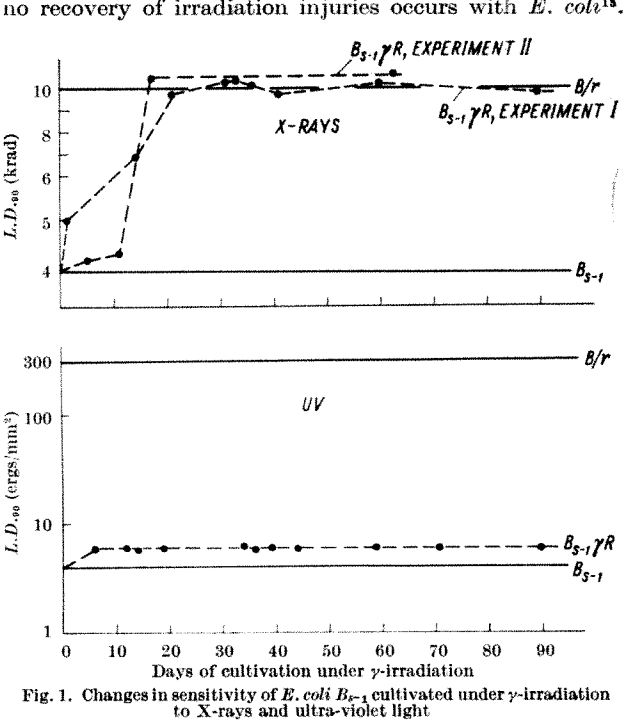

Fig. 1. Changes in sensitivity of *E. coli* B_{s-1} cultivated under γ-irradiation to X-rays and ultra-violet light

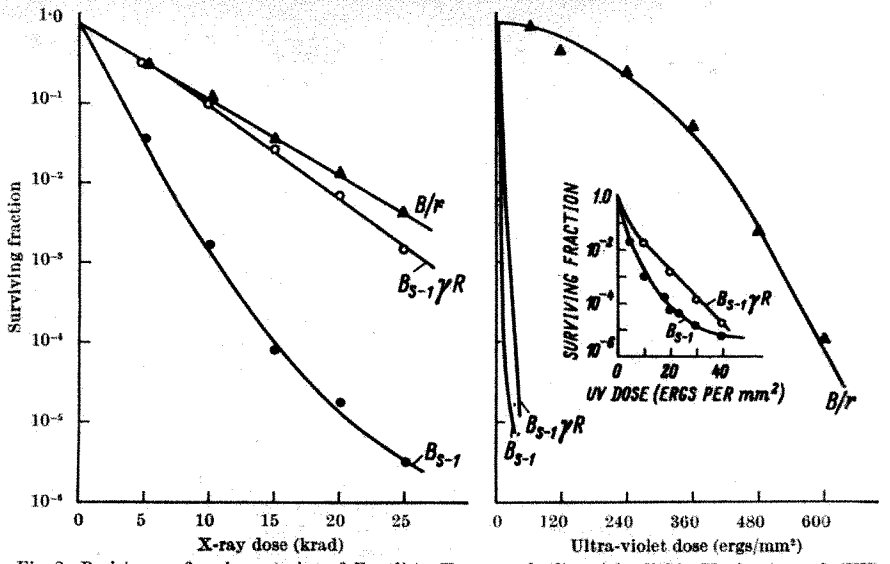

Fig. 2. Resistance of various strains of *E. coli* to X-rays and ultra-violet light. The inset graph (UV) shows the low dose portion of the survival curves of strains B_{s-1} and $B_{s-1}\gamma R$

Significant differences in the sensitivity of different strains of *E. coli* to ultra-violet light (factor 77) and X-rays (factor 3·4) in the presence of a similar sensitivity of the same strains to α-irradiation (factor 1·33) indicates that a high resistance to ultra-violet light and X-rays is due to post-irradiation recovery in radio-resistant variants of *E. coli*[16]. Hence this high resistance of *E. coli* $B_{s-1}\gamma R$ to X-rays demonstrates the capability of a mutant to repair injuries induced by X-ray irradiation. The ultra-violet sensitivity of the mutant $B_{s-1}\gamma R$ differs insignificantly from that of the strain B_{s-1}, and does not revive the ultra-violet-irradiated phages *T*1. Thus this mutant, as well as the initial strain B_{s-1}, does not make good injuries induced by ultra-violet light. This capacity of one strain to repair X-ray injuries coupled with its inability to revive ultra-violet damage shows that the recovery mechanisms of these injuries must at least differ in some respects.

The results obtained can be used to explain the following facts: (*a*) the character of the dose curves obtained with pigmentless strains of *Micrococcus radiodurans* after X-ray irradiation varies, yet this is not so in the case of ultra-violet irradiation[17]; (*b*) *Paramecia* isolated from radio-active natural sources have proved to be more resistant

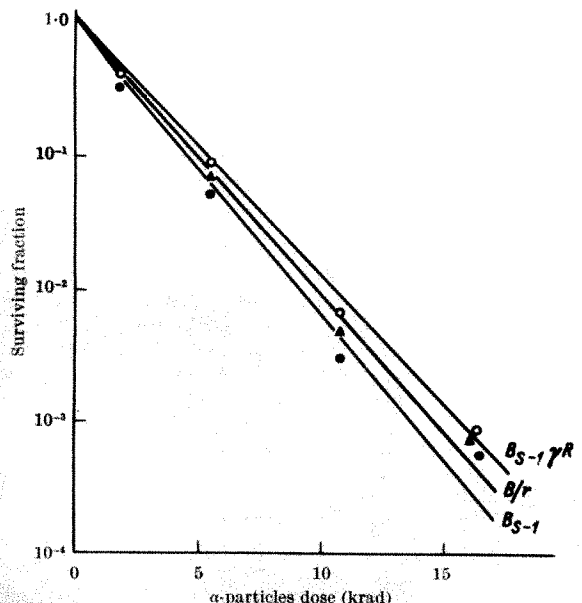

Fig. 3. Resistance of various strains of *E. coli* to α-particles

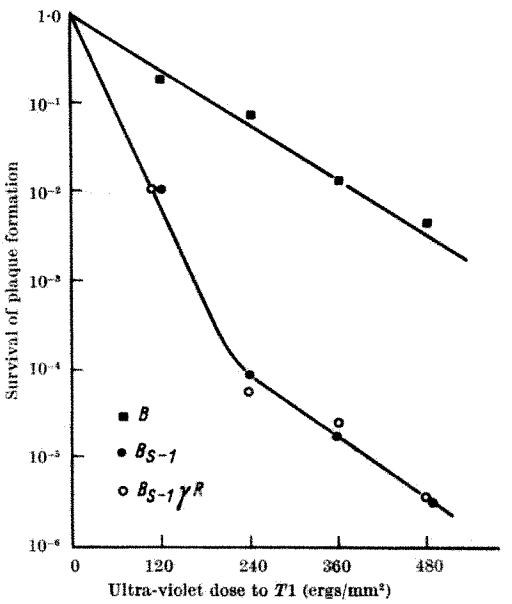

Fig. 4. Survival of bacteriophage *T*1 after ultra-violet irradiation as determined in bacteria strains *B*, B_{s-1} and $B_{s-1}\gamma R$ as hosts

to X-rays, yet have retained their increased sensitivity to ultra-violet light[18,19].

I thank E. A. Valdstein for her assistance in experiments on host cell reactivation of phages.

ADAPTATION OF MEASLES VIRUS TO THE CHORIO-ALLANTOIC MEMBRANE OF CHICKEN EMBRYOS *in ovo*

By DR. VICTOR J. CABASSO and DR. PAUL H. FRICKEY

Viral and Rickettsial Research Section, Lederle Laboratories, American Cyanamid Co., Pearl River, New York

THE development of measles vaccines[1,2] was made possible by Enders and his associates, who propagated measles virus in human and simian kdiney cultures[3], adapted the Edmonston strain of the virus to chicken embryos inoculated by way of the amniotic sac[4], and cultivated that strain in monolayers of chicken embryo cells[5]. Within the past 2 years, vaccines incorporating either live or inactivated measles virus have become generally available.

Live-virus vaccines prepared from the Edmonston strain after thirteen to twenty passages in cultures of chicken embryo tissue proved to be highly immunogenic when administered to measles-susceptible children. However, as many as 40 per cent of these children reacted with temperatures of 103° F or higher, and about 50 per cent developed a rash[6]. In attempts to eliminate these reactions, human gamma globulin was administered at the same time as the vaccine[6-8], or the vaccine virus was further attenuated by additional passages in cultures of chicken embryo tissue at various incubation temperatures[9-10]. Both these approaches to the problem significantly reduced the incidence of reactions to measles vaccination, but did not entirely eliminate them[11].

This laboratory attempted to eliminate the reactions by further attenuating the virus in a different way, by adapting it to the chorio-allantoic membrane (CAM) of the chicken embryo. CAM adaptation of measles virus had already been unsuccessfully attempted by other investigators[4], but nevertheless seemed possible because another myxovirus, that of canine distemper, which is taxonomically proximal to measles virus, had been adapted in this way. Distemper virus adapted to the chicken embryo when passed by way of the CAM produced characteristic inflammatory and necrotic lesions on the CAM, and after further CAM passages became completely attenuated for its naturally susceptible hosts[12,13].

This article reports the adaptation of the Edmonston strain of measles virus to growth on the chicken embryo CAM. Serial CAM-passage eventually produced inflammatory and necrotic lesions on measles-infected CAMs which resembled those produced by canine distemper virus.

The measles virus used for CAM adaptation was derived from Enders vaccine *B* (ref. 1), and was received here at the thirteenth level of passage in chicken embryo tissue culture. Before CAM adaptation was begun, the virus was serially passed ten additional times in monolayers of chicken embryo cells. The first three of these passages were incubated at 37° C, the other seven at 32° C. The cells used for the first five of these passages were of unknown RIF status. The embryo cells used for the other five passages came from an RIF-free flock of chickens developed here from a commercial flock intensively tested for RIF[14]. The fifth and seventh passage levels of the virus were treated with a chicken RIF antiserum for 45 min at 37° C before further passage. The level with which CAM adaptation was initiated (the tenth passage in this laboratory, or the twenty-third passage altogether) was shown to be free of RIF and had a measles virus titre of $10^{4.5}$ *T.C.I.D.*$_{50}$ per ml. in cultures of an established line of cercopithecus monkey kidney cells (*BS-C*).

The *BS-C* cultures used for titrating measles virus were grown in stationary tubes in a medium consisting of Earle's balanced salt solution, 0·1 per cent lactalbumin hydrolysate and 2 per cent horse serum, and after 2 days were renewed with a medium consisting of Medium 199, without glutamine, containing 1 per cent horse serum. To titrate the virus in either a 20 per cent suspension of infected CAM or tissue culture fluid, tenfold dilutions were prepared in Hanks's balanced salt solution, and each culture tube was inoculated with 0·1 ml. of a virus dilution. After 4–5 days' incubation at 37° C, the medium in the tubes was renewed. On the seventh day, end points were calculated by the formula of Reed and Muench[15].

Neutralization by a measles antiserum prepared by hyperimmunizing horses with measles virus that had been passed six times in HeLa cells was used to identify the virus. This antiserum had a serum neutralizing end point against approximately 100 *T.C.I.D.*$_{50}$ of measles virus of the order of 1 : 4,000. Neutralization of th[illegible] was tested either in *BS-C* cultures or on the CA[illegible] chicken embryos.

For CAM passage of the virus, 8-day-old embr[illegible] the aforementioned RIF-free flock were inoculate[illegible] at the base of an artificial air sac formed on the side of the egg. Inoculated eggs were incubated for 7 days, at the various temperatures specified later, and on the seventh day were opened aseptically. CAMs were examined for macroscopic changes, and infected portions were removed, pooled and used to prepare a 20 per cent CAM suspension in sterile distilled water containing 100 μg each of streptomycin and neomycin. Until the twenty-fifth serial CAM passage, each embryo was inoculated with 0·5 ml. of infected CAM suspension. The inoculum in subsequent passages was 0·2 ml.

To subculture CAM-adapted virus, Blake or Povitsky bottles containing cell monolayers were prepared from 9-day-old RIF-free chicken embryos, overlaid with a medium consisting of Earle's solution, 0·5 per cent lactalbumin hydrolysate, 10 per cent calf serum and 100 μg each of streptomycin and neomycin, and incubated for 24 h at 27° C. The monolayers were then renewed with the same medium as used for growth except that the calf serum was omitted, infected with a 20 per cent suspension of infected CAM by inoculation in the proportion of 5·0 ml. to each 300 ml. of overlaying medium, incubated for 7 to 10 days at 34° C and gathered for virus by pooling fluids and cells.

The virus was followed in several lines of CAM passages, at various incubation temperatures, but only the line giving continuous virus propagation is described in detail here. The first eleven passages of this line were incubated at 37°–38° C, and at all passage levels tested except the seventh, the virus titre was within the range of $10^{2.5}$–$10^{4.0}$ *T.C.I.D.*$_{50}$ per ml. of 20 per cent infected CAM suspension (Table 1). Subsequent passages of this line were incubated at 34° C, and at all but the twenty-first passage level the virus titre was within the range of $10^{2.5}$–$10^{5.5}$ *T.C.I.D.*$_{50}$ per ml. (Table 2). It cannot be ascertained whether the titres of less than $10^{1.6}$ obtained for both the seventh and the twenty-first passage levels of the virus were actual or whether they reflected virus inactivation as a result of manipulation, but in both cases the titre of the virus at the next passage level was within the expected range.

No significant change was visible macroscopically in the infected CAMs until the fifteenth passage, when transparent areas of swelling, gelatinous in appearance, could be seen. By the eighteenth passage, infected portions

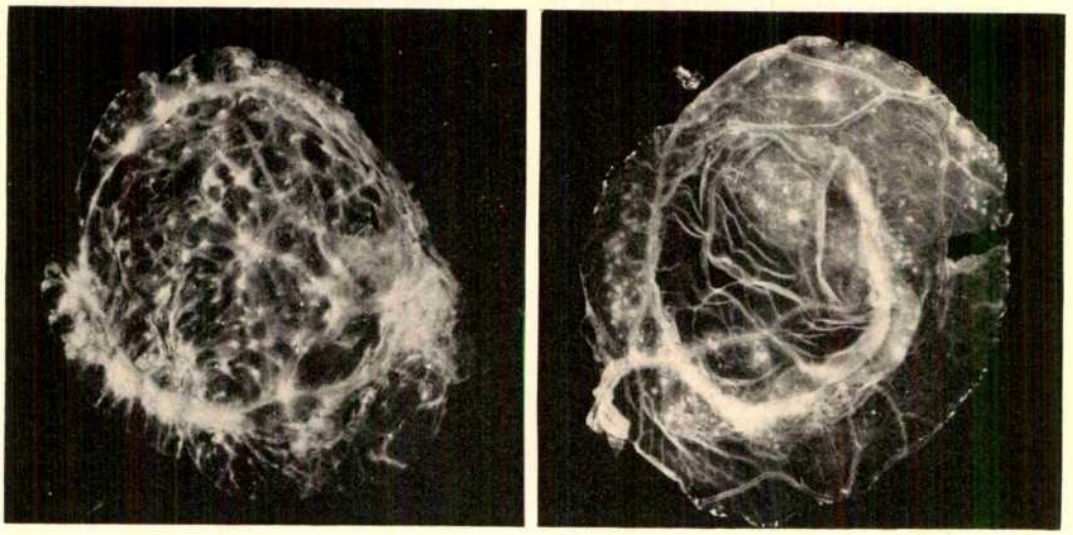

Fig. 1. Left, CAM-adapted canine distemper virus (Cabasso strain). Right, CAM-adapted measles virus (Edmonston strain). Note ring-like formation of inflammatory and necrotic lesions and discrete plaque-like lesions on both chorio-allantoic membranes

of the CAMs contained frank inflammatory and necrotic [redacted] which became more pronounced with continued [redacted] of the virus. The lesions appeared as large, [redacted]d opaque areas, most often in the form of a ring [redacted]e of contact between shell membrane and CAM, [redacted]ialler, discrete plaque-like lesions both inside and outside this ring. These lesions were macroscopically indistinguishable from CAM lesions produced by chicken-embryo-adapted canine distemper virus (Fig. 1), and histological examination of CAMs infected with measles virus or distemper virus substantiated the similarity of the lesions. Both viruses produced focal epithelial plaques that consisted of proliferating epithelial cells with oedema, degeneration and sometimes vacuolization. There were also marked changes in the underlying stroma, with many neocapillaries and fibroplasia, and in addition a few cytoplasmic Shorr-positive inclusions.

30	5·0			4·9

Changes in incubation temperature seemed at times to interfere with the CAM propagation of measles virus. For example, when virus representing the fifth CAM passage at 37°–38° C was passed and the infected embryos were incubated at the same temperature, the titre of the virus was $10^{2\cdot5}$ $T.C.I.D._{50}$ per ml. of 20 per cent CAM suspension, but when infected embryos in which the fifth-passage virus was subcultured were incubated at 35° C, no virus was detectable by titration. Similarly, when virus had been successfully passed ten times at 34° C and was then passed five times at 37° C, virus was detectable only after the first of these latter passages.

CAM-adapted virus was identified by measles-antiserum neutralization at the fifteenth, nineteenth and twenty-eighth passage levels (Table 2). All three passage levels were completely neutralized when mixed with antiserum in *BS-C* cultures. The antiserum also suppressed CAM lesions produced by nineteenth passage virus in the presence of normal serum, and neutralized the infected fluid from subcultures of twenty-first passage virus in chicken embryo cells. Antiserum to respiratory syncytial virus, which was used as a control, did not neutralize fifteenth passage virus. The development of measles antibody by three rhesus monkeys that had no antibody before their intramuscular inoculation with harvest from chicken-embryo tissue subcultures of the thirtieth CAM passage of the virus served further to identify it as measles virus. At thirty-five and fifty-one days after inoculation with 0·5 ml. of virus (50,000 $T.C.I.D._{50}$), each monkey had measles haemagglutination-inhibiting antibody within the titre range of 1 : 64–1 : 128. In contrast, three rhesus monkey controls kept in the same cages as the inoculated monkeys for 51 days after their inoculation remained free of measles antibody. This finding also indicated that the CAM-propagated virus had not regained the ability of measles virus to spread among monkeys kept in close contact.

Four passage levels of the CAM-adapted virus (the eighteenth, twenty-eighth, twenty-ninth and thirtieth) were subcultured in monolayers of chicken embryo cells (Table 2). No cytopathic effect was evident in any of these subcultures, but they all had infective titres within the range of $10^{4\cdot9}$–$10^{5\cdot5}$ $T.C.I.D._{50}$ per ml. of pooled infected fluid and cells after 7–10 days of incubation.

In summary, after propagation in live chicken embryos inoculated by way of the amniotic sac for six serial passages, and in cultures of chicken embryo tissue for twenty-three passages, the Edmonston strain of measles virus was adapted to growth on the chorio-allantoic

membrane (CAM) of 8-day-old chicken embryos free of RIF and was propagated through thirty serial CAM passages. The incubation temperature was 37°–38° C for the first eleven CAM passages and 34° C for subsequent passages. The CAM-propagated virus was identified as measles at the fifteenth, nineteenth and twenty-eighth CAM passage levels, and was also identified after subculture of the twenty-eighth passage virus in chicken embryo cell monolayers. Inflammatory and necrotic lesions began to appear on the infected portions of CAMs at the level of the eighteenth CAM passage of the virus and increased in intensity as passage continued. The taxonomical proximity of the viruses of measles and canine distemper gains support from the similarity of the CAM lesions they produce when adapted to the chicken embryo. Canine distemper virus became completely attenuated for ferrets, mink and dogs when CAM passage of that virus was continued after lesions had appeared on infected CAMs. Clinical trials of the CAM-adapted measles virus will determine whether that virus also was further attenuated by serial passage following the appearance of lesions on infected CAMs.

We thank Dr. S. W. Nielsen for histological examinations of infected CAMs, Mr. Walter Olson for able technical assistance, and Mrs. Esther Chasan for help in the preparation of the manuscript.

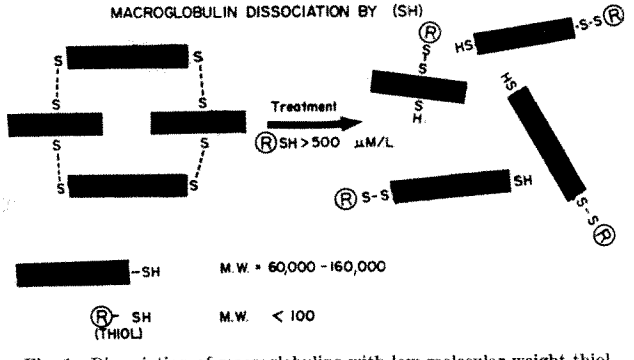
PENICILLAMINE THERAPY FOR RHEUMATOID LUNG DISEASE: EFFECTS ON PROTEIN SULPHYDRYL GROUPS

By PROF. ARTHUR LORBER

Research, Veterans Administration Hospitals, Sepulveda and Wadsworth, California, and Department of Medicine, University of California, Los Angeles, California

THE rheumatoid factor, a macroglobulin (mol. wt. 1,000,000) possessing many of the attributes of an auto-antibody, is frequently detectable in the sera of patients with rheumatoid arthritis[1]. It has been reported that these patients also have decreased serum protein sulphydryl content[2–5]. We recently suggested that the subnormal serum protein sulphydryl content could contribute to the formation of abnormal, disulphide-linked proteins such as the rheumatoid factor, due to an impairment in the mechanism for regenerating and maintaining protein sulphydryl groups[3].

Thiol compounds such as *d*-penicillamine are known to dissociate polymeric proteins by cleaving disulphide bonds[6–10]. It might be expected, therefore, that the therapeutic administration of *d*-penicillamine to patients with rheumatoid arthritis would result in an increase in the serum protein sulphydryl content and a decrease in the rheumatoid factor titre (Fig. 1). The purpose of this investigation was to determine what changes were brought about in serum protein sulphydryl content before, during, and after *d*-penicillamine therapy, and to relate these findings to the clinical course of the disease and to changes in rheumatoid factor titre.



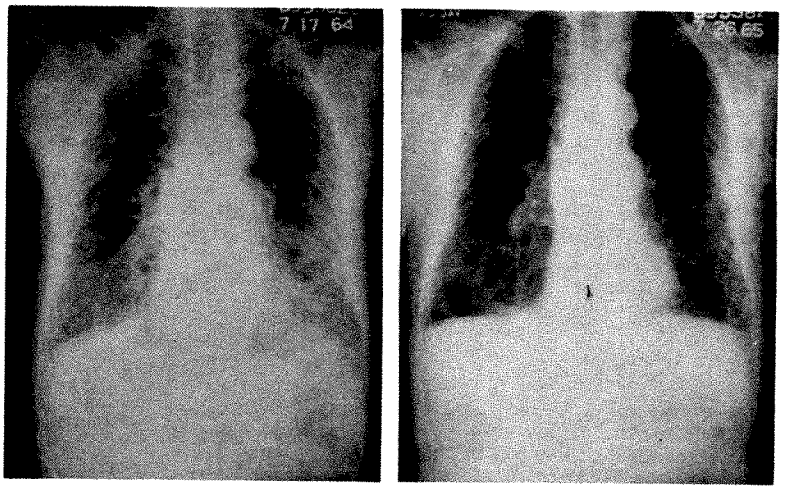


Fig. 1. Dissociation of macroglobulins with low molecular weight thiol compound (®SH). The solid rectangles represent peptide chains interlinked by S–S bonds. Dissociation results in increased serum protein SH

Three patients with rheumatoid lung disease were observed at bi-weekly intervals for 6–14 months. All the patients had abnormal pulmonary function, incomplete oxygen saturation of the arterial blood, and progressive lesions of the lung (these were demonstrated by chest X-ray). Neoplastic and infectious aetiologies were ruled out by appropriate investigations, and the pulmonary lesions were attributed to the underlying rheumatoid process[11]. Open lung biopsies were performed on each patient, and the histopathology of the lesions disclosed the formation of lymphoid follicles, interstitial and parenchymal lymphocytic and plasmacytic infiltrations, including involvement of the pulmonary vessels (Fig. 2). The vascular lesions included a spectrum of inflammatory, hypertrophic and occlusive changes. Serum protein sulphydryl content and rheumatoid factor titre were determined at bi-weekly intervals before, during and after *d*-penicillamine therapy. (*d*-Penicillamine ('Cuprimine') was kindly supplied by Dr. E. Alpert of Merck, Sharp and Dohme, and administered in dosage of 1–3 g per day supplemented with 50 mg pyridoxine per day.) Electrophoretic and ultracentrifugation investigations were also regularly performed.

Serum protein sulphydryl content was determined by a modified polarographic technique[3]. Spectrophotometric methods (that is, 5,5-dithio*bis*-(2-nitrobenzoic acid) (DTNB)[12], parachloromercuribenzoate (*p*CMB, more recently designated as *p*-hydroxymercuribenzoate)[13] and *N*-ethylmaleimide (NEM)[14]), for determining sulphydryl content, were used to confirm the findings obtained by the polarographic method. Total protein and albumin–globulin fractions were determined by the biuret and sodium sulphite fractionation methods[15]. The protein sulphydryl content (µmoles sulphydryl/mole of protein) was calculated on the basis of the molecular weights of 60,000 for albumin and 160,000 for globulin. Ultracentrifugation was performed with the use of a Beckman model *E*

analytical ultracentrifuge[16]. Rheumatoid factor titre was determined by tube incubation of serum with latex-coated γ-globulin[17].

Within 4 weeks of commencing the *d*-penicillamine therapy, the patients reported relief of pain, stiffness and shortness of breath. Subjective clinical improvement was confirmed objectively by investigations of the articular and pulmonary functions. Increased oxygen saturation of arterial blood and resolution of pulmonary infiltrates (as demonstrated by chest X-ray) were observed (Fig. 3). A further lung biopsy, performed 3 months after initiating penicillamine therapy in one patient, disclosed considerable resolution of the lymphocytic infiltrate and of the inflammatory changes involving the pulmonary vessels. Both the rheumatoid factor titre and the macroglobulin fraction decreased during penicillamine therapy. (A decline in rheumatoid factor titre averaging four tube dilutions was observed during therapy. In one patient the titre decreased from 10,240 to 320 on 5 months of sustained penicillamine therapy.)

a *b*

Fig. 3. Radiographic investigations of a patient with rheumatoid lung disease. Bilatera llower lobe infiltrates are noted to resolve with penicillamine therapy (*a*) before therapy; (*b*) progressive resolution of pulmonary infiltrates at the eleventh month

Serum protein sulphydryl content was noted to increase by more than 50 per cent during therapy and to decrease after withdrawal of the medication (Table 1). Patients were maintained on penicillamine supplemented with pyridoxine for intervals of 2–7 months. Therapy was discontinued in two patients because of undesirable side reactions (that is, nephrosis and bone marrow depression) which were attributed to the medication.

Table 1. EFFECTS OF PENICILLAMINE THERAPY ON SERUM PROTEIN SULPHYDRYL (SH) CONTENT AND RHEUMATOID FACTOR TITRE OF THREE PATIENTS WITH RHEUMATOID LUNG DISEASE

	No.* of determinations	SH (μmole/l.)	SH (μmole/g total protein)	SH (mole/mole protein)	Average rheumatoid factor titre tube dil.

After therapy	17	282	3·9	0·38	5
Percentage of increase		61	60	56	
Normal subjects (18)	34				
Average		512	7·5	0·61	
Range		400–600	5·5–8·6	0·50–0·72	

* Serial determinations performed at 2–4 week intervals.

The serum protein sulphydryl content was noted to be decreased initially by about 30 per cent in the three patients reported here. (Serum protein sulphydryl content determined in 8 M urea confirmed that the decreased serum sulphydryl content could not be attributed to unreactive sulphydryl groups.) Similar findings have also been observed in more than 150 patients with clinically active rheumatoid disease. It is suggested that the inability to maintain and regenerate sulphydryl groups might contribute to the formation of abnormal, disulphide-linked proteins such as the rheumatoid factor (PSSP) and that these abnormal proteins can be dissociated with thiol administered or endogenous low-molecular-weight thiol compound (RSH). PSH represents the protein with the reduced disulphide, that is, free sulphydryl group (Fig. 1 and equation (1)):

$$PSSP + RSH \rightleftharpoons PSSR + PSH \quad (1)$$

It was observed that rheumatoid factor titre decreased and the serum protein sulphydryl content increased following *d*-penicillamine therapy. It has also been noted that some patients with high rheumatoid factor titre have a high incidence of systemic lesions (that is, pulmonary and neurovascular lesions[18]). Thus it is suggested that there is a relationship between the severity of rheumatoid disease, rheumatoid factor titre and subnormal protein sulphydryl content.

The formation of abnormal disulphide-interlinked proteins, such as the rheumatoid factor, may be caused by impaired biochemical reduction of disulphide bonds (ref. 10 and equation (2)):

$$PSSR + NADPH \rightleftharpoons PSH + RSH + NADP^{+} \quad (2)$$

(NADPH is reduced nicotinamide adenine dinucleotide phosphate.) The oxidation of sulphydryl groups resulting in the formation of disulphide bonds is favoured by the presence of divalent trace metals such as copper, and by the high oxygen tension and by the alkaline *p*H of the blood (ref. 10 and equation (3)):

$$2PSH + \text{oxidant} \rightleftharpoons PSSP + 2H^{+} + 2e + \text{reductant} \quad (3)$$

The expenditure of energy is, therefore, necessary to reverse the oxidation of sulphydryl groups and to maintain the reduced state. The formation of abnormal proteins such as the rheumatoid factor and the clinical activity of rheumatoid arthritis may have a common origin—a biochemical disturbance in the mechanism for regenerating and maintaining serum protein sulphydryl groups. Such a disturbance might contribute to the process of the disease in the following ways: (1) The loss of sulphydryl groups could change the physical and chemical configuration of structural proteins and enzymes, thus altering or destroying their function. (2) The inability to reduce disulphide bonds and to regenerate sulphydryl groups could result in the formation of abnormal proteins (that is,

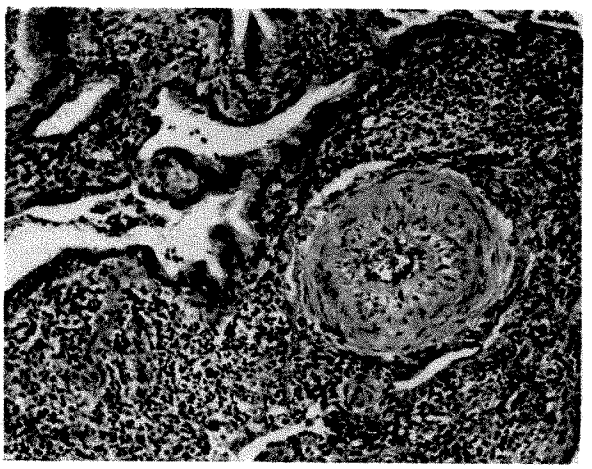

Fig. 2. Photomicrograph of lung biopsy illustrating the lymphocytic and plasmacytic infiltrate about a pulmonary vessel and a small bronchus. The wall of the artery is thickened and the lumen is almost occluded (× 30)

antigenic substances) or adversely affect the synthesis of immune globulins (by altering the specific disulphide inter-linkages of protein sub-units, that is, the *H* and *L* chains composing the immune globulins), causing formation of 'auto-antibodies'.

The mechanism(s) for the therapeutic action of *d*-penicillamine is not known; however, the following possible modes of action have been postulated:

Immunosuppressive. Suppression of γ-globulin production has been reported in animals with the administration of *d,l* penicillamine[19,20]. However, the immunosuppressive effect of the racemic compound has been attributed to the *l*-isomer, which exerts an antimetabolic effect on pyridoxine. The patients in this investigation were placed on pyridoxine supplements and recent reports indicate that *d*-penicillamine is not significantly antagonistic to pyridoxine[21,22]. Therefore, immunosuppression seems an unlikely mechanism.

Chelation. Penicillamine is an effective chelator of metal ions, and it is possible that removal of these metals could exert a beneficial therapeutic effect[23]. Copper and other trace metals have been reported to be elevated in the serum and synovial fluid of patients with rheumatoid arthritis[24]. These divalent metals are known to catalyse the oxidation of sulphydryl groups[25]. Thus, penicillamine could retard the formation of disulphide bonds by chelating metals and preventing the subsequent formation of abnormal disulphide-linked proteins.

Exchange-dissociation. Penicillamine has been shown to cause dissociation of disulphide-linked immune globulins *in vitro* and *in vivo*[7-9,26]. It was recently reported that several patients with diagnosed cysteinuria excreted penicillamine-cysteine disulphides following penicillamine therapy[27,28]. This substantiates the hypothesis that *d*-penicillamine can act *in vivo* through an exchange dissociation with disulphide bonds.

Although the exact mode of action of *d*-penicillamine has not been elucidated, serum protein sulphydryl concentrations were shown to increase with therapeutic administration of this drug. Changes in serum protein sulphydryl concentrations were accompanied by improvement in the patient's clinical condition, a decrease in the concentration of rheumatoid factor, and reduction of immunogenic cellular pulmonary infiltrate.

COMPARISON OF CHANGES IN THE CHEMICAL COMPOSITION OF RABBIT CARTILAGE MATRIX WITH AGE AND FOLLOWING INTRAVENOUS PAPAIN

By PROF. THEODORE T. TSALTAS and DR. KENNETH A. GREENAWALD*

Department of Pathology, Jefferson Medical College, Philadelphia, Pennsylvania

THE intravenous administration of papain solution in young rabbits has been shown to produce marked softening of the ear cartilage accompanied microscopically by considerable reduction of the metachromatic cartilage matrix[1]. Adolescent or mature rabbits were originally thought to be refractory to these effects of papain[1]. Recently we have been able to demonstrate that papain produces changes similar to the aforementioned ones in rabbits of all ages, but with diminished intensity[2-4]. We have also shown that these gross and microscopic changes are due to a marked depletion of chondromucoprotein (CMP) from the cartilage matrix and a change in the ratio of nitrogen to hexosamine in CMP as a result of the injection of papain.

In the course of these investigations, it was noted that the CMP content of the cartilage of normal rabbits varied, depending on the weight and age of the animals. These age-related changes appeared to be similar to the ones observed following the intravenous administration of papain.

This article deals with a detailed comparison of the changes in the composition of normal rabbit cartilage with ageing and with those found following papain injection.

All experiments were performed on New Zealand albino rabbits of both sexes. A total of 144 animals were used. Of these, 63 animals were used as normal controls, while the remainder were injected with papain. The weight of the animals ranged from one to approximately 5 kg. They were divided into three major groups.

The first group were the very young rabbits that were obtained right after the end of lactation, and they weighed 800–1,300 g. They are classified in this report as "young rabbits". The second group of animals weighed between 2–3 kg, and they are called "adolescent rabbits". The third group consisted of old animals repeatedly bred, and they weighed between 3·5 and 5 kg. They are called "adult rabbits".

The animals were maintained on Purina Rabbit Chow for at least a 2-week period before any experiments were undertaken. All rabbits were weighed accurately at the time that they were purchased, immediately before the injection of papain, and at the time that they were killed. No significant changes in weight were observed after the injection of papain.

A 2 per cent papain solution was prepared for injection from a highly purified powdered papain (donated by the Sterling-Winthrop Research Laboratories, Rensselaer, New York). Crystalline and crude papain have been

* Post-doctoral fellow, U.S. Public Health Service, National Institutes of Health.

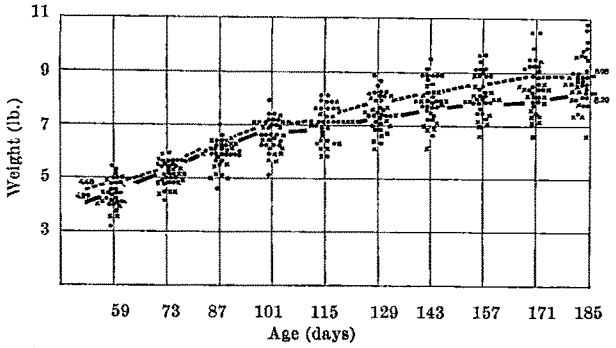

Fig. 1. Comparison of weight increase with ageing in normal New Zealand albino rabbits. Average: thirteen bucks, ———×, twenty-five does, — — — —●

used in the past and have been shown to be as effective. It was preferable not to use crystalline papain because of its high rate of oxidation and the very high cost. The papain was prepared by mixing 2 g of powdered papain with 100 ml. 0·15 M sodium chloride in water. This was placed on a magnetic stirrer for 30 min and then filtered through pre-sterilized Boerner bacteriological centrifuge filters. This produced a straw-coloured, clear solution that was free of bacteria.

35 mg of papain per kg body weight were injected in the marginal vein of the ear of the rabbits. The cartilagenous plate of the ear was used for the isolation of the CMP. This is because the cartilage from the ear can be obtained easily without delay and can be quite easily freed of skin and perichondrium by a few simple manipulations.

All animals were killed by air embolism at the end of each experiment. The ears were removed promptly after death and the skin and perichondrium were stripped as rapidly as possible. They were minced, weighed, and then homogenized in a 'Virtis 45' high-speed homogenizer at 45,000 r.p.m. and 4° C.

The chondromucoprotein was extracted from the homogenate by the methods of Malawista and Schubert[5]. The extracted CMP was dried and portions were analysed for nitrogen content by a micro-Kjeldahl method, and the hexosamine content of the CMP was determined by a modification of the Schloss method[6]. The molar ratio of nitrogen to hexosamine in the extracted CMP was calculated from these values. The results obtained were plotted against the weight of the animal, and the data were analysed for statistical significance using the least squares method of linear correlation.

Since the precise age of all the animals could not be determined, it was necessary to establish some uniform criteria for the age of the animals. From tables that we obtained from commercial breeders, animal food manufacturers, and from the U.S. Government Department of Agriculture, it was established that a direct relationship exists between the age and the weight of the rabbits. This was also confirmed by X-ray investigations of the epiphyseal plate of the animals.

Fig. 1 shows the relative increase in weight of New Zealand albino rabbits with ageing and was used as the main criterion for the selection of the rabbits used in these experiments. In Figs. 2–5, the weight of the animals is shown, and their age can be extrapolated by referring to Fig. 1.

Table 1 gives a summary of the changes that occurred in the ear cartilage matrix of three groups of rabbits, as specified earlier in the article. It should be pointed out here that while the maximum changes (that is, the maximum depletion of the cartilage matrix following administration of papain) in the very young rabbits occurred 24 h after papain, in the adolescent rabbits the same changes occurred 48 h after papain; while in the adult rabbits they occurred 72 h after papain. The details of these experiments have been described elsewhere[2–4].

Table 1

	Young rabbits*		Adolescent rabbits*		Adult rabbits*	
	Control	After papain	Control	After papain	Control	After papain
mg CMP/g wet cartilage	37·4	22 0	44 82	32·23	40 21	33·55
mg hexosamine/CMP	8 6	6·6	7·47	6 43	7 46	6·76
mg nitrogen/g CMP	7 7	9 2	8 39	9 35	8 69	9·45
Nitrogen/hexosamine molar ratio	11·5	17·8	14·79	19·55	15·29	18 27

* For details of the effect of papain on these three groups, see refs. 2, 3 and 4

Table 1 shows that in all groups papain produced a statistically significant decrease in the amount of CMP extracted from the ear cartilage. It can also be seen that there was a decrease in the hexosamine content of the extracted CMP. Conversely, there was an increase in the nitrogen content of the extracted CMP and an increase in the molar ratio of nitrogen to hexosamine in CMP. It is also interesting to note that the changes that occurred following papain, even though of a decreasing magnitude as the age of the animals progressed, are statistically significant for all groups.

Fig. 2 shows that the amount of the extracted CMP decreased as the weight and age of the animals increased. The solid line represents the line of least squares for the plotted points ($P_{(t)} < 0{\cdot}001$).

Fig. 3 shows the correlation between the hexosamine content of the extracted CMP and the weight and age of the rabbits. The hexosamine content of the extracted

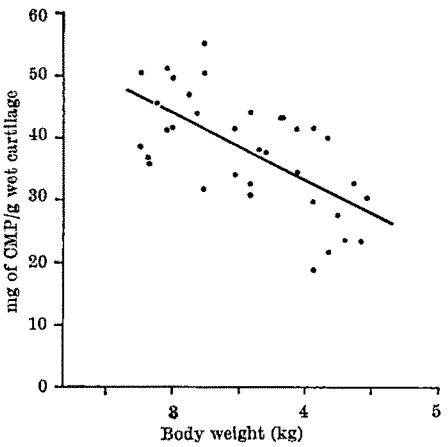

Fig. 2. Changes in the amount of CMP/g wet cartilage with ageing. Solid line represents the line of least squares for the points shown ($P(t) < 0{\cdot}001$). Each point represents one animal

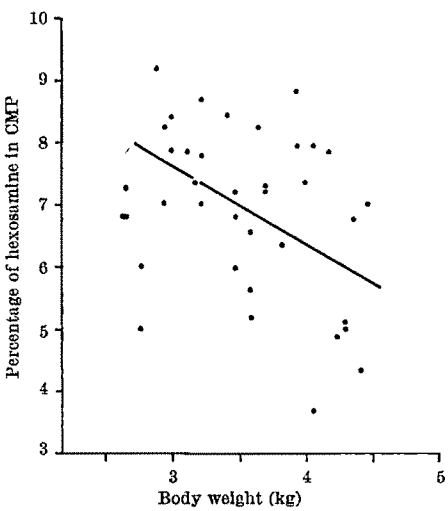

Fig. 3 Changes in the percentage content of hexosamine in the extracted CMP with ageing. Solid line represents the line of least squares for the points shown ($P(t) < 0{\cdot}005$). Each point represents one animal

CMP decreased as the weight and age of the rabbits increased. The solid line represents the line of least squares ($P_{(t)} < 0{\cdot}005$).

Fig. 4 shows the correlation between the nitrogen content of the extracted CMP, and the weight and age of the rabbits. It can be seen that the nitrogen content of the extracted CMP increased as the animals increased in weight and age. The solid line represents the line of least squares ($P_{(t)} < 0{\cdot}005$).

The correlation between the nitrogen to hexosamine molar ratio and the weight and age of the rabbits is shown in Fig. 5. The nitrogen to hexosamine molar ratio increased as the weight and age of the animal increased. Again the solid line represents the line of least squares ($P_{(t)} < 0{\cdot}025$).

The data presented here support results published by other investigators[7-9] that cartilage matrix undergoes chemical changes with ageing. These changes consist of a decrease in the amount of extractable CMP and a decrease in the amount of hexosamine in the extracted CMP. An increased nitrogen content in the extracted CMP is also found, with a consequent increase of the molar ratio of nitrogen to hexosamine.

These changes are very similar to those produced in the cartilage matrix of rabbits by the intravenous administration of papain.

It is interesting that the maximal changes in the cartilage matrix after papain required longer periods of time as the age of the animals increased. Thus the young rabbits showed maximal response to papain 24 h after injection. In the adolescent group these changes occurred 48 h after injection, and in the adult animals they did not reach their maximum until 72 h after injection of papain.

Concurrently, the percentage change between control and papain-injected animals decreased as the age of the animals advanced. The delay in the response to the injection of papain and the decrease in the percentage change could be explained on the basis of the data recently published by Stockwell and Barnett, who showed that ageing reduces the permeability of cartilage[10]. On the basis of these data, it could be concluded that papain diffuses with diminished ease through the cartilage matrix as the animals age and, therefore, it not only produces smaller chemical changes in the matrix, but also requires a longer time to achieve these changes.

Matthews[11] and, recently, Bollet *et al.*[12] have reported on the chemical changes occurring in the cartilage of persons with degenerative arthritis. Both authors found a decreased hexosamine content in the CMP of the degenerated cartilage. We also found that this occurred as a result of the administration of papain to our experimental animals. The animals used in our experiments were not followed for long periods after the administration of papain to determine whether or not they would develop

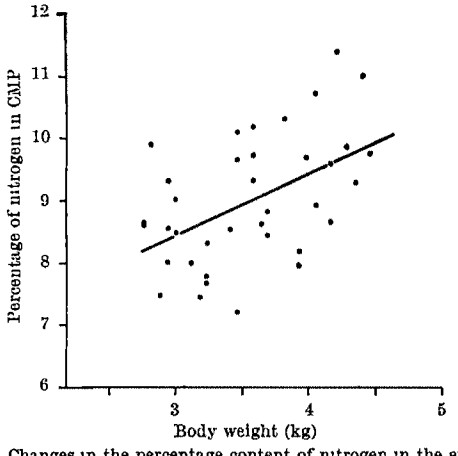

Fig. 4. Changes in the percentage content of nitrogen in the extracted CMP with ageing. Solid line represents the line of least squares for the points shown ($P_{(t)} < 0{\cdot}005$). Each point represents one animal

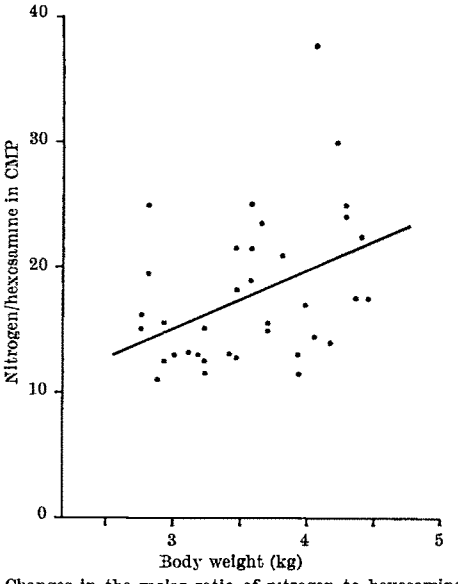

Fig. 5 Changes in the molar ratio of nitrogen to hexosamine in the extracted CMP with ageing. Solid line represents the line of least squares for the points shown ($P_{(t)} < 0{\cdot}025$). Each point represents one animal

degenerative changes in the joints. However, as pointed out by Bauer and Bennett[13], the early changes in degenerative arthritis are merely an accentuation of the normal ageing process.

Supporting this possibility are data published by Fell *et al.*[14-18] and Thomas *et al.*[19]. Using excessive quantities of vitamin A *in vivo* and *in vitro*, they have been able to produce chemical changes in cartilage similar to those produced with papain. The basis of these changes has been reported to be the release of an intracellular protease induced by the excessive vitamin A, thus indicating that such an enzyme exists within normal chondrocytes.

By comparing these published data with our present findings, we feel that the action of an intracellular papain-like enzyme in the pathogenesis of degenerative arthritis is a distinct possibility and that further attention should be given to its eventual isolation, and its implications to the pathogenesis of degenerative arthritis.

To sum up, the amount of chondromucoprotein (CMP) present in the cartilage matrix as well as the hexosamine content of such CMP were found to decrease with the ageing of normal rabbits. Identical changes were also found after the intravenous injection of papain in rabbits. These changes are postulated to be produced by the presence of an endogenous papain-like enzyme. The relationship of these changes to degenerative arthritis is discussed.

"FERTILE" INTESTINE NUCLEI

By DR. J. B. GURDON
Department of Zoology, Parks Road, Oxford
AND
V. UEHLINGER
Station de Zoologie Expérimentale, Université de Génève

NUCLEAR transplantation experiments carried out on *Xenopus laevis* since 1958[1] have shown that nuclei from the majority of differentiating endoderm cells[2] and from fully differentiated intestine cells[3] can support the formation of normal muscle and nerve cells after transplantation to enucleated eggs. We describe here some adult frogs which are derived from transplanted intestine nuclei and some of which are fertile. This result is of interest since it shows that genetic factors required for the formation of a fertile adult frog are not lost in the course of cell differentiation, at least in the case of some intestine cells.

Preparation of nuclear-transplant frogs. Cells from the intestinal epithelium of *Xenopus laevis* tadpoles which had just started feeding were dissociated and their nuclei transplanted into unfertilized eggs enucleated by ultraviolet irradiation as described previously[4]. The development promoted by intestine nuclei is often more normal if serial nuclear transfers are carried out using a first-transfer blastula to provide nuclei for serial transplantation[3]. The reason for this apparent improvement in development is thought to be the variable quality of *Xenopus* eggs laid in the laboratory[5]. Of the intestine nuclear-transplant frogs described below, all but one were obtained by serial nuclear transplantation (Table 1). The nuclear transplantation experiments which yielded these frogs were carried out in Oxford by J. B. G. and the majority of the mating records were obtained in Geneva by V. U.

Nuclear-transplant frogs derived from intestine nuclei. The embryos and tadpoles which grew into the frogs listed in Table 1 were normal as larvae, and the adult frogs do not differ from other frogs reared in the laboratory, whether from fertilized eggs or from other kinds of transplanted nuclei. In an attempt to demonstrate that these nuclear-transplant frogs are normal in respect of all cell types, they were mated to wild-type and other nuclear-transplant frogs, an activity promoted by the injection of gonadotrophic hormone (300–500 I.U. for females, and 100–150 I.U. for males). Table 1 shows that five of these seven intestine nuclear-transplant frogs are fertile. The females produced the numbers of eggs expected of frogs reared in the laboratory. One female and one male were not shown to be fertile although they contained apparently normal ovaries and testes. Among frogs reared from eggs laid in the laboratory, it has generally been found that about 5 per cent (17/386) are sterile.

The intestine nuclear-transplant frogs which gave fertile eggs in some matings failed to do so in other matings; the question therefore arises whether they are less fertile than normal. Under laboratory conditions, the fertility of *Xenopus laevis* is variable and only rarely are 100 per cent of the eggs fertile. This is likely to be due partly to the unnatural conditions provided in the laboratory (especially diet), and partly to the induction of mating by hormone injection at unnatural seasons and frequencies. We must therefore compare the fertility of nuclear-transplant frogs with that of other *Xenopus laevis* reared to maturity in the laboratory. Even this can provide only an approximate comparison, since the fertility of frogs reared in the laboratory is affected by a number of factors such as the age of the frogs, degree of crowding, temperature, and season, and these conditions are not known to have been the same for the frogs which we compare in this article. We consider here two measurements of fertility: (*a*) the percentage of matings which yielded at least a few fertile eggs (Table 2), and (*b*) the percentage of total eggs laid which were fertile (Table 3).

Table 2 shows the proportion of matings in which at least ten eggs started cleaving normally. The female nuclear-transplant frogs derived from intestine nuclei (row 1) participated in fertile matings with the same frequency as wild-type frogs reared in the laboratory or imported from Africa (rows 6 and 7). Furthermore, this is also true of frogs reared from the F_1 progeny of the intestine transplant-frogs (row 4). Male nuclear-transplant frogs obtained from intestine nuclei (row 1) failed to fertilize eggs as often as males usually do, but this result has been obtained with only two frogs.

Table 3 provides another measurement of fertility. Here we have excluded all matings in which no fertile eggs were produced, and the percentage figures show what proportion of eggs laid started to cleave normally. The female nuclear-transplant frogs (Table 3, rows 1–3) from intestine nuclei are as fertile in this respect as other frogs reared in the laboratory. Male nuclear-transplant frogs from intestine nuclei (row 1) as well as from tadpole nuclei (row 2) appear to be subnormally fertile, but the number of males concerned is small.

Table 1. REPRODUCTIVE CAPACITY OF FROGS OBTAINED FROM TRANSPLANTED INTESTINE NUCLEI OF *Xenopus laevis*

Number and sex of frog	Genetic constitution	Origin of transplanted nuclei: First transfer donor*	Origin of transplanted nuclei: Serial transfer donor*	Reproductive capacity of nuclear-transplant frogs†: First mating (per cent)	Reproductive capacity of nuclear-transplant frogs†: Subsequent matings (per cent)
♀ 1	Diploid, 1-*nu*	Stage 46	Stage 8 (Blastula)	85 (2000)	0 (270); 0 (1500); 20 (3000); 0·1 (1900); 10 (3800); 20 (5200)

Table 3. PERCENTAGE OF FERTILE EGGS IN SUCCESSFUL MATINGS OF NUCLEAR-TRANSPLANT FROGS

	Origin of frogs (Nieuwkoop and Faber stages (ref. 6))	Number and sex of frogs mated	Fertile eggs: First mating (per cent)	Fertile eggs: Subsequent matings (per cent)
(1)	Intestine nuclear-transplant frogs (stages 45–47)	5 ♀s 2 ♂s	42 (3) 0 (0)	17 (3) 9 (2)
(2)	Tadpole nuclear-transplant frogs (stages 33–42)	8 ♀s 1 ♂	18 (3) 2 (1)	18 (19) 9 (3)
(3)	Embryo nuclear-transplant frogs (stages 8–26)	23 ♀s 7 ♂s	34 (14) 36 (4)	31 (40) 35 (11)
(4)	F_1 progeny of intestine nuclear-transplant frogs	19 ♀s 21 ♂s	35 (13) 35 (13)	16 (8) 19 (8)
(5)	F_1 progeny of tadpole nuclear-transplant frogs	13 ♀s 16 ♂s	18 (12) 17 (13)	11 (6) 8 (10)
(6)	Frogs reared from eggs laid in the laboratory by wild-type frogs	28 ♀s 31 ♂s	25 (24) 52 (23)	32 (46) 46 (90)

These figures apply only to matings in which some fertile eggs were obtained. The percentage of fertile eggs in each mating is very variable, ranging from 2–99 per cent, and different numbers of eggs were obtained in each mating. The average values for each group of frogs are not significantly different.
The figures in brackets in the last two columns show the number of successful matings on which the percentage is based. Matings which took place between two nuclear-transplant frogs are recorded in the results for each parent frog.

We make no attempt to describe here the quality of development of fertile eggs provided by nuclear-transplant frogs, since this varies considerably from one mating to another even with the same frogs. It is sufficient to state that we have observed no early developmental abnormalities characteristic of the progeny of any intestine nuclear-transplant frogs, and that at least some of the progeny of the frogs have been reared into mature males and females of normal fertility (row 4 of Tables 2 and 3).

The frogs described earlier are known to have been derived from intestine nuclei and not egg nuclei for two reasons. First, all except one of the intestine nuclear-transplant frogs were obtained from the injection into unfertilized wild-type eggs of nuclei from tadpoles heterozygous for the anucleolate mutation[1]. Since all but one of the frogs in Table 1 were diploid and one-nucleolated, their nuclei must be mitotic products of the transplanted nucleus, and not of an unsuccessfully irradiated egg-nucleus. There are no germ-cells in the intestine in stage 45–47, since these have all migrated to the germ-ridge about 24 h before this stage[6]. The nuclei used for transplantation almost certainly came from differentiated epithelial cells of the intestine since, when dissociated, these are visibly larger and different from other cell types in this organ owing to their possession of yolk at this stage. Study of the intestinal epithelium at stages 45–47 reveals only columnar epithelial cells with a striated border for absorption and a small proportion (about 1 per cent) of gland cells.

In Amphibia it has been generally found that only a small proportion of nuclear-transplant embryos reach advanced developmental stages, especially when the transplanted nuclei are taken from differentiating cells. The intestine nuclear-transplant frogs described here were obtained from experiments in which a total of 120 intestine nuclei were transplanted. However, in other experiments with over 600 intestine nuclear transfers, none of the resulting nuclear-transplant embryos became sexually mature. Most of these intestine nuclear-transplant frogs were obtained by serial nuclear transplantation, and the seven frogs can be seen from Table 1 to have resulted from the transplantation of four original intestine nuclei only two of which have been demonstrated to yield fertile frogs. It is permissible to draw definite conclusions from these very small numbers, since all but one of the seven frogs discussed were obtained from genetically marked donor nuclei. The existence of fertile nuclear-transplant frogs shows that at least some intestine nuclei have promoted normal cell differentiation without accumulating dominant mutations of essential genes. Furthermore, the genetic analysis of nuclear-transplant frogs has shown that transplanted somatic nuclei capable of supporting normal development do not differ markedly from typical germ-cell nuclei in respect of recessive mutations[7].

The seven adult frogs described here show that nuclei from differentiated intestine cells can support the normal formation, after transfer to enucleated unfertilized eggs, of adult male and female frogs, some of which are fertile. The processes involved in permitting the activity of those genes required for the differentiation of an intestine cell, and in repressing those not so required, cannot therefore entail the irreversible loss or inactivation of genes needed for the differentiation of other cell types.

We thank Dr. A. W. Blackler, A. Droin, and J. Reynaud for permitting us to include in Tables 2 and 3 the results of some nuclear-transplant frog mating tests carried out by them, and Dr. A. W. Blackler for supervising the care of the intestine nuclear-transplant frogs at an early stage in their life. One of us (J. B. G.) thanks the Medical Research Council for financial support.

LETTERS TO THE EDITOR

ASTRONOMY

Probable Value of the Time of Rise for the Sunspot Cycle No. 20

IT has been shown[1-5] that the time of rise T_R, that is the time interval between the minimum of solar activity and the next maximum, is a basic parameter for determining the variation of values of the various indices of solar activity (relative sunspot numbers, areas of the sunspots, umbrae and faculae, etc.) within each sunspot cycle and from cycle to cycle. Therefore, knowledge of the value of T_R for future sunspot cycles enables a prediction to be made of the probable variation of the values of these indices of solar activity during the corresponding cycles.

King-Hele found[6] that the value of T_R for the current cycle No. 20 will be equal to $T_R = 3{\cdot}4$ years. Therefore, if we take into account the fact that the minimum of cycle No. 20 occurred in 1964·7, we should expect the maximum of this cycle to happen in 1968·1. This result is based on the hypothesis of the existence of "a 7-cycles recurrence tendency in the time of rise" postulated by King-Hele[7].

In the present report a new approach is used to study the variation of the values of the time of rise T_R from cycle to cycle of solar activity. For this purpose the data given by Waldmeier[8] are used: these are summarized in Table 1.

Table 1

Cycle No.	Yr of maximum	Time of rise T_R(yr)	Cycle No.	Yr of maximum	Time of rise T_R(yr.)	Cycle No.	Yr of maximum	Time of rise T_R(yr.)
−12	1615·5	4 1	−1	1738 7	4 7	10	1860·1	4 1
−11	1626·0	7 0	0	1750 3	5 3	11	1870·6	3 4
−10	1639·5	5 5	1	1761 5	6 3	12	1883 9	5 0
−9	1649 0	4·0	2	1769·7	3 2	13	1894·1	4 5
−8	1660 0	5 0	3	1778·4	2 9	14	1907 0	5·3
−7	1675·0	9 0	4	1788·1	3 4	15	1917 6	4·0
−6	1685·0	5 5	5	1805·2	6·9	16	1928·4	4 8
−5	1693 0	3·5	6	1816·4	5·8	17	1937·4	3 6
−4	1705 5	7·5	7	1829 9	6 6	18	1947 5	3·3
−3	1718·2	6·2	8	1837 2	3 3	19	1957 9	3·6
−2	1727·5	4 0	9	1848·1	4·6	(20)	(1968·7)	(4 0)

In Fig. 1 the continuous line gives the values of T_R for cycles Nos. 7–19 and the broken line the values of the same parameter for the cycles Nos. −5 to 6. The data concerning the latter group of cycles are scant and, therefore,

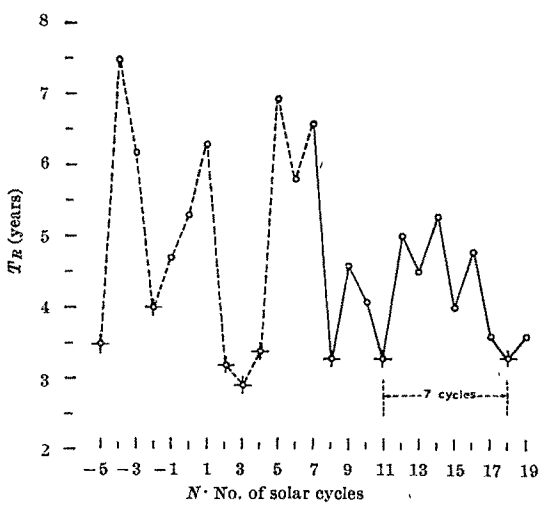

Fig. 1

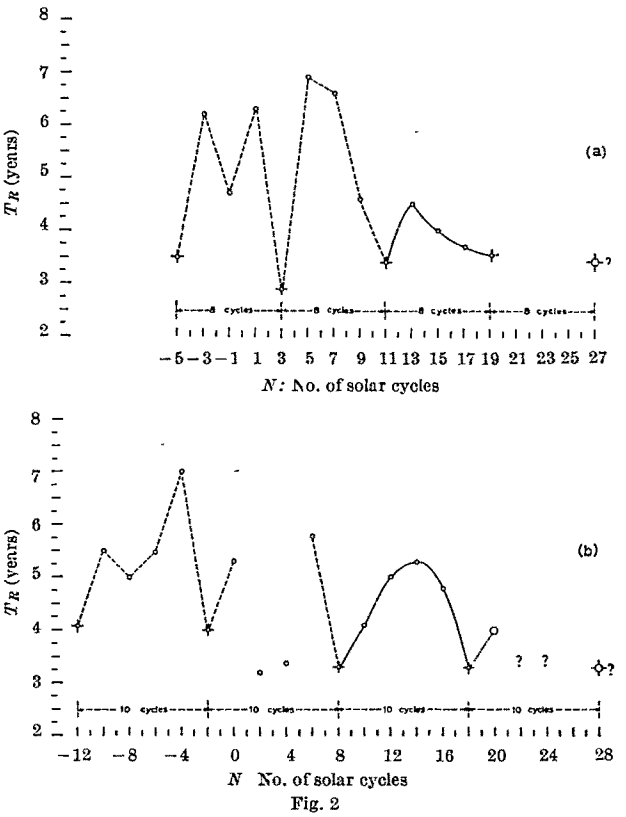

Fig. 2

care should be exercised in taking into account the corresponding values of T_R. It can be seen in Fig. 1 that the minima of T_R (marked with the symbol -⊙-) correspond to cycles Nos. −5, −2, 2, 3, 4, 8, 11 and 18. If we disregard cycles Nos. 2 and 4, then the time interval contained between the successive minima of T_R is correspondingly equal to 3, 5, 5, 3 and 7 cycles. Therefore, the values of T_R do not seem to show a constant periodicity. If we consider the two groups formed by cycles Nos. 4–11 and 11–18 only, then we have the seven-cycles recurrence tendency found by King-Hele. This tendency is, however, destroyed, if we also take into account the previous cycles Nos. −5 to 4.

The situation becomes quite different if we consider the values of T_R corresponding to cycles with even and odd current number, that is, cycles with the same polarity in the sunspot magnetic fields, separately.

Figs. 2*a* and 2*b* show, respectively, the values of T_R corresponding to sunspot cycles No. $N = 2n + 1$ ($n = -3$ to 9) and $N = 2n$ ($n = -6$ to 9). From these figures we see that the values of T_R show in this case a more or less smooth variation with minima occurring every eight (Fig. 2*a*) and ten (Fig. 2*b*) cycles respectively. Only the values of T_R corresponding to cycles Nos. 2 and 4 (Fig. 2*b*) are disproportionally low. If we take into account that these values are more or less precise (Xanthakis, in the press) this means that probably cycles Nos. 22 and 24 should also show low values of T_R, as compared with the values corresponding to cycles Nos. 20 and 26.

It is worth mentioning that a similar periodicity with periods respectively equal to eight and ten cycles is also

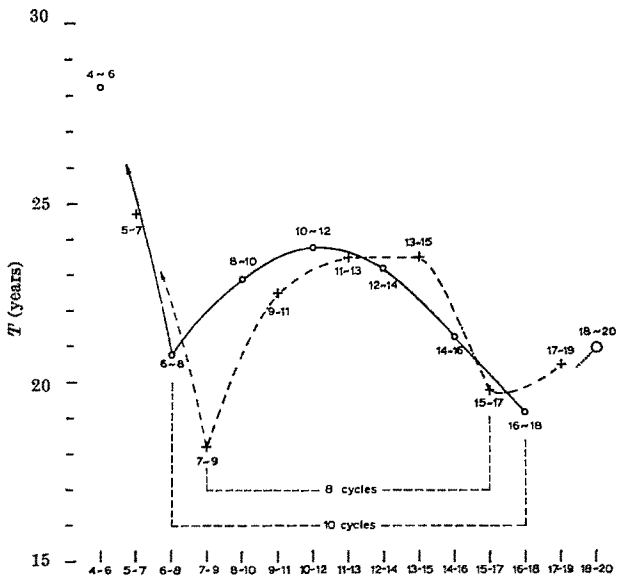

Fig. 3

found if we consider the time interval between the successive maxima of cycles Nos. $N = 2n + 1$ ($n = 2$–9) and $N = 2n$ ($n = 2$–9). This is clearly shown by Fig. 3, where the continuous line represents the time interval between the maxima of cycles No. $N = 2n$ ($n = 2$–9), that is, cycles Nos. 4–6, 6–8, . . ., 16–18, while the broken line represents the same interval for cycles No. $N = 2n+1$ ($n = 2$–9), that is, cycles Nos. 5–7, 7–9, . . ., 17–19.

We thus conclude that the cycles with different polarity in the sunspot magnetic fields also show different variation of the time of rise T_R as well as of the time interval between the successive maxima.

Unfortunately, even on the basis of these periodicities it is not possible to determine with certainty the value of T_R which corresponds to the current cycle No. 20, because of the fact that the amplitude of the variation of the values of T_R changes from one eight- or ten-cycle period to the other. From Fig. 2*b* it can be guessed, however, that the value of T_R for cycle No. 20 will probably not be less than 3·5–4 years. Therefore, if we take into account that the minimum of cycle No. 20 occurred in 1964·7, we come to the conclusion that the next maximum will happen not earlier than in 1968·2–1968·7. We can get an analogous result also from the continuous line of Fig. 3 that gives the variation of the time interval between the successive maxima of solar activity for the cycles No. $N = 2n$ ($n = 2$–9). From this figure we can guess that the time interval between the maxima of cycles Nos. 18–20 will probably be not lower than 21 years. Therefore, if we take into account the fact that the maximum of cycle No. 18 occurred in 1947·5, we conclude that the maximum of cycle No. 20 will not occur earlier than 1968·5.

In a forthcoming paper the probable values of the relative sunspot numbers (R) and the areas of the sunspots (A), umbrae (u) and faculae (f) for the successive years of the cycle No. 20, computed with the help of analytical relations (Xanthakis, in the press), will be given.

METEOROLOGY

Polar Lobe of the Quasi-biennial Stratospheric Wind Oscillation

EVIDENCE was first reported in 1960 (by Reed[1] and Ebdon[2]) of a wind oscillation in the tropical stratosphere possessing a quasi-biennial rhythm in the zonal component. As more adequate wind data became available during the following years, the existence, beyond the 1953–59 epoch, of an equatorial oscillation of about 26 months average period and 20-knot maximum amplitude (at *c.* 25 km height) was established. (A comprehensive review has already been provided by Reed[3] of the stratospheric zonal wind oscillation and the similar cycles in stratospheric temperature and total ozone which were later discovered.)

The basic features of the structure of the wind oscillation are: (i) a vertical downward propagation of the (temporal) maximum amplitude at a rate of about 1 km per month and disappearance at the tropopause level; (ii) maximum amplitude at the equator and rapid amplitude attenuation to 15° N. and S.

Reed demonstrated that phase relations between zonal wind, temperature and ozone (serving as an indicator for meridional-plane circulations in the lower stratosphere) meet the criteria of a perturbation of the tropical stratosphere in thermal-wind balance.

Tucker[4] found evidence of quasi-biennial cycles in the divergence of eddy-transports of momentum in the tropical belt of the stratosphere. His results helped to elucidate the problem as to how, with west winds maintained for many months, absolute angular momentum is conserved in the vicinity of the equator.

No adequate theories have so far been propounded to explain the origin of the oscillation of tropical winds which is complicated by features such as asymmetry in pole-ward attenuation and the emergence of similar periodicity in the data for some middle- and high-latitude stations.

Although the sparseness of observations in southern middle latitudes means that a less conclusive analysis can be made than in the northern hemisphere generally, soundings in the Australasian and South American sectors, and over Antarctica, have yielded evidence of a more pronounced extratropical oscillation. There is, for example, a sharp increase in the temperature amplitude at the 50–60-mbar levels (*c.* 20 km) from middle latitudes to Macquarie Island (54° S.)[5], and a similar increase to Hallett (72° S.)[6] and McMurdo Sound (78° S.)[7]. Furthermore, Sparrow and Unthank[8] have reported a comparatively strong quasi-biennial zonal wind oscillation at 60,000 and 70,000 ft. over Hobart.

The existence of a polar lobe would have an important bearing on external theories which postulate a direct drive of the tropical oscillation by extraterrestrial effects such as fluctuations in ultra-violet radiation, possibly connected with the spectrum of sunspot number (Shapiro and Ward[9]). (Such theories must also deal with the meridional interactions between the polar and subtropical stratospheric régimes.) Impulsive modes of heat transfer associated with the breakdown of the stratospheric polar-night vortex in late winter or spring may have a particularly important bearing on the processes involved. Investigations conducted at the International Antarctic Meteorological Research Centre in Melbourne[10] have provided some evidence of alternating modes in stratospheric spring warming during the years 1958–62.

The purpose of this report is to discuss some novel features of the wind régime in high southern latitudes. There is evidence that during 1958–62 marked 24-month cycles occurred in the meridional wind component at 60,000 ft. over Wilkes (Australian Antarctic Research) Station at 67° S. This can be seen in Fig. 1 from the

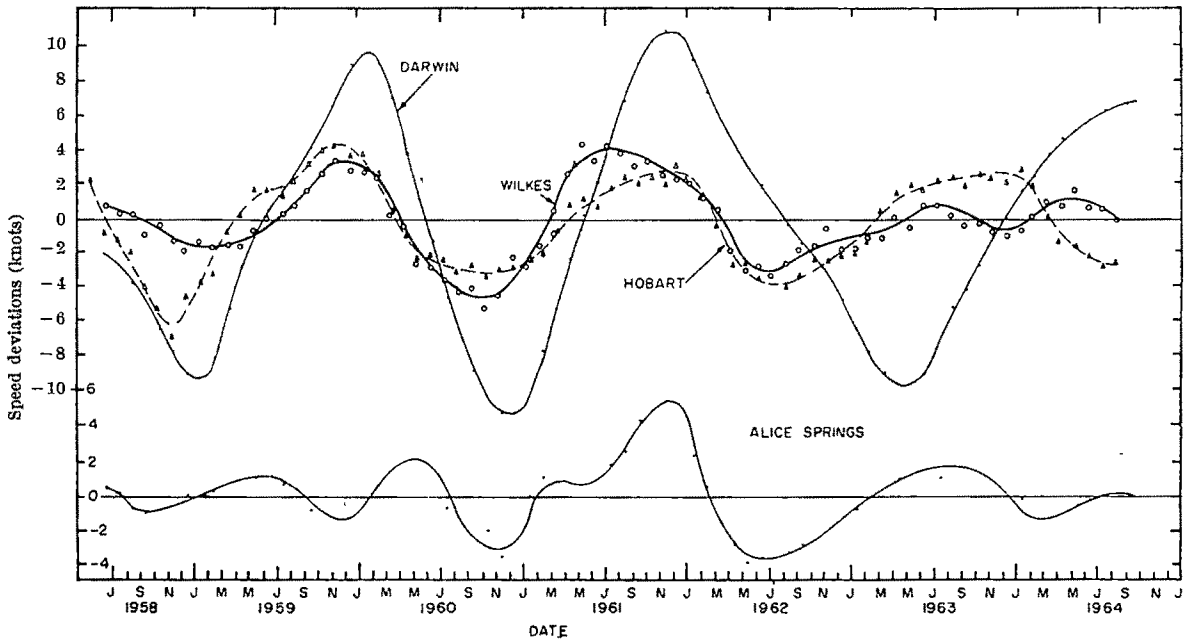

Fig. 1. Oscillations of the zonal wind at 70,000 ft over Darwin (12° S) and Alice Springs (23° S.); at 60,000 ft. over Hobart (43° S.); and of the meridional wind at 60,000 ft. over Wilkes (67° S.) Ordinate scale gives the deviation of a 12-month from a 24-month moving average of mean monthly components, a filtering device for the suppression of short periodic fluctuations and the elimination of mean annual waves and long-term trends in the time series (July 1957–June 1965). A positive deviation indicates excess of west or south wind

curve for Wilkes—peaks and troughs of the 1959–62 oscillation occur between winter and late spring. The latter is broadly in phase with the zonal wind oscillation at 60,000 ft. over Hobart, but leads in phase the tropical zonal wind oscillation by several months. This is shown by way of example at 70,000 ft. over Darwin where it undergoes a considerable lengthening of period after 1962.

In the curve for the zonal wind at Alice Springs, which mainly demonstrates the pole-ward attenuation of the tropical oscillation, the occurrence of a 24-month cycle between 1960 and 1962 is apparent. While in phase with the tropical oscillation at Darwin, this subtropical oscillation is later damped away in a manner strikingly similar to the fading of the oscillation at Wilkes.

Attenuation at Wilkes and Alice Springs is apparent during the middle of 1963. This suggests the possibility of a connexion with the large reduction in direct solar radiation at southern hemisphere stations following the eruption of Mount Agung, Bali (8° S., 115° E.) on March 17, 1963, as reported by Dyer and Hicks[11] for Aspendale (Southern Australia) and Flowers and Viebrock[12] for the South Polar Station.

A detailed correlation analysis is being carried out of the coupling mechanism between quasi-biennial oscillations in polar and tropical latitudes of the stratosphere. An investigation of relevant connexions in the northern hemisphere would seem highly desirable.

GEOPHYSICS

Transfer of Northern Hemisphere Fall-out to the Southern Hemisphere

THE detonation of a low-yield nuclear device in Western China at 1900 h, October 16, 1964 (New Zealand time), was reported, and tests for barium-140 were included in our routine investigations of fall-out at Gracefield, Wellington (41° 14′ S., 174° 55′ E.), to identify debris from this test. Barium-140 was detected in rainwater samples collected between December 1, 1964, and January 1, 1965, and the deposition was 50 ± 10 mc. per square mile. It would appear, therefore, that debris from this first Chinese bomb took between 45 and 76 days to reach Wellington.

Monthly samples of rainwater taken from January to May 1965 gave only background levels of barium-140, but for the sample collected between June 3 and July 2, 1965, the barium-140 deposition value was 30 ± 5 mc. per square mile. A second Chinese bomb test was reported to have taken place on May 14, 1965. Thus the debris from this second test took between 19 and 48 days to reach New Zealand.

Previous occurrences of barium-140 in New Zealand rainwater have been reported in this journal[1]. Rain samples collected between February 13 and March 26, 1960, contained barium-140 assumed to be from the French atomic bomb test at Reggan in the Sahara (27° N. 0°) of February 15, 1960. The barium-140 in the sample collected during May 1–3, 1960, followed the French low-yield explosion of April 1, 1960, and similarly an atomic bomb test on December 23, 1960, at Reggan gave barium-140 in the rain sample collected at Gracefield between January 24 and 31, 1961.

After the French tests, the Soviet Union began a series on September 1, 1961, using the Novaya Zemlya site (approximately 75° N., 60° E.) mainly for megaton yield tests and the Semipalatinsk area (50° N., 80° E.) for low and low-intermediate yield explosions. No barium-140 from the Soviet experiments was detected in monthly rain samples collected between September 1961 and April 1962, but, as was to be expected, new fall-out was evident in the May 1962 sample after American tests began on April 25, 1962, in the South Pacific area at

Christmas Island (4° N., 157° W.). Deposition of barium-140 at Gracefield reached 50,000 μc. per square mile for May 1962.

To summarize, barium-140 has been found in rainwater at Wellington a few weeks after low-yield nuclear explosions from test sites south of about 50° N. It is reasonable to assume that this trans-equatorial movement of nuclear debris takes place by way of the troposphere. It is surprising that barium-140 from low-yield tests at Semipalatinsk has not been detected in New Zealand rain. This test-site at about 50° N., 80° E., is roughly 10,000 miles from Wellington, bearing north-west. The Chinese tests, from which barium-140 has been noted, were reported as being carried out "somewhere in Sinkiang, Western China". The middle of this province is about 9,000 miles from Wellington, again bearing to the north-west. It seems likely that debris from the Semipalatinsk tests was injected into the stratosphere. Barium-140 from Reggan, more than 13,000 miles from Wellington lying west-north-west, has been detected here.

Strontium-90 deposition at Gracefield has shown a marked increase since about July 1964, as is shown in Fig. 1.

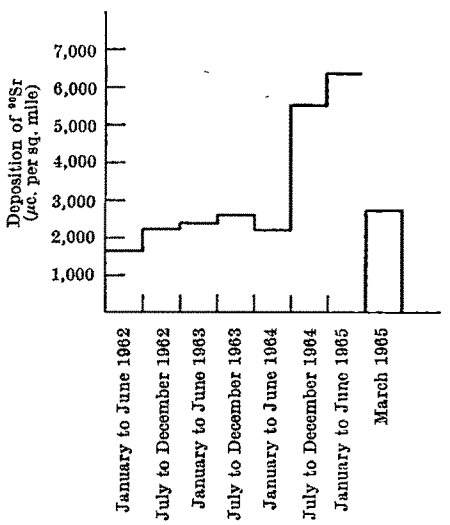

Fig. 1. Deposition of strontium-90 in rainwater at Wellington, New Zealand, 1962–65

The most likely source of this increase is the last major series of tests carried out from early August to the end of December 1962 by the Soviet Union, when many megatons of nuclear energy were put into the stratosphere. Whether this debris returned to the troposphere above the Northern Hemisphere, and crossed the equator in the troposphere, or whether the trans-equatorial movement was in the stratosphere cannot be determined from our available data. Another instance of the transfer is afforded by the United States *Starfish* shot of July 7, 1962. In order to investigate the movement of nuclear debris at very high altitudes, a device was detonated 400 km above Johnston Island (17° N., 169° W.) and cadmium-109, a radioisotope not normally present in nuclear debris, was included as a marker. As reported previously in this journal[2], cadmium-109 was detected in rainwater collected at Gracefield during September 1964, but could have been present in earlier samples. Here again we do not know whether the actual passage of the fall-out across the equator took place by way of the troposphere or the stratosphere, because we have not heard of cadmium-109 being detected in rainwater in the Northern Hemisphere.

I thank the Director of the Institute of Nuclear Sciences, Department of Scientific and Industrial Research, New Zealand, for his interest in these investigations.

Isotopic and Alkali Measurements from the Vema Seamount of the South Atlantic Ocean

THE Vema Seamount is an isolated volcanic pile which rises from the ocean floor near the centre of Cape Basin at 30° 38′ S., 8° 21′ E., approximately midway between the Walvis Ridge and the South African mainland[1]. It is approximately 1,500 miles north-east of Gough Island and 2,300 miles south-east of Ascension Island, which lie on the mid-Atlantic Ridge, and 1,500 miles south-east of St. Helena Island, which lies close to the Ridge. Isotopic measurements have previously been obtained for samples from all three localities[2,3].

The Seamount was explored extensively by Simpson and Heydorn[1]. It extends for about 5 square miles at approximately 40 fathoms and consists mainly of tuffaceous material. The present sample was taken by Simpson from Collins Peak, which rises to within 14 fathoms from the main plateau. It is a dense green semi-glassy phonolite which was sent to Dr. Ian McDougall for potassium–argon dating, and yielded an age of 11 m.y.[1] which must be regarded as minimal because of the altered state of the sample. Analytical details are included here with his permission.

The lead was isolated by vacuum volatilization[4] and solvent extraction during which the approximate lead concentration (48 p.p.m.) was estimated. A steady lead-ion beam of approximately 5×10^{-11} amp was obtained in a 12-in. radius of curvature, 60° sector single-focusing mass-spectrometer, using single filament thermal-ion source and a single plate collector. Ratios were obtained by the usual magnetic peak switching procedures, using voltage-to-frequency conversion and digital printout[5]. The strontium isotope measurement was made on the same machine using procedures described elsewhere[6,7]. The strontium and rubidium abundance data were obtained by courtesy of Dr. A. J. R. White, using X-ray fluorescence with precise mass absorption corrections, and the potassium analysis was made by flame photometry[8,9]. A. Turek wrote the programme for treatment of the lead results; M. J. Vernon extracted the strontium sample. Results are listed in Table 1.

From the lead isotope plot of Fig. 1, it can be seen that this sample provides yet another example of an "anomal-

ous" oceanic volcanic lead[2,10], in that it does not fall anywhere near the 11 m.y. isochron: it is enriched in lead-206 and in lead-208 to an extent slightly greater than that for the volcanics from Ascension Island[2]. A limit on the uranium content may be estimated, from the published range of potassium–uranium ratios on volcanic extrusives[11], to be less than 5·6 p.p.m. Thus, because the lead content is approximately 48 p.p.m., the uranium-238–lead-204 ratio must be less than 8·9. Since this is not greater than the accepted "primary ore–lead source" of about 8·99 (ref. 12) the "excess" lead-206 cannot have grown in since eruption and must be characteristic of the lead of the source material. The rock is an alkaline differentiate (phonolitic) as are some of the Ascension rocks (trachytic), but it is different from some of the other oceanic extrusives for which excessive lead-206 has been reported (such as Gough[2], Ascension[2] and Easter[10] Islands) in that its source does not lie on a seismically active mid-ocean ridge. However, if Wilson[13,14] is correct in his recent suggestions about the generation of the Atlantic Ocean and the phenomenon of transform faulting, then it follows that the Vema Seamount and also St. Helena may have been on or near the ridge at the time of eruption.

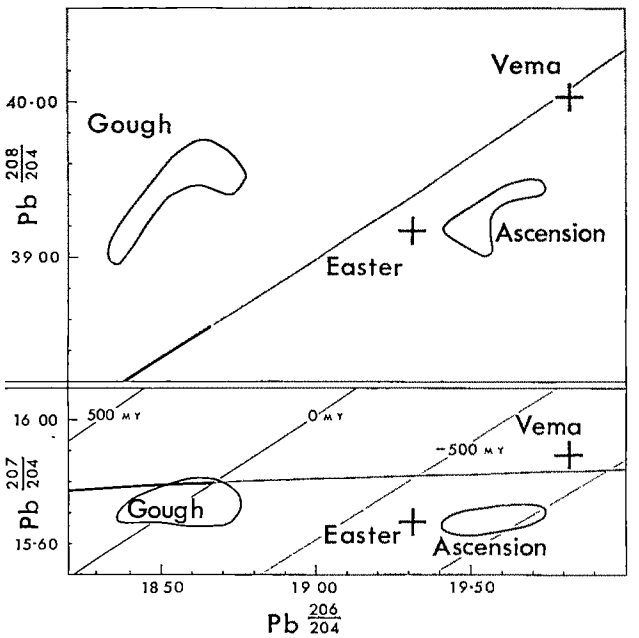

Fig 1. Lead isotope ratio plots of the Collins Peak phonolite showing its relationship with those from other oceanic volcanics The heavy line growth curve and isochrons, and the dotted extensions, have been constructed from the parameters·

primordial lead: $\frac{206}{204} = 9{\cdot}56$, $\frac{207}{204} = 10\,42$, $\frac{208}{204} = 29\,71$,

$t_0 = 4\,55 \times 10^9$ years, $V = 8{\cdot}99$; $W = 35\,55$

The strontium-87–86 ratio of 0·7034 ($^{86}Sr/^{88}Sr = 0{\cdot}1194$) lies within the narrow range of 0·702–0·706 reported for oceanic volcanics[2,6,15,16], being closer to the lower limit for those which are radiogenically unenriched. The low ratio of rubidium to strontium (0·23) and the low age preclude the possibility of any significant contribution to the strontium-87 by radiogenic decay.

Some enrichment of rubidium content over potassium could reasonably have been expected because of the comparatively high (2·8 per cent) potassium content. This is particularly so because its glassy nature suggests that the sample could be a residual liquid in which the rubidium would concentrate because of its low solubility in the lattice of crystallizing sodium-rich potassium feldspars[17,18]. Nevertheless it yields a potassium–rubidium ratio of 269 which cannot in any way be regarded as anomalous, although it is close to the lower limit of those reported for oceanic volcanics.

GEOLOGY

Palaeocurrent Directions in the Upper Cambrian of North Wales

RECENTLY, Evans, Garrett and Whitaker[1] recorded some palaeocurrent measurements from the Maentwrog and Ffestiniog beds of North Wales. They suggest that their measurements show that currents came generally from the south-south-west during Maentwrog and Ffestiniog times. The authors make no acknowledgment of the work of Kopstein[2], who reached the same conclusion using, in part, the same criteria and localities (*op. cit.*, p 81, and appendix 3). I have made a detailed investigation of the palaeogeography of these and other Cambrian sediments in North and South Wales[3] and have recorded the presence of palaeocurrents from the south-westerly quadrant from widespread localities in the Upper Cambrian rocks of North Wales[4,5].

The statistical, sedimentological and structural problems involved in the production of a viable interpretation of the palaeogeography of these rocks are, however, far more complex than Evans *et al.* imply. Their map (ref. 1, Fig. 1) shows palaeocurrent readings based on the orientation of cross-stratification, but neither the exact type of cross-stratification nor the statistical significance of their results is indicated. They show, for example, westerly and south-westerly derived palaeocurrents based on cross-stratification measurements at localities to the south of Bethesda. I have made a detailed study of the exposures in question. Alpha, beta and xi cross-stratification types[6] are common and I have taken eighty palaeocurrent readings from cross-strata. The wide spread of these results suggests that any mean or resultant palaeocurrent direction deduced from measurements of cross-stratification at these localities will have little or no statistical significance. Bassett and Walton[7] have similarly studied the orientation of small-scale cross-lamination from upper portions of grit and siltstone beds from the Hell's Mouth Grits of St. Tudwal's Peninsula. The palaeocurrent directions showed a large standard deviation (± 57°). This indicated an absence of preferred orientation which was confirmed by a χ^2 test. They concluded that "this mean has little or no significance". The validity of palaeocurrent arrows deduced by Evans *et al.* from cross-stratification (ref. 1, Fig. 1) is, in the absence of statistical treatment, therefore open to question.

The record[1] of flute cast(?s) showing a south-westerly derived current at localities to the south of Bethesda is interesting. I have also observed the orientation of flute casts at these localities: my measurements (thirty-one) show considerable variation, but in general suggest that palaeocurrents travelled from a north-easterly quadrant.

Evans *et al.* also refer to asymmetric ripples in the Ffestiniog grits of Cwm Graianog. In addition to the asymmetric type mentioned by them, there are four other types—symmetric, flat topped, interference and cuspate. They describe the direction of the asymmetric ripples as anomalous because they do not lie at right angles to the palaeocurrent trend postulated from their observations on sole markings. They suggest that the asymmetric ripples may be due to surge waves set up by the nose of a turbidity current which are reflected back from the marginal slopes of the trough. This explanation presupposes that these beds are turbidites. It also implies that they were deposited in relatively deep water, since the turbidity currents are unlikely to have travelled far up the marginal slope of 'the trough'. Williams[8], however, has suggested that these beds were deposited in shallow water. I have found[3] sedimentological evidence which indicates, by comparison with modern environments, deposition within reach of wave or tidal scour. These sediments also contain a wide variety of trace fossils. The origin of many biogenic structures is uncertain, but Seilacher[9] has concluded that they can sometimes be used as an indication of the depth of water during deposition. I have observed numerous examples of 'trilobite tracks', *Repichnia* (Cruziana) and *Cubichnia* (Cruziana). These are characteristic of the Cruziana Facies which Seilacher (*op. cit.*) considers to be deposited above wave base. The biogenic and non-biogenic sedimentary structures both, therefore, indicate deposition in shallow water.

There also appears to be little evidence to suggest that these beds are turbidites. I would not question the conclusion of Evans *et al.* that they are greywackes but, as Cummins[10] has insisted, not all greywackes are turbidites. Dzulynski and Walton[11] have also emphasized that non-biogenic sedimentary structures found in turbidites also occur in non-turbidite sediments. They conclude that "the operation of turbidity currents is suggested above all by evidence for deep water conditions combined with indications of violent and episodic inflow of coarse clastics". The shallow water features associated with these grits clearly reduce the possibility of a turbidite origin. The evidence suggests that these are shallow water greywackes. Ripple formation would, therefore, probably be at least partly wind controlled[12]. The trend of the asymmetric ripples would thus not be expected to maintain a definite relationship to any sole markings that might be developed in these or other Ffestiniog sediments. These particular grits seem to be a local development confined to the north-western part of North Wales. They do not appear to be connected with the south-westerly derived palaeocurrents observed elsewhere[2–5].

Evans *et al.* make no mention of the structural problems involved in interpreting the palaeogeography of these rocks. They state, for example, that in re-orientating the palaeocurrent directions they have allowed for dip and, where possible, plunge. This method of re-orientation is clearly invalid if the arcuation of the cleavage in North Wales is due to refolding about a large-scale F_3 fold, as Helm, Roberts and Simpson[13] have suggested. Evans *et al.* produce no evidence on this point, which is, however, considered elsewhere by me[3].

It must therefore once again be stressed that the structural and palaeogeographical complexity of these sediments is such that it would be unwise to arrive at any regional conclusions on the basis of the evidence so far published.

I thank Mr. P. G. Sly for many useful discussions concerning modern environments and also Mr. R. G. C. Bathurst, Dr. R. J. Bailey and Dr. J. C. Harper for critical reading of this manuscript.

Quicksand Structures in the Bedded Tuffs of Great Langdale, Westmorland

QUICKSAND structures similar to those described by Selley (ref. 1, Fig. 1*a* and *b*) abound in the bedded tuffs (Ordovician) of Great Langdale. These sediments appear to have been highly susceptible to the type of behaviour suggested by Shearman[2] and called by him "'quicksand' movement". These authors described examples in Torridonian[1] and Devonian[2] sandstones where this process, involving the repacking of sand grains and the expulsion of excess pore-water from the sediment, had, they assumed, operated "penecontemporaneously". It appears that both authors consider that this process took place below a thin (less than 1 m ?) cover of sediment.

Fig. 1 illustrates a structure in the bedded tuffs thought to have been produced by "quicksand" movement. Laminated mudstone rests on sandstone. A rectangular embayment projects upwards into the mudstone. Within this embayment, and also along the base of the laminated mudstone, angular, sharply bounded fragments of the laminated mudstone occur dispersed in the sandstone. Sand grains have not been pressed into the mudstone fragments.

From this structure it is concluded that: (*a*) the sand was mobilized after the laminated mud had been compacted to mudstone; (*b*) mobilization must, therefore, have occurred beneath a sediment overburden thick enough to have compacted the mud to mudstone. This overburden would also have provided the hydrostatic pressure which enabled the mobilized sand to penetrate into the mudstone.

This structure shows that sand can remain loosely packed during the accumulation of sufficient sediment

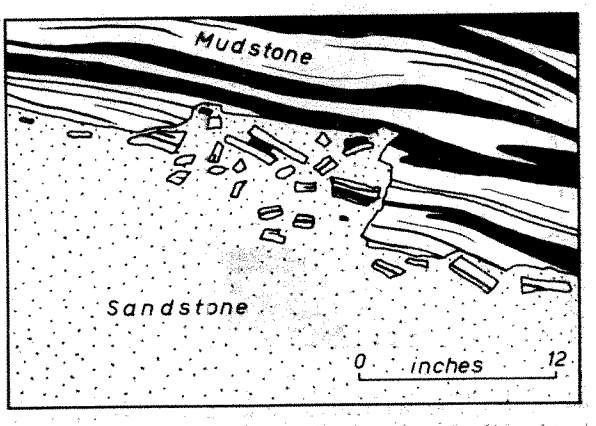

Fig. 1. Structure in bedded tuffs believed to have been produced by "'quicksand' movement". Simplified diagram from a photograph

overburden to compact overlying mud to mudstone. The behaviour of the sand in a manner called by Shearman "'quicksand' movement" may occur at a time so long after its deposition as to be outside the broadest interpretation of the meaning of 'penecontemporaneous'.

Sandstones of Sublittoral (Neritic) Facies

A SANDSTONE unit which is considered to be unique to, and diagnostic of, a sub-littoral (neritic) environment occurs at many levels in the stratigraphic column. It shows several features which allow it to be clearly distinguished from units either associated with fluviatile sequences, or supposedly deposited from turbidity currents.

Characteristically, each unit (Fig. 1), which appears generally to be up to 1·0 m thick, is fine- to very fine-grained, and moderately to well sorted, with an overall upward decrease in the median grain size of the quartz of about 0·5φ. The base is sharp, frequently flat or undulose, and lacks sole structures, such as flute casts, which indicate a unidirectional current flow. Stratification is typically sub-horizontal or at a very low angle, whereas cross-stratification is much less common. Primary current lineation is difficult to establish because of the fineness of the grain, but has been observed in some instances. The top of the unit may be strongly bioturbated, giving a transition zone to the overlying clay grade sediment, or may show oscillation ripple (often ripple-drift), or a gradation by decrease in grain size to clay grade sediment. Where micaceous minerals are abundant, the upper part of the unit is finely laminated. Penecontemporaneous erosion has often removed the upper, finer-grained portion of a unit prior to the deposition of the succeeding sediment.

Fossils may be numerous on partings, although, apart from the trace fossils, they are not in a life position. The common fossiliferous sandstones, yielding, for instance, in the Lower Palaeozoics of Wales and the Welsh Borderland,

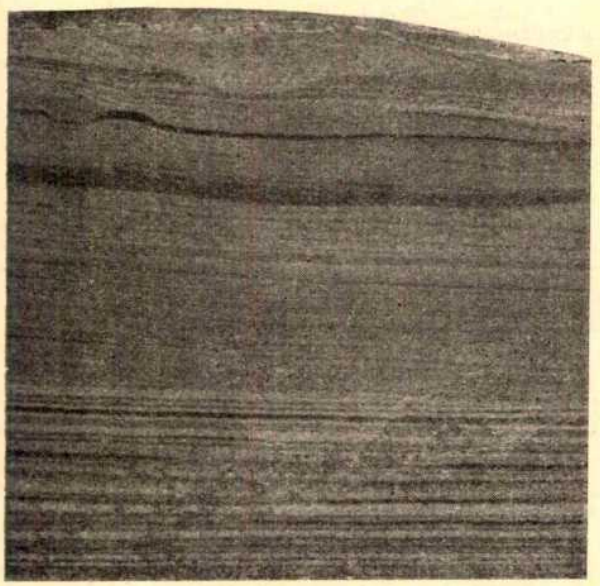

Fig. 1. Single unit (×1) from upper part of Baggy Beds (Upper Devonian), North Devon (*SS* 42254026). Face approximately east–west, and showing sub-horizontal stratification at base, grading into straight ripple-drift (section parallels ripple crests) with oscillation ripple above. A thin seam of clay grade sediment is present below a scoured surface marking the base of a second unit

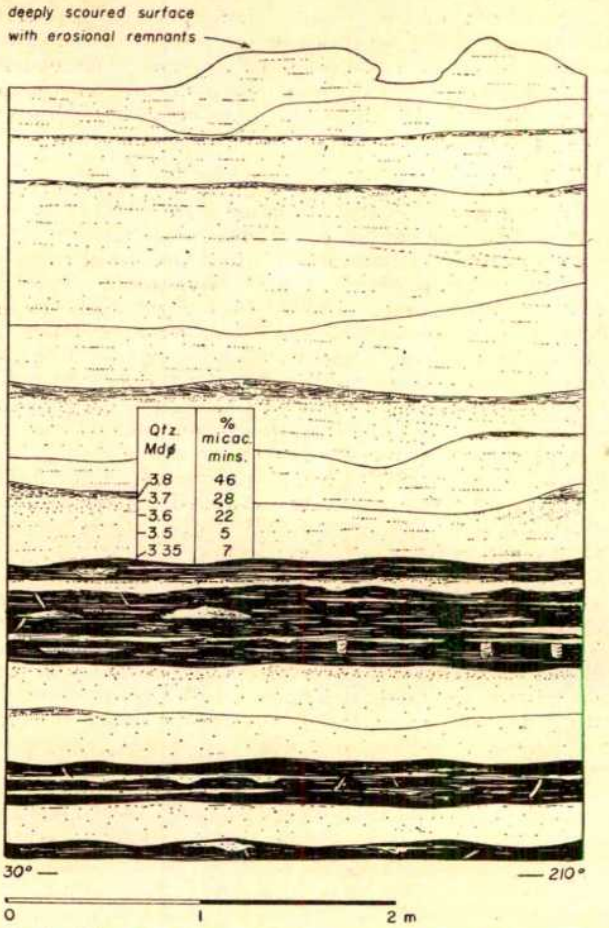

Fig. 2. Diagram of co-set developed in the Baggy Beds (Upper Devonian), North Devon (*SS* 42114039). The units are of well sorted, very fine, calcareous, feldspathic sandstone. The base follows several single units with interbedded siltstones and shales. The upper surface is strongly scoured and is followed by sandstones considered to represent a shallow water environment

a trilobite-brachiopod fauna, are associated with this sandstone unit, although the more fossiliferous sandstones generally show cross-stratification. Plant debris is uncommon at all levels. Although bioturbation is for the most part only developed at the top of the unit, it may involve more or even most of the unit. It is not generally possible to determine current direction in a unit, unless cross-stratification is developed. When this is only weakly developed a polarity of provenance may well be suggested by the main part of the unit. Load casting is uncommon. This is probably an indirect result of the degree of wave action.

Units occur either as single sets in a predominantly clay grade sequence, or grouped into co-sets (Fig. 2) of up to at least 55 ft. The latter may be bounded by gradational sequences of single sets, or, with a lower gradational sequence, the co-set may be followed, and probably truncated, by a sequence of sediments considered to represent deposition in shallower water or a fluviatile environment, as with the Fort Collins Member in the Lower Cretaceous of North America[1]. Co-sets seem to be less fossiliferous than individual sets.

The erosion which preceded deposition of the unit may in some cases have been sufficient to cut a series of parallel, and generally straight but sometimes sinuous, grooves of up to 1·2 m in width and 30 cm depth, as in the Baggy Beds (Upper Devonian) of North Devon and the Llandovery Sandstone (Silurian) of the Gullet Quarry, Malvern Hills[2]. In North Devon, on one strike surface 30 m across, more than thirty filled grooves are displayed, some of which merge locally in an irregular manner. The

original lateral extent of individual units is not known, and in several instances penecontemporaneous erosion has determined the present extent. The oil-producing co-set described by MacKenzie[1] has a blanket form recognizable over much of Wyoming and eastern Colorado, but farther south it appears to interdigitate with marine shales.

In several instances in the Baggy Beds, and in the contemporaneous Condroz Sandstone of Belgium[3], where the sediment is calcareous, penecontemporaneous erosion following deposition of the unit has scoured out irregularly shaped hollows 3–4 m in diameter, or removed the unit so as to leave only hummocky erosional remnants similar to the *talards* of Brittany[4]. The scoured surfaces may be followed by sand or clay grade sediment. The groovings and the erosional remnants recall the backwash channelling of recent intertidal mud flats[5], but no evidence whatsoever of emergence has been observed. They are also similar to the submarine scour structures described by Norrman[6] from Lake Vättern, Sweden, and by Seibold[7] from the Baltic, and attributed by both to wave action. There is no evidence that the course of the grooves was influenced by plant growth as in recent aggradational marshes, although in the Baggy Beds, colonies of the tube-building organism, *Diplocraterion*[8,9], may have determined their development to some extent.

Table 1. SOME DEVELOPMENTS OF THE UNIT

Ordovician, Llanvirn. Ffairfach group (iii), Llandeilo (Carmarthen) (*SN* 628212) (ref. 13);
Silurian, Llandovery. May Hill Sandstone, Malvern Hills (*SO* 762381) (ref. 2);
Wenlock. Buckover, near Tortworth (Gloucester) (*ST* 667907) (ref. 10);
Ludlow. Black Cock Beds, Pont-ar-llechau (Carmarthen) (*SN* 727247) (ref. 14);
Devonian, Downtonian. Above Ludlow Bone Bed at Ludlow (Shrewsbury) (*SO* 513741) (ref. 15);
Downtonian. Downton Castle Sandstone (Hereford) (*SO* 454750) (ref. 16);
Givetian. Ilfracombe Beds, Avill Sandstone (Somerset) (*SS* 940405) (ref. 17);
Famennian. Baggy Beds (Devonshire) (*SS* 4240) (refs. 8, 9);
Jurassic, Upper. Kellaways Rock, Cayton Bay (Yorkshire) (*TA* 0784) (ref. 18);
Cretaceous, Lower. Fort Collins Member and Skull Creek Shale of Dakota (ref. 1);
Eocene, London Clay, Whitecliff Bay, Isle of Wight (*SZ*639860).

Four characters may be considered especially diagnostic of the facies unit: (1) The unquestionably marine (though sometimes brackish) origin of the unit, as indicated by the associated fauna. (In the section showing the unconformity between marine Wenlock and the continental Upper Old Red Sandstone at Buckover, near Tortworth (Gloucestershire), the unconformity can readily be marked at the termination of the sandstone and siltstone units of the type described, although Curtis and Cave[10] comment that its position is not at first sight obvious.) (2) The form of the sole, and the style of penecontemporaneous erosion. (3) The graded bedding. This recalls the grading associated with turbidites and deep-sea sands[11], but the main part of the unit never shows such a considerable proportion of clay grade. The general absence of bioturbation in the main part of the unit suggests that sediment deposition was too rapid for organic colonization. (4) The form and variation of the upper part of the set.

No unidirectional current system such as a turbidity current or a river, can be invoked as the cause of the scour preceding and succeeding deposition of the unit, or can be considered to have operated during deposition of the upper part of the unit. In a marine sequence, only wave action remains as an effective agent which could have operated before and after deposition, and at least during the deposition of the upper part of the unit. Because of the amount of sediment represented by the main part of the unit it is unlikely that this was deposited without associated current action. Wave action has been invoked by Daly and Passega[12] as the cause of turbidity currents, but in these units there is no evidence that actual currents were produced. This could have been because the sedimentary slope was insufficient. The considerable thickness to which the units have accumulated in several examples indicates strong, though not necessarily local, sediment sources. These may have been deltaic, possibly associated with long-shore drift. In North America[1] co-sets can be oil producing, and individual units may well have been important in oil migration in connecting marine clay grade to coarser grade sequences.

Kink-bands and Related Geological Structures

ANDERSON[1] has proposed that kink-bands develop in response to a maximum principal pressure acting within, or close to, a strong planar anisotropy, and that their orientation is controlled by shear movements on the intra-kink-band folia. He has also stated that these shears make an angle of $\frac{90 - \varphi}{2}$ degrees with the maximum pressure (P_{max}), while the kink-bands form angles of $\frac{90 + \varphi}{2}$ degrees with the same stress axis. This theory has been criticized[2] on the grounds that, in planar anisotropic rocks, the maximum principal stress cannot be given unless the kink-bands are truly symmetrical about the anisotropy, that the known variation in the angle formed by kink-bands about P_{max} was not wholly explained, and that the intra-kink-band movements are a secondary response to a primary direction of shear paralleling the kink-band. It was also stated that Anderson's figured example was not truly conjugate and that the kink-band system in the Ards Peninsula might not be symmetrically arrayed about the cleavage. Anderson's inadequate reply[3] to these criticisms merits a further communication.

Anderson[3] stated that he fully realized symmetrically arrayed conjugate kink-bands comprise a special case and that kink-bands are not necessarily produced by a maximum principal pressure acting exactly along the foliation. I agree that kink-bands result from a maximum pressure acting within or at an angle to the anisotropy, provided that the orientation of one or both of the potential shear-surfaces is such that the displacement would tend to 'open out' the individual folia (Fig. 1). The point which appears to have eluded Anderson is that should P_{max} not be contained within the planar aniso-

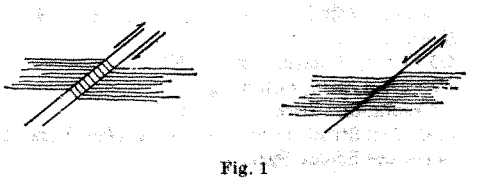

Fig. 1

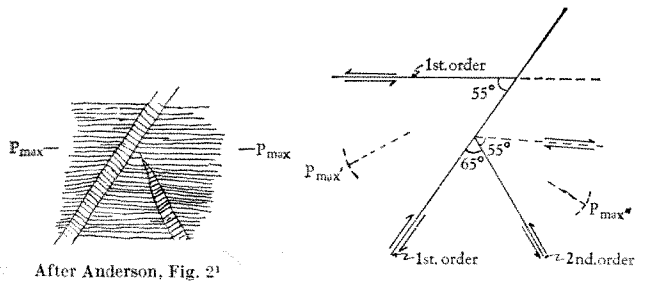

tropy, the consequent rotational strain will result in the kink-bands being asymmetrical about both the anisotropy and the maximum compressive stress. This is the fabric-type [F1 m_1] of Hoeppener[4], who stated that the precise locations of the least and maxima principal stresses cannot be given. It has been shown[5] that in strongly anisotropic rocks the surface of shear-failure will always lie in the anisotropy or between it and the nearest of the planes predicted by the Coulomb–Navier theory. Consequently, varying with the angle of impingement of the maximum compressive stress on the anisotropy, the angle between the plane of practical shear-failure and P_{max} will either be smaller or larger than in a corresponding isotropic system. In view of the difficulty of locating P_{max} in any but a perfectly symmetrical, truly conjugate system of kink-bands, it is meaningless to ascribe values of $\frac{90 - \varphi}{2}$ degrees and $\frac{90 + \varphi}{2}$ degrees to the respective angles made by P_{max} with the intra-kink-band shears and the kink-bands.

Regarding the orientation of the kink-bands in the Ards Peninsula, Anderson[1] wrote: "The vertical dextral kink-bands have a strongly preferred orientation striking N. 15° E., while *most* (my italics, B. M.) sinistral kink-bands strike at about E. 40° S.". Implicit within this statement is that the sinistral kink-bands are less strongly preferred. Thus, my conclusion[2] that the kink-bands are not truly symmetrical would seem justified, and my remarks concerning the statistical evaluation of regional data would appear apposite.

Johnson[6] coined the term conjugate folds to describe "paired reversed folds that are controlled by a pair of symmetrically arranged slip planes which are inclined towards one another and intersect parallel to the . . . fold axes". Should Anderson accept that kink-bands of differing orders or of differing phases of tectonism, provided that they fulfil the orientational requirements, may be conjugate, I am prepared to acknowledge his usage. However, Johnson, as is apparent from his diagram (Fig. 1, ref. 6), envisaged the synchronous development of the conjugate folds, and this is not evident in Anderson's Fig. 2 (ref. 1), where the dextral kink-band is dominant. Such a relationship has been interpreted by Moody and Hill[7] as indicating displacements of differing order, the lower order movement terminating against that of the higher order.

Anderson[3] questioned my usage of shear as applied to the sense of displacement paralleling a kink-band. In this I followed Ramsay[8], whose usage Anderson[1] noted without demur. He[1] also recorded Knill's conclusion that dextral kink-bands may be complementary to contemporary sinistral wrench faults without questioning the implication that kink-bands parallel the complementary direction of shear.

Applying Moody and Hill's[7] work on the development of lower order stress-systems, Anderson's Fig. 2 (ref. 1) may readily be explained in terms of first- and second-order structures. This is illustrated in Fig. 2; φ is taken as approximately 35°, being the value necessary to explain the angle between the dextral kink-band and the cleavage, whereas the angle with which the second-order maximum compressive stress impinges on the first-order displacement-surface is ascribed a value of approximately 87° (Moody and Hill[7] indicated that the angle may vary between 60° and 90°).

After Anderson, Fig. 2[1]

Fig. 2

Fig. 1 (ref. 2) was drawn to illustrate that "I have traced a kink-band along its strike into a single kink-plane . . ." (ref. 2). I readily accept Anderson's[3] correction that "The two kink-planes of the kink-band illustrated converge and pass into a shear-plane . . .", since it emphasizes that a single shear-surface may substitute for a kink-band a feature recorded by Anderson[1]: In some examples shearing has occurred along the kink-plane, but it is not an essential feature and probably post-dates the folding, while unsheared kink-planes passing into faults along their length are not common", but do occur. Thus, Ramsay[8] would appear justified in figuring and describing the axial surfaces of conjugate folds as conjugate shear-planes.

In Fig. 1 (ref. 2) the same sense of displacement is expressed by kink-band, shear-plane, and sigmoidal tension gashes, these structures all being symptomatic of a couple acting along the kink-band. In the development of the kink-band, the shear movement is accommodated by contrary rotation on the intra-kink-band folia which play an essentially passive role in the deformation. Actual displacement on the kink-planes may be expected when the intensity of shearing exceeds the rate of accommodation.

Having quoted extreme values of φ, Anderson[3] remained unable to explain, in terms of his theory, the full range[2] of the dihedral angle enclosed by conjugate kink-bands. He stated that values of less than 90° are uncommon, yet Ramsay[8] reported that kink-bands form on "one or more shear surface which usually (but not invariably) make an angle of less than 45 degrees to the principal stress axis", and by implication suggested that they might not affect the correctness of his conclusions. However, no matter what percentage of the total number of kink-bands they comprise, a theory regarding the mechanism of formation should encompass the available facts.

Anderson[3] concluded that experimental results of Paterson and Weiss[9] "are in good agreement with the geometrical relationships and mechanisms of formation I (T. B. A.) outlined . . .". Certainly, Anderson's modal values appear to have been duplicated, although it is perhaps more significant that the full range[2] of field relationships have yet to be reproduced, but I fail to see how he was able to claim support for his mechanism of formation. Anderson[1] stated that "In a conjugate set of kink-bands the small shear planes make an acute angle about the same major principal stress which bisects the obtuse angle formed by the kink bands. . . . In effect, while shear makes an angle of $\frac{90 - \varphi}{2}$ degrees with the major principal stress . . . kink-bands might be expected to make an angle of $\frac{90 + \varphi}{2}$ degrees with the same major principal stress"; yet in the excellent photographs of Paterson and Weiss (Figs. 2 and 3)[9] the intra-kink-band shears enclose P_{max} in angles exceeding 115°. Anderson presumably must advocate minus values of φ in excess of $-25°$ since he claimed support from this experimental work.

Finally, in his Fig. 6, Anderson[1] showed the intra-kink-band folia varying between 0° and approximately 48° in their angle with the anisotropy. If their orientation is a function of $\frac{90 - \varphi}{2}$, φ must be continuously variable between 90° and a minus quantity; if their orientation controls that of the kink-bands it is peculiar that they change their attitude as shearing proceeds while the kink-band remains obdurately constant.

Anderson's[1] theory was apparently formulated to explain the special case in the Ards Peninsula; it has no general application and I consequently doubt its specific application.

PHYSICS

Ultrasonically induced Etching of Quartz

SOUND waves have been excited in quartz from 20 kc/s to 3,000 Mc/s. Frequencies of greater than 20 Mc/s are usually excited either by placing a quartz rod in a re-entrant cavity and exciting the surface layer[1], or by exciting 1–10 Mc/s quartz plates at high odd harmonics[2]. Both these methods suffer from the fact that the acoustic power produced is only of the order of mW/cm². A distinct improvement in power level is obtained if the quartz is excited at its fundamental frequency[3]. This frequency is, of course, dependent on the thickness of the quartz plate—the latter is equal to half the wave-length for this frequency in the quartz. Difficulties arise because for frequencies above 10 Mc/s the thickness of the quartz plate must be less than 0·3 mm. However, by conventional grinding techniques, using fine 'Carborundum' powders, thicknesses as low as 150μ can be achieved. To obtain thinner plates, of higher fundamental frequencies, is exceedingly difficult, and requires very expensive machinery. Quartz, because of its brittleness, is easily damaged during grinding, especially because of the large particle size of even the smallest 'Carborundum' particles used. Graded grit sizes average 13μ and may be as large as 40μ. Even after polishing the ground quartz, deep score marks are visible on its surface.

A simple solution to this problem devised in this department is the use of an etchant liquid agitated by 40 kc/s sound waves. The apparatus is shown in Fig. 1. The 40 kc/s transducer must be plated with a material resistant to the acid etchant used. In the case of quartz a suitable etchant is hydrofluoric acid, and the faces of the transducer are plated with copper. A mixture of 40 per cent hydrofluoric acid in water has been found to be the best for etching quartz. For appreciable etching to occur, the vibrating face of the 40 kc/s transducer must be only a short distance, h cm, from the quartz surface. The theory of acoustic streaming, which describes the production of a steady flow of fluid from an alternating pressure field, predicts that the streaming occurs very close to the vibrating surface. The streaming is especially marked in a thin layer of fluid on the vibrating surface. The thickness of this layer at 40 kc/s is calculated to be about 10μ, which is approximately equal to the experimentally established distance h already mentioned. This fact clearly implicates acoustic streaming as the agent for enhancing etching. Nyborg[4] has commented that acoustic streaming would greatly increase the rate of such mass transfer processes, and has ascribed the removal of loosely adherent films to boundary layer streaming[5]. This is precisely the effect needed here.

Two precautions must be observed. The first concerns the production of small bubbles in the sound field which cause large local increases in fluid velocity and thus in mass transfer processes occurring near their surfaces[6].

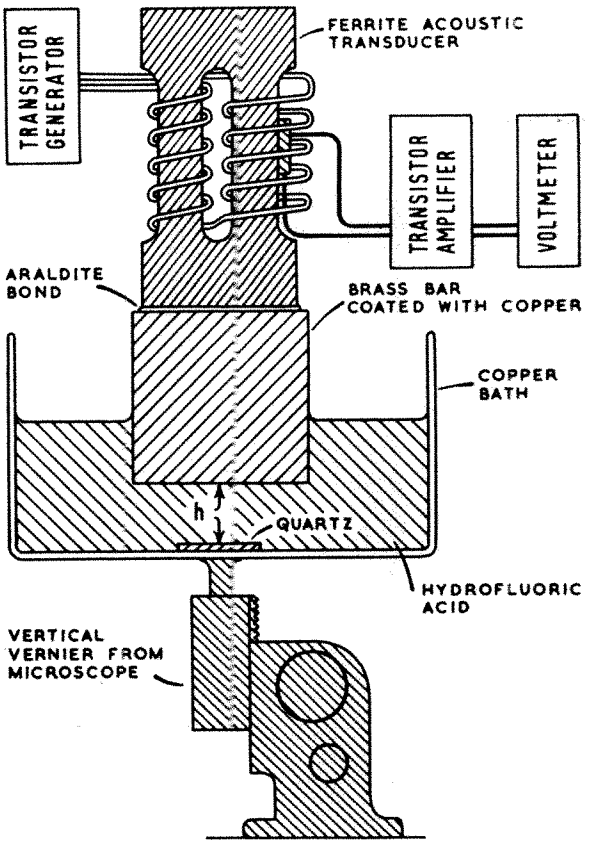

Fig. 1

This can be avoided by the use of very low acoustic powers from the transducer—certainly no higher than 0·5 W/cm²—or by establishing static pressures up to 10 atm. in the treatment vessel. Secondly, the diameter of the transducer head must be more than three times the diameter of the plates being etched. The reason for this is that the acoustic field must be relatively uniform over the quartz surface, for the sharp fall which occurs at the perimeter of the transducer must be avoided.

By this method, quartz sections 50μ thick have been readily obtained here for frequencies up to 90 mc/s. Plates for even higher frequencies could doubtless be obtained by the etching technique described, which could indeed be utilized for many purposes where the production of very thin plates is a requisite (for example, hard biological tissues, metals).

Direct Current Electroluminescence in the Zinc Sulphide/Copper/Manganese System

WORK on electroluminescence at the AEI Central Research Laboratory has been aimed at producing layers for a solid-state image intensifier. These usually consist of a combination of an a.c. electroluminescent layer with a photoconducting layer. To avoid the problems associated with capacitive coupling we have concentrated our attention on electroluminescent layers which operate

Figs. 1 and 2. Efficiency and luminance in the zinc sulphide/copper/manganese powder phosphor system. *A*, Air fired; *B*, nitrogen fired. . . . . , Power efficiency; ——, quantum efficiency

under d.c. conditions. Initial investigations were directed at the production of thin films showing good d.c. electroluminescence; the results of these investigations have been reported elsewhere[1–3], but subsequent investigation has shown that brighter and more efficient cells could be prepared using powder phosphors.

Although there are many reports on the a.c. electroluminescent properties of zinc sulphide powders[4,5] (usually activated with copper and/or manganese and halogen), there is very little information on the d.c. electroluminescent characteristics of such materials. The bulk of the investigation of d.c. electroluminescence in zinc sulphide has been on thin films[6–8] because it was thought that thin films would be more efficient, have higher resolution, and yield more information as to the fundamental processes occurring, due to the fact that the effect of grain boundaries would be obviated. Although some workers have studied the d.c. electroluminescent properties of zinc sulphide, copper manganese activated powders[9,10], no quantitative details are available as to the efficiency of the systems. The lack of published data on powder d.c. electroluminescent phosphors is probably due to the great care that is required in the preparation of such phosphors. A phosphor showing good a.c. electroluminescence, for example, in the zinc sulphide copper chloride system can quite readily be prepared. To obtain some sort of electroluminescence it does not matter if an intergranular or a small surface excess of copper or halide is present, or if a very small proportion of highly conducting powder particles is produced, as an insulating layer is always placed between the electrodes. However, if such a phosphor is tested under d.c. conditions such irregularities would form 'shorts' and the panel would burn out immediately. With control of the starting material and careful control of the addition of halide, copper and manganese, the firing temperature and atmosphere and suitable particle size separation, useful d.c. electroluminescent phosphors can be prepared.

We have recently made d.c. electroluminescent cells consisting simply of such specially prepared zinc sulphide powders in an organic matrix sandwiched between two conducting electrodes; these electrodes were, respectively, glass coated with tin oxide and graphite. The quantum efficiency and brightness that can be achieved with these panels are illustrated in Figs. 1 and 2. It will be noted that the firing atmosphere has a marked effect on both the brightness and efficiency characteristics. The quantum efficiency that can be achieved with these panels can reach 20 per cent and the power efficiency 0·1 per cent. We have observed that the current voltage relationship is exponential over several orders of the applied voltage. All measurements were made at room temperature.

It can be seen that high efficiencies can be obtained with this system over a large range of current and voltage. It will also be noted that the efficiency of this system is considerably higher than that reported by Thornton[6] (using d.c. electroluminescent thin films), who reported an efficiency at 10 ft. L of 0·05 lm/W $\approx$ 0·01 per cent. It is felt that these preliminary results are very pertinent to the elucidation of the mechanism of the electroluminescent processes in zinc sulphide, and with further analysis will indicate the actual mechanism of the processes occurring.

This work was carried out under the sponsorship of the Ministry of Defence.

METALLURGY

Austenite–Martensite Interface Dislocatio in Stainless Steel

WHEN 18 chromium : 8 nickel austenitic stainless ste is plastically deformed at room and sub-zero tempera tures, ε (hexagonal closest packing) and α′ (body centred cubic) martensites are formed. The ε phase forms as the result of the propagation of Shockley partial dislocations on every second {111} γ plane and appears in the form of thin disks having a {111} γ habit[1]. The mechanism of the γ → α′ transformation in this steel is not yet entirely understood. Venables[1] suggested that α′ martensite nucleates from the ε phase and grows by the motion of a parallel grid of screw dislocations such as that postulated by Frank[2]. Bogers and Burgers[3] showed, by geometrical arguments, that the shears necessary for the transformation correspond to 'well-known' (that is, Shockley partial) dislocations and also suggested the possibility that the transformation proceeded by way of the motion of a parallel array of screw dislocations. Lagneborg[4] found that deformation induced α′ nucleated preferentially at the intersections of two ε disks or at the intersections of active slip planes with ε disks, and proposed that the martensite-like region existing near the centre of a Shockley partial dislocation was a favourable nucleation site. He did not discuss a mechanism for the subsequent growth of α′. To our knowledge, no direct evidence for

ated dislocation interfaces has been observed. a recent investigation of the effects of shock loading romium : 8 nickel stainless steel, an experimental ion was made that showed a matrix-martensite composed of an array of dislocations. This ication presents this observation and discusses ce to the previously postulated transformation ms.

pecimens used were type 302 austenitic stainless lates of the following composition (in weight per : carbon, 0·054; manganese, 1·04; phosphorus, ; sulphur, 0·012; silicon, 0·54; nickel, 9·49; mium, 18·26; molybdenum, 0·16; copper, 0·16; lt, 0·095. The plates were annealed at 1,066° C for nin, water quenched, and subsequently shocked to kbar pressure in a plane wave generator similar to that ribed by Dieter[5]. A photomicrograph of the shock-aded steel is shown in Fig. 1. The structure is very similar to type 302 stainless steel deformed by conventional methods[4].

For examination by transmission electron microscopy, samples were cut from the shocked plates and hand lapped to a thickness of 5 mil. Foils were then prepared by electropolishing the mechanically thinned samples in a chromic-acetic acid electrolyte using the window technique.

A transmission electron micrograph of a region containing both shock-induced α' martensite and austenite is shown in Fig. 2. The direction of shock propagation was perpendicular to the foil surface which was determined to be a few degrees from (001) γ. The martensite is in the form of needles and contains dislocations lying along {110} α' or {112} α' planes. Since a one-surface trace analysis was all that could be used, the exact slip system operating in the martensite could not be determined. A number of the needles appear to be along directions that are close to [110] γ. The orientation relationship between the shock-induced martensite and the austenite was found by electron diffraction to be close to the Kurdjumov–Sachs relationship; namely, $(111)\gamma//(011)\alpha'$, $[101]\gamma//[111]\alpha'$. This relation is also found in 18 chromium : 8 nickel stainless steel deformed by conventional means[4].

Fig. 1. Light micrograph of type 302 stainless steel shocked at 158 kbar at ambient temperature (× c. 170)

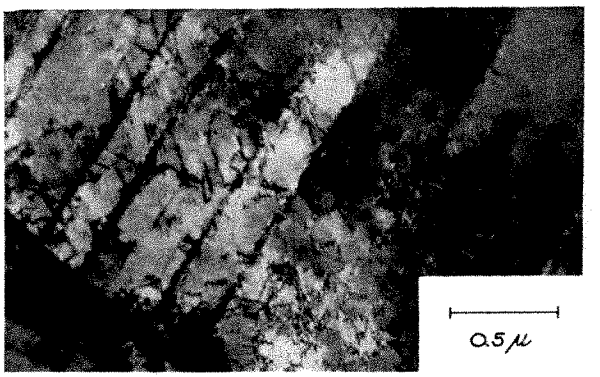

Fig. 3. Untransformed austenite in type 302 stainless steel shocked at 158 kbar at ambient temperature

The austenite in the vicinity of the martensite needles is heavily faulted on $(11\bar{1})\gamma$ planes. This was a common occurrence in most of the foils examined, provided a sufficient amount of martensite was present in the structure. Since the austenite in areas remote from shock induced α' martensite did not have the heavy faulted appearance (Fig. 3), it is believed that the stacking faults were a result of the propagation of martensite needles and were not due to the transient strain present at the shock front. Most of the habit planes were curved and contained a high density of dislocations which gave them the fuzzy appearance observed in Fig. 2. The habit plane AB in Fig. 2 is, however, relatively straight and contains resolvable detail. The habit plane was determined by one-surface trace analysis and knowledge of the foil thickness to be close to $(1\bar{1}1)\gamma$. The regular array of dislocations mentioned here is visible along this habit plane. An enlargement of the interface region at point C is shown in Fig. 4. A parallel grid of dislocations that appear to lie along the intersections of the $(11\bar{1})\gamma$ fault planes and the $(1\bar{1}1)\gamma$ habit plane is clearly visible. The presence of the observed interface dislocations can be explained by the following argument if it is assumed that the $(1\bar{1}1)\gamma$ habit plane of the growing α' needle contained a parallel array of dislocations with $a/2 <110>\gamma$ Burgers vectors moving on parallel $(11\bar{1})\gamma$ glide planes. When propagation of the interface ceased, the stresses holding the dislocations together relaxed thus allowing the dislocations to dissociate into two Shockley partial dislocations lying on $(11\bar{1})\gamma$ glide planes. One partial then glided into the austenite, creating the observed stacking faults while the other remained pinned due to the mismatch at the interface. The dislocations confined to the interface AB shown in Fig. 2 are believed to be pinned Shockley partials.

CHEMISTRY

Effect of Crack Propagation Velocity on the Fracture Surface Energy of Poly(methyl methacrylate)

WE have measured values of the fracture surface energy (γ) at $+20°$ C of a sample of high molecular weight poly(methyl methacrylate) sheet ('Perspex', manufactured by Imperial Chemical Industries, Ltd., Plastics Division). In order to measure γ over a wide range of crack propagation velocities ($\dot{c}$), we used three different experimental techniques:

(1) A modification of the static loading method described by Van den Boogaart and Turner[1] in which the crack length was measured as a function of time. From the results it was possible to deduce the relation between γ and $\dot{c}$ by assuming a value for Young's modulus ($E = 2{\cdot}85 \times 10^{10}$ dynes/cm^2). This technique covered the range of velocities from comparatively slow rates ($\simeq 10^{-4}$ cm/sec) up to about 1 cm/sec. Beyond this the crack propagation rate increased rapidly and the specimen failed catastrophically.

(2) A modification of the cleavage technique described by Broutman and McGarry[2] which produced controlled crack growth at various lead screw speeds.

(3) Charpy impact tests on sharply notched specimens. γ was taken as the ratio of the energy to break to the area of the new surfaces created during crack growth. Although $\dot{c}$ was not measured accurately, it is between the pendulum velocity at the point of impact (240 cm/sec) and maximum possible crack propagation velocity (~ cm/sec). Thus it is substantially higher than in the o experiments.

Table 1

Experimental technique	Crack propagation velocity (cm/sec)	Fracture surface energy (10^5 dynes/cm
1	10^{-4}	3·65
2	$7{\cdot}4 \times 10^{-4}$	3·7
1	10^{-3}	3·65
2	$6{\cdot}8 \times 10^{-3}$	3·0
1	10^{-2}	4·0
1	3×10^{-2}	4·75
2	$3{\cdot}3 \times 10^{-2}$	5·8
1	10^{-1}	5·5
2	$1{\cdot}4 \times 10^{-1}$	5·1
1	3×10^{-1}	6·2
2	$7{\cdot}6 \times 10^{-1}$	8·9
2	4·3	6·8
2	33	5·3
3	>240	4·5

The results are given in Table 1.

The principal conclusion that can be drawn from these experiments is that γ, like all other mechanical properties of poly(methyl methacrylate), is rate-dependent. It would seem to have a maximum value of about 9×10^5 dynes/cm at about 1 cm/sec at $+20°$ C. This conclusion is qualitatively confirmed by the fact that crack propagation was stable at all in the static loading experiment. Stable crack propagation, in this experiment, implies that γ increases as $\dot{c}$ increases; a change to unstable, catastrophic crack propagation implies that a maximum value of γ has been reached.

In the static loading experiment the change-over point from stable to unstable crack propagation is readily seen by examination of the fracture surface. This makes it possible to calculate K_c by the equation given in ref. 1. K_c can also be calculated from the cleavage experiments by assuming that the maximum value of γ is 9×10^5 dynes/cm and that E is $2{\cdot}85 \times 10^{10}$ dynes/cm^2. $K_c^2 = E\gamma$ for plane stress. Both techniques give:

$$K_c = 1{\cdot}6 \times 10^8 \text{ dynes/cm}^{3/2}$$

Another implication of these results is that γ will be higher when measured on notched tension specimens than when measured in equilibrium cleavage experiments as found by Berry[3] for both poly(methyl methacrylate) and polystyrene.

It is well known that, however it is characterized and measured, the 'ductility' of poly(methyl methacrylate) increases as the temperature is raised above $+20°$ C; it reaches a peak value and then decreases again with further increase in temperature. We suggest, therefore, that the cause of the rate-dependence of the fracture surface energy may be the heat produced by the localized 'plastic' deformation at the tip of the propagating crack. As the crack-propagation velocity increases, the process changes from isothermal to adiabatic. It follows that as the crack-propagation velocity increases, the temperature at the crack tip increases and therefore the fracture surface energy first increases and then decreases.

Structure of Desmosine and Isodesmosine

IN 1963 Partridge, Elsden and Thomas[1] reported the isolation of two new amino-acids named desmosine and isodesmosine from bovine ligamentum nuchae elastin. Since then the presence of these amino-acids has been demonstrated in elastins from various sources[2].

ıe basis mainly of close resemblances of the ultra-iet absorption and proton magnetic resonance spectra of these compounds with those of substituted pyridinium salts, it was proposed[3,4] that desmosine and isodesmosine are 1, 3, 4, 5 and 1, 2, 3, 5 tetra-substituted pyridinium salts.

Hantzsch[5] in 1886 showed that the treatment of *N*-methyl nicotinic acid with 6 N potassium hydroxide yields methylamine: Huff and Perlzweig[6] on steam distillation of *N'*-methylnicotinamide were able to recover CH_3–N≡ group from the ring as methyl amine (as shown in Fig. 1) in 97–98 per cent yield.

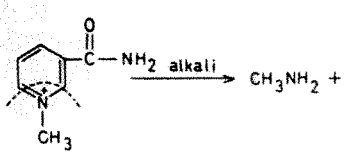

Fig. 1

In the light of these observations with nicotinic acid derivatives, the action of alkali on desmosine and isodesmosine was studied with the hope of liberating the pyridinium nitrogen in the form of amino group still attached to its side chain.

Some of the results of this study are summarized in Table 1. One of the compounds liberated by the action of alkali on both desmosine and isodesmosine has been identified as lysine. The liberation of lysine was confirmed by (1) ion exchange chromatography (*a*) on the short column of the Beckman-Spinco amino-acid analyser using 0·35 N citrate buffer (*p*H 5·28), and (*b*) with a Technicon amino-acid analyser using *p*H gradient from *p*H 2·75 to *p*H 6·1; (2) paper electrophoresis in pyridine-acetate buffer *p*H 3·5; (3) paper chromatography on a buffered, Whatman No. 3 *HR* paper using *n*-propanol, ethanol, and aqueous pyrophosphate buffer (50 : 25 : 25) as the solvent[7]. As shown in Table 1, lysine could be obtained in a 73 per cent yield from isodesmosine and in a 41 per cent yield from desmosine. The maximum yield of lysine from isodesmosine was obtained with 10 N sodium hydroxide at 110° C for 16 h in a sealed tube and from desmosine with 6 N sodium hydroxide at 110° C for 70 h.

Table 1. LIBERATION OF LYSINE FROM DESMOSINE AND ISODESMOSINE BY THE ACTION OF ALKALI

Treatment	Compound used	Lysine yield: Percentage of total	Lysine yield: Percentage of degraded compound
6 N sodium hydroxide at 100° C for 4 h	Desmosine	Trace	Trace
" " "	Isodesmosine	10·6	31·3
6 N sodium hydroxide at 110° C for 16 h	Desmosine	12·0	28·8
" " "	Isodesmosine	17·4	59·5
10 N sodium hydroxide at 110° C for 16 h	Desmosine	12·5	19·2
" " "	Isodesmosine	73·4	84·0
6 N sodium hydroxide at 110° C for 70 h	Desmosine	41·0	61·2
" " "	Isodesmosine	17·2	17·2

The liberation of lysine from desmosine and isodesmosine by the action of alkali provides independent proof of the pyridinium structure of both desmosine and isodesmosine. The ε-amino nitrogen of the liberated lysine is evidently the pyridinium ring nitrogen of the parent desmosine or isodesmosine. This also shows that the side chain attached to the pyridinium nitrogen in both cases is a 6 carbon side chain ending in α-amino carboxylic acid. These results provide additional support for the proposed structure[3,4] of desmosine and isodesmosine. This degradative method also provides a technique for determining the distribution of radioactivity in the desmosine and isodesmosine molecules after the incorporation of the activity from radioactive precursors. This technique is already being used to investigate the distribution of radioactivity in desmosine and isodesmosine after the incorporation of the activity from uniformly labelled lysine-^{14}C, and the results support the hypothesis[8,9] that four lysine molecules condense to form a desmosine or isodesmosine molecule.

Variation of the Isothermal Compressibilities of Liquids with Temperature

THE effect of pressure (P) on the isothermal compressibilities (κ_T) of liquids is well expressed in most cases by the empirical equation (1) of Tait[1]:

$$\kappa_T = \frac{C}{L + P} \qquad (1)$$

For a given substance, C is a constant independent of temperature and L is a constant at a given temperature. Attempts in the past to give a formula for the variation of L, or the isothermal compressibility, with temperature have not proved satisfactory, and Gibson and Loeffler[2] found that the empirical polynomial (2) gave the best fit with their results:

$$L = L_{25} + a(t - 25) + b(t - 25)^2 \qquad (2)$$

where L_{25} is the value of the Tait constant L at 25° C, t is the temperature and a and b are constant for a given substance.

The simple relationship (3) between the isothermal compressibility and surface tension (γ) has been found to hold[3] for many liquids:

$$\kappa_T \gamma^{3/2} = \text{a constant } (1{\cdot}33 \times 10^{-8} \text{ cgs units}) \qquad (3)$$

The elimination of the surface tension and the molecular volume term from equation (3); the equation of Sugden for the parachor (V_p); and Katoyama's modification of the Eotvos equation leads to an expression[3] which can be written as equation (4):

$$\left(\frac{1}{\kappa_T}\right)^{5/9} = \frac{K(t_c - t)}{V_p^{2/3}} \qquad (4)$$

where t_c is the critical temperature and K is a constant which equals about 5×10^4 cgs units for unassociated substances with molecules not too far from spherical in shape.

The compressibilities of a number of organic substances which have recently been measured[4] over a range of temperature and earlier values[5] have been combined and used to test equation (4) which has not previously been tested. The regression equations of $\left(\frac{1}{\kappa_T}\right)^{5/9}$ on t were calculated, and results for the compounds for which most values of compressibilities have been given are shown in Table 1. The equation (4) clearly does not apply to water which is peculiar in that the compressibility goes through a minimum[6] at about 50° C. For all the other twelve compounds, the plots of $\left(\frac{1}{\kappa_T}\right)^{5/9}$ against temperature give satisfactory straight lines. The critical temperatures were taken from tables[5] and the parachors were calculated[7].

Table 1. VARIATION OF ISOTHERMAL COMPRESSIBILITY (κT) WITH TEMPERATURE (t)

Compound	Equation $\kappa T^{-5/9} \times 10^{-3} =$	Intercept on t-axis	Correlation	No. of data points	Slope $\times V_p^{2/3}$ ($= -K$)	t_c observe (° C)
Aniline	$-1{\cdot}58605t + 589{\cdot}229$	372·0	−0·999583	13	$-5{\cdot}978 \times 10^4$	426
Anisole	$-1{\cdot}49687t + 488{\cdot}361$	327·3	−0·987139	9	$-6{\cdot}092 \times 10^4$	369
Benzene	$-1{\cdot}51454t + 402{\cdot}024$	266·5	−0·991664	26	$-5{\cdot}233 \times 10^4$	288·5
Carbon disulphide	$-1{\cdot}54611t + 406{\cdot}744$	263·2	−0·991489	16	$-4{\cdot}151 \times 10^4$	273
Carbon tetrachloride	$-1{\cdot}4548t + 379{\cdot}438$	261·4	−0·997455	32	$-5{\cdot}134 \times 10^4$	283·1
Chlorobenzene	$-1{\cdot}36579t + 453{\cdot}056$	332·7	−0·993770	18	$-5{\cdot}242 \times 10^4$	359
Chloroform	$-1{\cdot}49868t + 386{\cdot}79$	258·7	−0·987434	25	$-4{\cdot}686 \times 10^4$	263
Ethyl alcohol	$-1{\cdot}23542t + 363{\cdot}836$	295·5	−0·998770	16	$-3{\cdot}128 \times 10^4$	243·1
Ethyl ether	$-1{\cdot}71215t + 287{\cdot}305$	168·4	−0·989415	9	$-5{\cdot}996 \times 10^4$	193·8
Ethylene chloride	$-1{\cdot}62768t + 441{\cdot}000$	271·1	−0·995244	16	$-5{\cdot}189 \times 10^4$	290
Methanol	$-1{\cdot}14523t + 345{\cdot}723$	302·4	−0·999020	13	$-2{\cdot}255 \times 10^4$	240
Toluene	$-1{\cdot}52568t + 414{\cdot}331$	271·9	−0·997583	18	$-5{\cdot}943 \times 10^4$	320·6
Water	$0{\cdot}10128t + 550{\cdot}423$	543·5	+0·234	21	$+1{\cdot}328 \times 10^3$	374

The two associated compounds, methanol and ethyl alcohol, give intercepts above the critical temperatures and values of K less than 5×10^4 cgs units. The intercepts for all the other compounds are below the critical temperatures (sometimes by as much as 10 per cent on T_c in °K) and the values of K vary between $4{\cdot}1 \times 10^4$ and $6{\cdot}1 \times 10^4$ cgs units. Thus the linear relationship, suggested by equation (4), between $\left(\frac{1}{\kappa_T}\right)^{5/9}$ and temperature is found to hold for most substances, but accurate values for compressibilities cannot be obtained from the equation, critical temperatures and parachors.

I thank Mr. K. Dobel, who carried out the regression analysis.

Oxyfluorides and Basic Fluorides of Aluminium

EARLIER[1], we reported the fact that despite the numerous syntheses of aluminium oxyhalides of the type AlOCl, AlOBr and AlOI, by methods generally applicable to all these aluminium oxyhalides, no preparation of AlOF has been reported. After experimental investigations on a number of reactions that might by analogy lead to the formation of AlOF, we have concluded that the lack of information concerning AlOF is not accidental, but stems from the general inapplicability with respect to AlOF of most preparative methods for AlOX compounds. This results from the greater bond strength of aluminium–fluorine bonds as compared with other aluminium–halogen bonds, the high crystallization energy of aluminium fluoride as compared with the other AlX_3 compounds, and the enhanced ability of fluorine to form higher complex anions with elements such as arsenic. It is the latter characteristic which prevents the use of the $As_2O_3 + 3AlX_3 \rightarrow 3AlOX + 2AsX_3$ reaction with aluminium fluoride[1].

In studying various possibilities of forming AlOF we have noted some interesting relationships between aluminium oxyfluorides and their corresponding basic fluorides. This communication describes some of the difficulties inherent in AlOF formation, relates aluminium oxyfluorides to their basic aluminium fluorides, and finally reports on a successful route to AlOF formation.

Cowley and Scott[2] attempted to prepare aluminium oxyfluorides by the pyrolytic dehydration of basic aluminium fluorides, in the composition range $AlF(OH)_2$ to $AlF_2(OH)$. However, they found that preparations dehydrated at 500° C exhibited the same X-ray diffraction spectrum that was characteristic of the hydrated basic fluorides; the same X-ray diffraction spectrum also characterized the entire composition range of basic fluorides. They concluded that the dehydrated samples were in fact still basic fluorides, rather than true oxyfluorides, a conclusion which we are able to confirm, as will be described here. Cowley and Scott also found that at 600° C the basic fluorides decomposed to form aluminium fluoride, indicating that one could not prepare oxyfluorides by the pyrolytic route at higher temperatures. These results, combined with our previous results[1], in which it was shown that AlOF cannot be prepared by the reaction in water solution between AlOCl and silver fluoride, because of the polymerized structure of AlOCl in aqueous solutions, rule out the possibility of AlOF formation by aqueous paths.

AlF_3—oxide reactions. The most common method used to prepare AlOX compounds is the reaction between AlX_3 and an oxide. The simplest of these is the one using Al_2O_3 as the oxide. The high sublimation point of 1281° C for aluminium fluoride and the 2042° C melting point for Al_2O_3 creates experimental difficulties with this system, and it was decided to investigate this reaction by differential thermal analysis. However, at temperatures up to the sublimation point of aluminium fluoride, there was no reaction detectable by this technique, even at very slow scan rates.

Aluminium oxyfluoride formation was then attempted by reaction in a nickel crucible between aluminium fluoride and the lower melting oxide, B_2O_3, according to $B_2O_3 + 3AlF_3 \rightarrow 2BF_3 + 3AlOF$. A slow reaction rate was noted at 600° C; after 20 h only 22 per cent of the reactants had reacted, as determined by the loss of volatile material. At 700° C, complete reaction was noted in 1 h. It was demonstrated, by the absence of a green boron emission band in the flame spectrum of the non-volatile residue from the 700° C reaction, that the entire boron content had volatilized. The product had an experimentally determined composition of 31·5 per cent fluorine and 40·5 per cent aluminium, corresponding nearly to AlOF which has a theoretical composition of 30·7 per cent fluorine and 43·6 per cent aluminium. However, the X-ray diffraction pattern showed the presence of only aluminium fluoride and alumina. Furthermore, on hydration of the sample, by boiling down a suspension of the product in water, the characteristic X-ray diffraction pattern of the corresponding basic fluoride hydrate[2] was not observed. Neither was the basic fluoride pattern observed on hydration of the 600° C product. As will be described later, the basic fluoride X-ray diffraction spectrum is found when the true oxyfluoride is hydrated by the foregoing procedure. Accordingly, the reaction with boron oxide proceeded according to equation (1) and aluminium oxyfluoride was not formed:

$$B_2O_3(l) + 2AlF_3(s) \xrightarrow{700^\circ} 2BF_3(g) + Al_2O_3(s) \qquad (1)$$

Aluminium alkoxide reactions. A promising path to AlOF formation was believed to be by the reaction forming AlOCl from aluminium alkoxides, as shown in equation (2) (refs. 3 and 4). Anhydrous hydrogen fluoride was added to a solution of aluminium tertiary butoxide in

$$Al(OR)_3 + 2HCl \xrightarrow{\text{benzene}} AlCl_2(OR) + 2ROH \quad (2)$$

$$\Big\downarrow \Delta$$

$$AlOCl + RCl$$

benzene solution, in the molar ratio of 2 : 1, at a temperature just above the melting point of the solvent. The reactants were then allowed to stand overnight at room temperature, and the precipitate formed was filtered. It was evacuated under high vacuum at room temperature and then heated in several stages to 600° C. The product which had been heated to 200° C had the empirical formula $AlF_{1\cdot84}(OH)_{1\cdot13}(OC_4H_9)_{0\cdot025}$ based on analyses for aluminium, fluorine, carbon and hydrogen. It evidently included a small residue of organic material which had not yet decomposed, but its composition indicated that the fluorination was almost complete. However, unlike equation (2), tertiary butyl fluoride had not been evolved, because both fluorine atoms were still bonded to aluminium. The presence of the OH group indicates that decomposition of the organic intermediate had been by elimination of butene rather than butyl fluoride, leaving an H from the butyl radical attached to the oxygen. Thus when hydrogen fluoride is substituted for hydrogen chloride or the other hydrogen halides, the reaction proceeds by way of equation (3), forming the basic difluoride rather than AlOF. The product originally obtained was amorphous, but on hydration it gave the characteristic basic fluoride X-ray diffraction spectrum. Although AlOF cannot be prepared by this path, it does constitute a new and relatively simple path to the basic difluoride.

$$Al(OC_4H_9)F_2 \xrightarrow{200^\circ} AlF_2(OH) + C_4H_8 \quad (3)$$

At 600° C, the non-volatile product had the empirical formula $AlF_{1\cdot54}(OH)_{0\cdot46}O_{0\cdot5}$, based on analyses for aluminium fluorine, carbon and hydrogen. On hydration of the sample, no indication was obtained by X-ray diffraction for the formation of the basic aluminium fluoride. It was concluded that the non-volatile product was an equimolar mixture of AlF_3 + AlO(OH), which was consistent with the observed X-ray diffraction spectrum. This observation is also consistent with the reported thermal stability of basic aluminium fluorides[2]. The drop in fluorine content between the samples heated to 200° C and 600° C is by loss of fluorine as hydrogen fluoride. The data indicate that $AlF_2(OH)$ decomposes according to equation (4)—a point not made in ref. 2:

$$2AlF_2(OH) \xrightarrow{600^\circ} AlF_3 + AlO(OH) + HF \quad (4)$$

Fluorination of AlOBr. It had become apparent for reasons already described that the most likely method of preparing AlOF (and perhaps the only practical method) was by fluorination of an existing AlO*X* compound, although this could not be done in an aqueous medium. Using this technique, aluminium oxyfluorides with compositions ranging from AlOF to Al_2OF_4 have been prepared by reaction of AlOBr with BrF_3 in appropriate ratios. At present we can only make a preliminary report on these compounds, and further details will be published later when the oxyfluorides are better characterized and their properties better understood. However, a significant relationship between the oxyfluorides and basic fluorides of aluminium, especially in regard to their inter-[illegible] has been found and will be described.

[illegible] each of the oxyfluorides prepared [illegible] tion the [illegible] n [illegible] es [illegible] to [illegible]

basic fluorides by simple hydration, although in the reverse direction aluminium oxyfluorides cannot be readily obtained from the basic fluorides.

Each of the aluminium oxyfluorides prepared by the AlOBr + BrF_3 reactions were only sparingly soluble in water. In this respect they differ significantly from the other AlO*X* compounds, which are all very soluble in water.

We thank Miss C. G. Johnson for performing the aluminium and fluorine analyses; Mr. S. Hotta for the carbon and hydrogen analyses; Dr. F. Wachi for the various thermograms; Messrs. J. H. Richardson and E. S. Elliott for numerous X-ray diffraction spectra.

Specific Conductivity of High-purity Water up to 300° C

THIS communication reports work in progress on the direct measurement of the conductivity of high purity water from 100 to 300° C along the saturated vapour pressure curve.

A knowledge of the specific conductivity of water is important in the study of the conductivity of dilute salt solutions, particularly at temperatures above 100° C where it increases to almost two orders of magnitude greater than its value at 25° C. At present the only values of the specific conductivity available above 100° C are those due to Noyes *et al.*[1] at 100°, 156°, 218° and 306° C, which were obtained indirectly from a study of the hydrolysis of acetates, and those due to Wright, Lindsay and Druga[2], which were obtained from conductivity measurements on relatively impure water.

The water used had a conductivity varying from 0·06 to 0·12 μmho/cm at room temperature and was prepared by passing distilled water successively through a demineralization unit, four stainless steel stills and a de-aerator. The high-temperature conductivity cell is contained in a platinum-lined autoclave as shown in Fig. 1. Two methods of operating this cell were used. First, water was pumped continuously through the autoclave, with the pump stroke and outlet valve adjusted to keep the autoclave full of water. Secondly, the autoclave was filled to the level *CD* (Fig. 1), isolated and measurements made with water distilling from the outer compartment into the cell. At present the first method is unsatisfactory above 200° C owing to temperature instability, while the second method gave less satisfactory results than the first below 180° C.

The most uncertain error in the measured conductivity is that due to contamination of the water in the system. Contamination may arise from hydrolysis of organic materials carried over from the resin of the demineralization unit and not removed by the stills, from corrosion of the stainless steel in contact with the platinum lining and from decomposition of the polytetrafluoroethylene gasket. The contamination occurring in a flowing system is indicated by the difference in the outlet and inlet water conductivities. The flowing results in Fig. 2 were taken from regions where the outlet conductivity was below 0·35 μmho/cm and the maximum increase relative to the inlet conductivity was 0·21 μmho/cm. Some of this conductivity increase was certainly due to contamination occurring during the cooling of the outlet to room temperature and so the contamination occurring inside the autoclave is thought to be quite small.

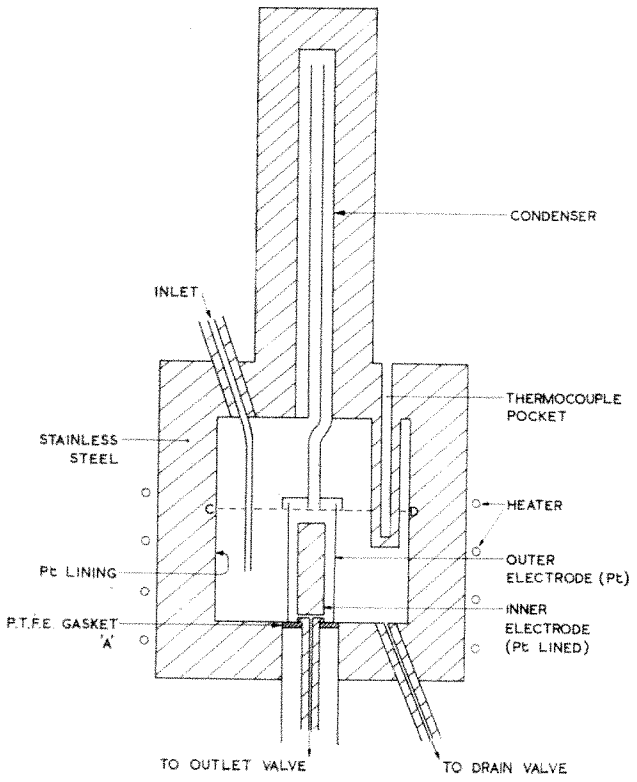

Fig. 1. Schematic diagram of autoclave

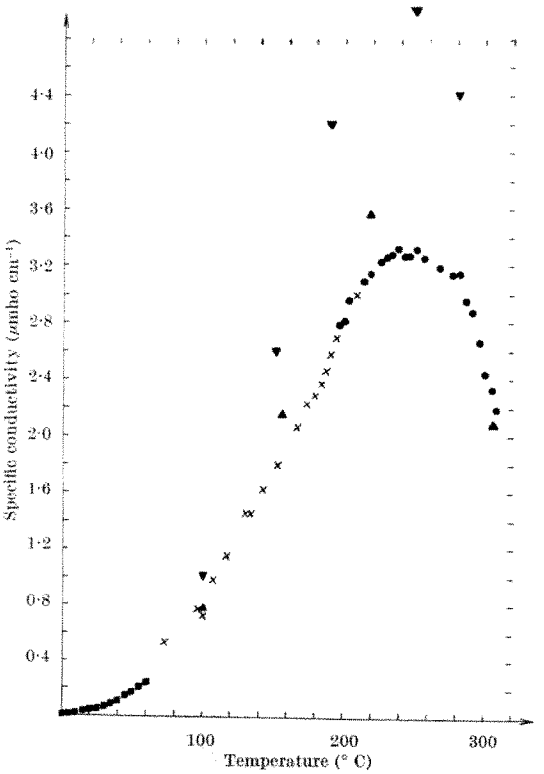

Fig. 2. Specific conductivity of water at saturated vapour pressure. ×, Present results, flowing; ●, present results, distilling; ■, Harned *et al.*[3]; ▲, Noyes *et al.*[1]; ▼, Wright *et al.*[2]

Preliminary experimental results are compared with previously reported data in Fig. 2. The estimated errors arising from contamination, and from temperature and cell constant errors, are ± 2 per cent below 200° C, ± 5 per cent from 200° to 280° C and ± 8 per cent above 280° C. The results are in good agreement with the data recalculated from the work of Noyes *et al.* and also wi[th] temperature data of Harned and Robinson[3].

Modifications to the apparatus are in progress to enable the conductivity to be determined with greater accuracy at temperatures up to at least 320° C and pressures up to 300 bars.

Two-phase Model for Structure of Polymers

Attempts to relate polymer properties to structure have usually involved the assumption of a two-phase structural model: crystalline regions embedded in an amorphous matrix. The crystalline and amorphous regions in the structure are each presumed to have well-defined properties which do not vary as the proportions change in different polymers. With this model, the variables available to compare different samples of the same polymer are: crystallite size, shape and orientation correlation; orientation effects in the amorphous material; and the relative amounts of crystalline and amorphous material present. The last parameter mentioned is termed 'degree of crystallinity', and it is measured in various ways: by techniques involving X-ray diffraction, density, infra-red, nuclear magnetic resonances, chemical reactivity, and swelling measurements. The degree to which the results of these techniques correlate is a measure of the validity of the two-phase model. Farrow and Ward[1] found little correlation between crystallinity measurements on polyethylene terephthalate fibres by X-ray diffraction, density and infra-red techniques. Similar comparisons between crystallinity measurements on polypropylene by various techniques were reported by Quynn, Riley, Young and Noether[2] with similar inconsistencies. Nuclear magnetic resonance studies of polyethylene and polypropylene fibres by Hyndman and Origlio[3] indicated the existence of a distinct phase intermediate in degree of order between the crystalline and amorphous phases. Sobue and Tabata[4] found X-ray evidence for polymorphism in polypropylene.

These and other investigations indicate that the two-phase model as defined earlier does not apply. The open question at the moment is: how far from the two-phase hypothesis and in which direction must we go to be consistent with the data? There is great reluctance to abandon completely this hypothesis, as its predicted results, though not correct, are of the right order of magnitude.

We would like to point out the significance with respect to the two-phase hypothesis of the shifting in the positions of diffraction peaks in polymer X-ray patterns. This shift has been observed in some polymers when subjected to various physical treatments which tend to change the degree of order. There are various industrial quality-control tests on polymers based on this effect, but its interpretation has only been in terms of an empirical relationship between the physical properties and the amount of splitting of diffraction spots. Crystals can only change size, shape, orientation [illegible] ance; these [illegible]

Sample	Spacing (cm) d_{100}	$d_{010} = d_{110}$

f, Annealed at 190° C	4·436	3·778

Fig. 1

between these kinds of regions are becoming somewhat obscure.

An obvious alternative is paracrystalline theory where the shifting of diffraction peaks is a necessary consequence of the statistical changes associated with varying degrees of order. According to this theory, a particular peak position represents an average lattice spacing. This suggests that, as the degree of order changes, one can measure the change in average lattice parameters.

Particularly accessible parameters for fibres are the projections of the inter-chain lattice vectors on to the cross-sectional plane perpendicular to the chain axes. If we make the approximation that each chain is equivalent, and (as is usually the case) the resultant Bravais cell contains but one chain, then in the X-ray fibre diagram there will be up to three particularly strong equatorial reflexions which result from Bragg planes passing through the axes of nearest neighbour chains. When the Bravais cell projection is a 60° rhombus, we have a hexagonal structure and only one such reflexion appears; when it is a general rhombus, we have a centred orthorhombic structure and two such reflexions appear; and when it is a general parallelogram, we have a monoclinic or triclinic structure and three such reflexions appear. The area of this latter Bravais cell projection is simply double the area of the triangle the three altitudes of which are the three measured spacings; the areas of the other Bravais cells are special cases of this. The vectors and angles of the projected Bravais cell can then be directly calculated. The area of the aforementioned triangle is the cross-sectional excluded area per chain, which is a [illegible] of density and consequently of degree of order.

We have observed a continuous variation in X-ray diagrams of nylon between a hexagonal pattern from material quenched from the melt to the standard pseudo-orthorhombic pattern in well-annealed material (Fig. 1). The cross-sectional area per chain was 19 per cent greater in the quenched material than in the annealed material. If we consider that there is complete rotational disorder of the planes of the chain zigzags in the quenched sample, and complete order in the annealed sample, then the percentage of rotational order in any intermediate sample could be defined in terms of a linear interpolation of the measured cross-sectional area per chain between the extreme values.

This approach might be considered as 'X-ray density' technique. A comparison between the density variation as measured by this technique with that measured in the standard way would give a good indication as to whether the material is homogeneously paracrystalline (as would be shown by good correlation) or whether there are truly amorphous regions in the structure which do not contribute to the crystalline pattern but do contribute to the total density.

Nitroxide Radicals from Methylmethacrylate interacting with Oxides of Nitrogen

A CHARACTERISTIC three-line electron spin resonance spectrum has been detected by other workers when nitric oxide or nitrogen dioxide react with methylmethacrylate at room temperature[1]. Spectra for both fluid and rigid solutions of the radical were recorded and, by the use of ^{15}NO, the triplet was shown to be a consequence of hyperfine coupling to nitrogen[1]. Both *X*-band and *Q*-band spectrometers were used.

We have confirmed these results, derived the isotropic and anisotropic parts of the ^{14}N hyperfine coupling tensor for this radical (Table 1), and have derived details of the molecular orbital of the unpaired electron on nitrogen by standard procedures[2]. Using the values of 550 G and 34 G for the 2*s* and 2*p* atomic orbitals on nitrogen[2] we obtain $a^2_{2s}(N) = 0{\cdot}026$ and $a^2_{2p}(N) = 0{\cdot}70$.

These data show that the radical is planar, with the unpaired electron in a π-molecular orbital which is very largely made up of a 2*p*-atomic orbital on nitrogen. The isotropic splittings and the value of g_{av} are almost identical with those of triacetonamine N-oxide (Table 1), while the perpendicular and parallel results are closely similar to those for the radical $(Me_3C)_2NO$ studied by Edelstein, Kwok and Maki[3]. We therefore postulate that the radical involved has the formula $(R_3C)_2NO$. Furthermore, as no strong hyperfine splitting due to protons was detected, there can be no β-protons, that is, no protons bonded to the saturated carbon atoms directly linked to

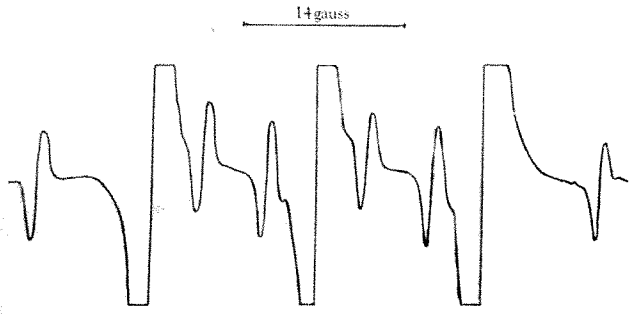

Fig. 2. Electron spin resonance spectrum at high gain showing features assigned to radical (II)

nitrogen. However, a small splitting of about 0·30 G has been resolved (Fig. 1), which is close to expectation for interaction with γ-protons[4]. Unfortunately, resolution is not sufficient to enable us to be certain of the number of γ-protons, but at least three of them are relatively strongly coupled.

This conclusion is strongly supported by the relatively high stability of the radical. Alkyl nitroxides[5,6] are indeed remarkably stable especially when the alkyl groups are bulky[4]. Perhaps the simplest mode of formation of such a radical would be:

$$2CH_2{=}C(Me)CO_2Me + NO \rightarrow \begin{array}{l} CH_2-C(Me)CO_2Me \\ \quad\quad\quad\quad\quad\quad NO \\ CH_2-C(Me)CO_2Me \end{array} \qquad (I)$$

Because nitric oxide does not give any detectable radicals directly with the olefine in the complete absence of the dioxide, we favour the alternative:

$$2CH_2{=}C(Me)CO_2Me + NO_2 \rightarrow \begin{array}{l} CH_2-C(Me)CO_2Me \\ O \quad\quad\quad\quad NO \\ CH_2-C(Me)CO_2Me \end{array} \qquad (I)$$

There are, of course, several more complicated possibilities involving more than two monomer molecules, but it is significant that stable nitroxide radicals have recently been reported in solutions of nitroso compounds[7] and have been attributed to dimers similar to the species postulated here[8].

If this formulation is correct, then the formation of radicals of types (II) and (III) might also have been expected:

$$\begin{array}{l} (Me)C(CO_2Me)-CH_2 \\ O \quad\quad\quad\quad NO \\ CH_2-C(Me)CO_2Me \end{array} \qquad (II)$$

$$\begin{array}{l} (Me)C(CO_2Me)-CH_2 \\ O \quad\quad\quad\quad NO \\ (Me)C(CO_2Me)-CH_2 \end{array} \qquad (III)$$

The three main lines of the former would be 1 : 2 : 1 triplets and those of the latter into 1 : 4 : 6 : 4 : 1 quintets. Under high gain, satellite lines flanking the main triplet have indeed been detected (Fig. 2), and if these are part of the expected 1 : 2 : 1 triplets due to radical (II), the proton hyperfine coupling constant is about 11·0 G. This value is close to that found for β-protons[5,6] in other nitroxides and is in good agreement with expectation for such radicals[5]. We were unable to detect any radicals of type (III) and conclude that such radicals, if formed, have too short a lifetime to be detected under our conditions.

We thank Dr. Golden of the Ministry of Aviation for supplying us with a sample of triacetonamine N-oxide. We also thank the Ministry of Aviation for financial support, and Dr. M. Ebert for helpful advice and assistance.

BIOCHEMISTRY

α-Farnesene in the Natural Coating of Apples

Earlier[1], we reported the presence in the natural coating of 'Granny Smith' apples of a hydrocarbon which we identified as the naturally occurring sesquiterpene β-farnesene (I)[2–4]. Identification was based on a comparison of its infra-red spectrum with that published for β-farnesene isolated from natural sources[4], together with the unequivocal identification of its fully hydrogenated product as farnesane (2,6,10-trimethyldodecane)[2,3] by comparison of its infra-red and mass spectra and gas chromatographic retention times with those of a pure authentic specimen. Additional evidence was, however, deemed necessary, and direct comparison with pure β-farnesene has now established that this identification was incorrect and that the farnesene present in apple coating is not the β- but the α-isomer (II), which has hitherto not been reported as naturally occurring or prepared in a pure state.

I, β

II, α

The evidence for the α-isomer embraces the comparison and interpretation of: (*a*) the nuclear magnetic resonance, mass, infra-red, and ultra-violet spectra of farnesene from apples; (*b*) the nuclear magnetic resonance, mass, infra-red and ultra-violet spectra of pure β-farnesene isolated from *Matricaria chamomilla* oil[4]; (*c*) the infra-red and ultra-violet spectra of β-farnesene prepared from farnesol by dehydration over potassium hydroxide[5]. It has been found impossible to synthesize α-farnesene by previously described methods[6]. However, the dehydration of nerolidol in dimethyl sulphoxide at 130° C yielded, besides β-farnesene and β-*bisa*bolene, a component the infra-red and ultra-violet spectra and gas chromato-

graphy retention times of which were identical with those of farnesene from apples.

A remarkable feature of the occurrence of α-farnesene in apple coating is that it is virtually the only sesquiterpene present. Simple column chromatography of the cold hexane extract of intact apples on highly active 'Florisil' or basic alumina yields α-farnesene in about 97 per cent purity.

α-Farnesene has also been found in the natural coatings of 'Crofton' and 'Delicious' apples, 'Packham' pears, and quinces. Its occurrence in these coatings, which have triterpene acids (mainly ursolic and oleanolic[7]) as major constituents, suggests a direct origin from a farnesyl or nerolidyl intermediate in the biosynthesis of these triterpene acids.

In 1919, Brooks, Cooley, and Fisher[8] obtained evidence that superficial scald, a serious storage disorder of apples, is due to volatile or gaseous substances (other than carbon dioxide) that are produced in the metabolism of the apple. The nature of such substances has hitherto remained obscure, but we now have evidence for a role of α-farnesene in scald. More farnesene was found in earlier picked apples, which are more liable to scald, and more in the scald-liable 'Granny Smith' than in the scald-resistant 'Crofton' variety. Oiled wraps, which reduce scald, have been found to absorb from the fruit more than half the farnesene that accumulates during storage. Diphenylamine, a more effective inhibitor of scald[9], delayed the oxidation of farnesene both in pure solution and in the natural coating of the fruit; this result suggests that scald may be caused by oxidation products. Farnesene has been detected in air which has passed over apples, and the effect of air movement on its loss from the fruit is at present being investigated.

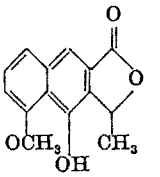
Isolation of 4-Hydroxyphthalide from Oat Grain

A NUMBER of substituted phthalide derivatives have been isolated from plant material[1] and most of these compounds carry either an alkyl substituent at position-3 (I) or an oxygen function at positions-5 and/or -7. Some of the latter group of compounds also carry a hydroxyl group at position-3 (for example, gladiolic acid (II)). It has been postulated[2] that all phthalides with an even number of carbon atoms or no alkyl group at position-3 have an oxygen function at position-7 and are derived from an even number of acetate units. On the other hand, phthalides with an uneven number of carbon atoms at position-3 (for example, eleutherol (III)) were considered to be related to 4-hydroxyphthalide by way of condensation of an odd number of acetate units. The isolation of 4-hydroxyphthalide from oat grain reported here offers an opportunity for further investigation of the origin of this group of compounds.



The isolation procedure used is outlined diagrammatically in Fig. 1. The petrol/benzene/water partition was carried out with a 5 per cent concentration of crude extract in the organic layer. Gradient elution was used to develop

I

II

III

the silica-gel column, the relevant fraction being eluted with about 50 per cent chloroform in benzene and partially solidified (vanillic acid). Bands on thin-layer chromatography plates were arbitrarily recognized by scanning the plate with ultra-violet light (350 mμ), bands (2) and (4) fluorescing blue and band (3) absorbing (vanillic acid) on the first plate, and band (2) fluorescing bright blue on the second plate. Material was recovered from the thin-layer chromatography plates by percolating ether through the adsorbent in a short chromatography column. The yield of solid material was very low (about 2·0 mg from 100 kg of grain), but proved reproducible with a second variety of grain (*Avena sativa* L., cultivar 'Blenda').

Mass spectrum analysis of the isolated material indicated a molecular weight of 150 and additional ions occurred at *m/e* 149, 121, 93 and 65. Examination of the metastable ions of the spectrum indicated that these represented losses of one mass unit followed by three successive losses of twenty-eight mass units, respectively. The formula $C_8H_6O_3$ (mol. wt., 150) would accommodate this cracking pattern with each of the oxygen atoms eliminated as carbon monoxide (ref. 3).

Ultra-violet (λ_{max}^{EtOH} 236 mμ and 293·5 mμ) and infra-red absorption spectra of the isolated material, when compared with those of authentic compounds, agreed most closely with those for 4-hydroxyphthalide (from G. T. Newbold via C. J. W. Brooks), the synthetic sample exhibiting one extra weak band at 1,285 cm^{-1} in the infra-red. Further confirmation of this comparison was obtained using gas–liquid chromatography on 7 per

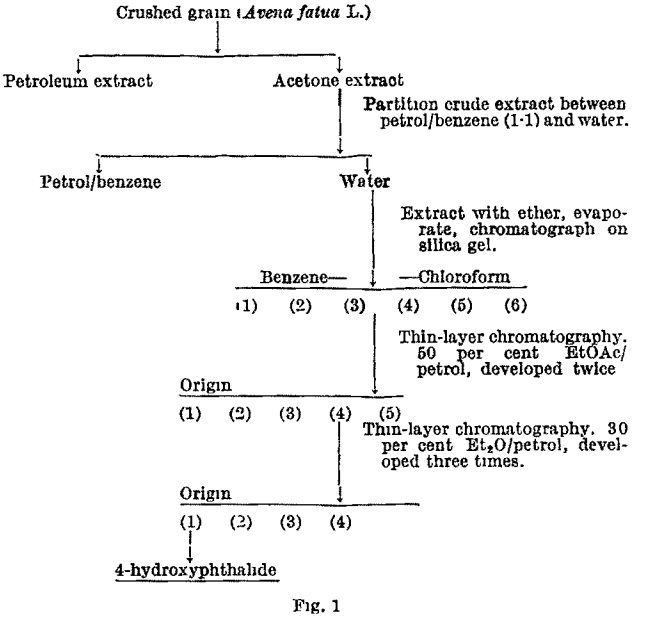


Fig. 1

cent *F*-60 + 1 per cent *EGSP-Z* at 175° C of the free phenols and the corresponding acetates, and using thin-layer chromatography of the acetates in 25 per cent ethyl acetate in petroleum ether. Respective mobilities of the compounds from the two sources were found to be identical.

While several other compounds were isolated during this work (for example, vanillic acid, ferulic acid), no other phthalides or closely related compounds have as yet been identified as present in oat grain and no evidence can be advanced concerning the origin of this compound. 4-Hydroxyl substituted phthalides are relatively a much less common group of compounds than the 7-hydroxyl substituted series, and the suggestion of a different biosynthetic pathway for the two series[2] cannot be ruled out without further investigation. It is hoped that this report will facilitate such an investigation.

Cholestasis in Rats induced by Taurolithocholate

THE taurine conjugates of cholic and chenodeoxycholic acid[1] are preponderant bile acids of murine bile. The systematic names of the bile acids referred to in the text are: taurocholic acid, 3α,7α,12α-trihydroxy-5β-cholanyl taurine; taurochenodeoxycholic acid, 3α,7α-dihydroxy-5β-cholanyl taurine; taurolithocholic acid, 3α-hydroxy-5β-cholanyl taurine; lithocholic acid, 3α-hydroxy-5β-cholanic acid. Although these bile acids are excreted as the sodium salts, by convention they are often referred to in the acid form. In this communication the suffix, '-ate', is used to indicate the sodium salt. Intravenous administration of taurocholate to rats is known to result in increased bile flow and bile acid excretion[2].

The taurine conjugate of lithocholic acid has been identified as a minor constituent of rat[3] and human[4] bile. This communication describes the decrease in bile flow and bile acid excretion (cholestasis) that occurred with intravenous infusion of taurolithocholate.

Male Wistar rats (230–360 g) were anaesthetized with intraperitoneal pentobarbital. '*PE* No. 10' polyethylene cannulas were inserted into a leg vein, femoral artery and common bile duct. Each animal was placed in a restraining cage and maintained on an infusion of 5 per cent dextrose in 0·45 per cent sodium chloride.

Taurolithocholate (6 mM) and/or taurocholate (6 mM) were infused in a mixture consisting of 30 ml. of 25 per cent human serum albumin, 6 ml. of propylene glycol and 64 ml. of 5 per cent dextrose in 0·45 per cent saline. Propylene glycol aids solution of taurolithocholate and has very low toxicity[5]. The infusion mixture itself did not affect bile flow or bile acid excretion. The bile salt infusion mixtures did not cause visible haemolysis of washed erythrocytes *in vitro*.

Bile acids were quantitatively assayed enzymatically with 3α-hydroxysteroid dehydrogenase[6,7].

In ten animals, infusions of taurocholate for 30–60 min (0·07–0·48 μmole/min/100 g body-wt.) always caused an increase in bile acid excretion. In contrast, similar infusions of taurolithocholate always caused cholestasis. However, infusion of equimolar amounts of taurocholate together with taurolithocholate invariably increased bile acid excretion. The sequence of administration of the different bile acid infusion mixtures to the same animal did not alter the type of response.

Chromatographic analysis[8] of the bile samples showed taurocholate and taurochenodeoxycholate. In addition, taurolithocholate became detectable within 15 min of its infusion. Glycine conjugated and unconjugated bile acids were occasionally present in trace amounts. The decreases found in total bile acid excretion, therefore, are attributable to a decrease in the normal preponderant components.

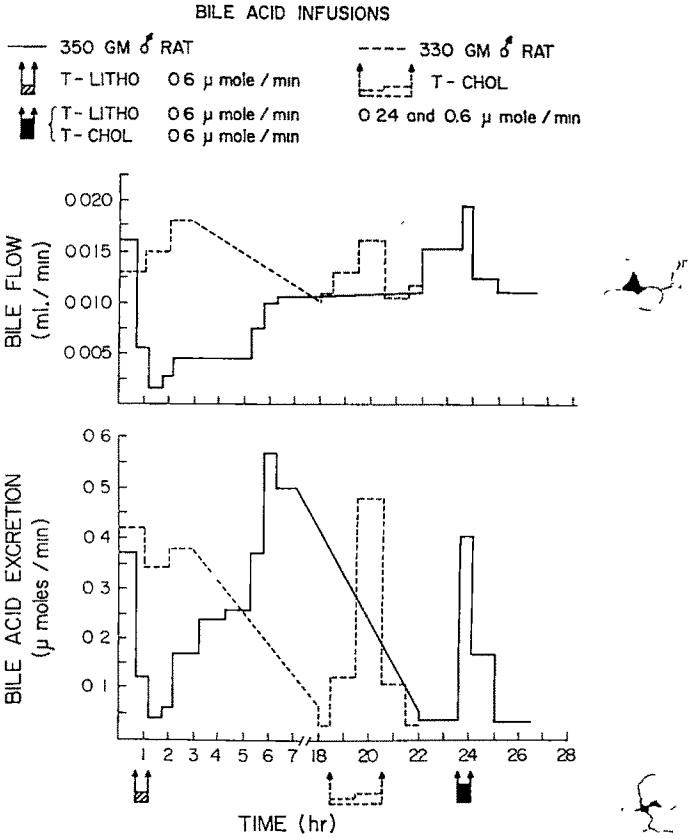

Fig. 1. Bile acid excretion and bile flow in rats beginning from time of bile duct cannulation. Bile acid excretion falls progressively (330 g rat) and is increased 18 h later by infusion of sodium taurocholate. Sodium taurolithocholate decreases bile acid excretion when given alone (350 g rat) but not when given together with sodium taurocholate

Fig. 1 shows the typical responses of the rats to bile acid infusions. The control rat (330 g) shows the progressive fall in bile acid excretion known to occur during the 24-h period following bile duct cannulation[9]. Replacement of the excreted preformed bile acids by taurocholate infusion restores bile acid excretion. In the experimental rat (350 g) the cholestatic effect of taurolithocholate is evident during an infusion given shortly after bile duct cannulation, before significant depletion of preformed bile acids has occurred. Following the period of cholestasis, bile acid excretion returns to the preinfusion levels before a progressive fall occurs. Simultaneous administration of taurocholate together with taurolithocholate to the same animal causes an increase in bile acid excretion.

Although the known direct relationship of bile flow to bile acid excretion was apparent during the infusion periods, a close correlation does not occur in the rat[10]. The lack of close parallelism has been attributed[11] to a significant biliary excretion of an inorganic electrolyte solution. The continuous infusion of saline in these experiments may have augmented electrolyte excretion

and lessened the relationship of bile flow to bile acid excretion.

During prolonged infusions of taurolithocholate, hyperbilirubinaemia occurred. Taurolithocholate was given at 0·2 μmole/min/100 g body-weight for 1 h, followed by one-tenth of this rate for 19 h. Average total serum bilirubin concentration[12] at the end of four experiments (in one experiment abdominal surgery and bile duct cannulation were omitted) was 5·6 mg/100 ml. Chromatographic analysis of the azo pigments[13] revealed azo *B* (glucuronide) and azo *A* (unconjugated). The occurrence of conjugated hyperbilirubinaemia was reflected in the development of deep yellow, diazopositive urine.

It is apparent from these results that the hepatic removal from plasma (uptake) and biliary excretion of taurocholate and taurolithocholate is rapid. Since both bile acids have a similar structure, it is probable that they share common pathways in their transfer from plasma to bile. In contrast to taurocholate, the excretion of taurolithocholate is relatively limited. Competition for either hepatic uptake or excretion, or both, could determine the occurrence of increased or decreased total bile acid excretion depending on the relative concentration of taurolithocholate. Thus, infusions of taurolithocholate sufficient to block excretion of endogenous taurocholate did not prevent the increase in bile acid excretion when larger amounts of taurocholate were given. The mechanism for these findings may be analogous to renal tubular transfer mechanisms, but a definitive explanation must await more precise knowledge of bile formation and of other metabolic effects of these bile acids. The solubilizing effect of taurocholate micelles[14] may have an important bearing on the excretion of taurolithocholate.

The small amounts of taurolithocholate normally present in bile are considered to be derived solely from bacterial dehydroxylation of chenodeoxycholate in the intestine[15]. In contrast to man, the rat can efficiently hydroxylate lithocholic acid brought to the liver by way of the enterohepatic circulation to form presumably less toxic derivatives. Investigations demonstrating morphological and metabolic effects of lithocholic acid have used greater amounts than are usually present in the intestine. Thus, lithocholic acid feeding to rats can cause bile duct proliferation with an inflammatory reaction[16] and also bile stone formation[17]. To these deleterious effects of lithocholic acid are added the cholestasis and jaundice that occur with infusion of taurolithocholate.

A Method for extracting Mucoproteins from Epithelial Tissues

MOST of the connective tissue polysaccharides which have been isolated in the native state as their protein complexes have come from cartilage tissues[1,2]. On the basis of past experience, attempts have been made to use an isolation method that preserves the mucoproteins as far as possible unaltered and effects only mechanical breakdown of the tissue structure, while allowing the macromolecules to be isolated from the extracts.

We have applied a similar method in the extraction of polysaccharide protein complexes from the epithelial tissue of the stomach wall. Exhaustive homogenization of the tissue in a 'Virtis 45' homogenizer at 45,000 r.p.m. for up to 4·5 h liberated only a minor part of the acid sulphopolysaccharides of the tissue. Washing of the tissue residue with several portions of distilled water did not lead to any substantial increase in the amount extracted. The *p*H of the solution in the range from 2 to 8 had very little influence on the amount extracted. We also subjected the washed tissue homogenate to the action of highly purified collagenase[3], but no significant amounts of polysaccharides were liberated during 2-h incubation at 37° C. The polysaccharide contents of the various samples were estimated by a modification of a method based on hydrolysis with papain[4,5].

However, when the homogenization was carried out in molar sodium chloride, all the acid polysaccharides were liberated from the tissues after periods varying from 15 to 30 min. If the tissue was homogenized in distilled water and the residue washed with 0·15 M or more concentrated sodium chloride solution, all the polysaccharides were transferred to the supernatant.

The procedure that finally proved successful consisted of homogenization of the tissue in distilled water, followed by washing with sodium chloride solution. The extracted polysaccharides in the sodium chloride solution were precipitated with a threefold volume of ethanol and redissolved in water, whereupon the greater part of the co-precipitated tissue proteins remained undissolved. The clear supernatant was quantitatively transferred to a column packed with cellulose which had been treated with a 1 per cent solution of cetylpyridinium chloride in 0·05 M sodium chloride. The polysaccharides were eluted successively with 0·3, 0·6, 1·0, 1·2, 1·6 and 2·4 M sodium chloride solutions. The 0·6, 1·0, 1·2 and 1·6 molar sodium chloride solutions each eluted a fraction that was precipitated by cetylpyridinium chloride after dilution of the effluent with distilled water. Portions of the four precipitates were subjected to hydrolysis with papain and refractionated on the cellulose column pretreated with cetylpyridinium chloride as described earlier[4]. Other portions of the precipitates were subjected to disc electrophoresis on polyacrylamide.

All the fractions eluted from the cellulose column with 0·6 and 1·0 M sodium chloride solutions migrated slowly as one band on electrophoresis. The fractions eluted with 1·2 and 1·6 M sodium chloride solutions did not move from the point of application. It was found that all fractions were stained by alcian blue and amido black. Refractionation after hydrolysis with papain revealed that the fractions extracted by 0·6 and 1·0 M sodium chloride solutions consisted mainly of what we have previously identified as epithelial sulphopolysaccharides, while the fractions extracted by 1·2 and 1·6 molar sodium chloride solutions consisted of chondroitin sulphuric acid *B* (refs. 4 and 5). Hyaluronic acid from the stomach wall and the less-sulphonated epithelial polysaccharides were not present in these fractions, but had already been released from the tissue during the first homogenization with water.

Vitamin B_{12} Concentrations in Human Tissues

THE development of microbiological technique for evaluating vitamin B_{12} concentration has made it possible to measure the wide variations in the quantity of vitamin B_{12} present in sera from humans in normal and various pathological states. By this means, the concentration of serum B_{12} has been found to be above normal in hepatitis[1], cirrhosis[2] and myelogenous leukaemia[3], but below normal in pernicious anaemia[4], total gastrectomy[5], sprue[6], old age[7] and pregnancy[8].

It has been demonstrated in patients that functional impairment of the ability to absorb B_{12} in the gastrointestinal tract results in a decreased level of serum B_{12} concentration. Because the B_{12} level is normally maintained at the expense of body stores, an evaluation of the magnitude of vitamin B_{12} storage in liver and other vital organs in disease may help to explain the mechanism of elevation of depression of serum B_{12} observed. This communication reports the measurement of B_{12} concentrations in various human organs, including the liver, kidneys, adrenals, heart, pancreas, spleen, lung and brain. The data obtained suggested that there is some association between chronological age and differences in liver stores of B_{12}. Certain diseases, including a hepatic tumour, also seemed to be related to differences that were observed in liver B_{12} concentration.

Tissue specimens were obtained from human organs during the course of examinations within 5 h of death and immediately stored at $-10°$ C. Within a week after sampling, the tissues were homogenized for a vitamin B_{12} assay. The procedure for the subsequent extraction of vitamin B_{12} from the organs and its quantification has been described elsewhere[9].

The vitamin B_{12} content was calculated in terms of μg/g of tissue wet weight on the basis of calibrated standard curves. Losses of B_{12} activity immediately after death and during the 7-day storage period after sampling were not estimated.

The distribution of vitamin B_{12} in various tissues is shown in Table 1. The tissues are ranked in order of diminishing concentration of the vitamin, which was greatest in liver. Considerable variations between replicate tissue sample concentrations are indicated by the magnitude of the standard deviations listed. The relatively high concentration of vitamin B_{12} in the adrenals in all the subjects examined suggests that this vitamin might in some way be involved in the metabolism of steroid compounds or the maintenance of the normal function of these glands.

Table 1. CONCENTRATION OF VITAMIN B_{12} IN HUMAN ORGANS

Tissues	No. of samples	Vitamin B_{12} (μg/g wet tissues)
Liver	6	0·653 ± 0·385*
Kidney	6	0·337 ± 0·338
Adrenal	6	0·161 ± 0·051
Heart	6	0·119 ± 0·041
Pancreas	3	0·116 ± 0·100
Spleen	5	0·055 ± 0·050
Lung	3	0·050 ± 0·053
Brain	2	0·027 ± 0·013

* Range estimate of standard deviation.

The data in Table 2 clearly show that there is an upward trend in hepatic B_{12} concentration associated with increased age of the subjects studied, although additional data would be required to establish this statistical pattern more definitely. Other related findings have also indicated a similar trend for liver B_{12} concentrations to increase progressively with advancing age[1,2].

Table 2. LIVER CONCENTRATIONS OF VITAMIN B_{12} IN HUMANS OF VARIOUS AGES

Age range	No. of cases	Vitamin B_{12} (μg/g wet tissue) Range	Average
Stillborn	5	0·026–0·090	0·056 ± 0·028*
4–48 (h)	3	0·096–0·123	0·108 ± 0·016
0·5–2 yr.	2	0·315–0·450	0·383 ± 0·120
20–40	5	0·240–0·497	0·310 ± 0·111
40–60	6	0·348–0·773	0·598 ± 0·168
60–85	6	0·270–1·562	0·775 ± 0·511

* Range estimate of standard deviation.

The weighted mean value of all the measurements observed for liver amounts to 0·41 μg/g. However, if the average hepatic concentration of B_{12} in the stillborn cases is excluded, the weighted mean value for the samples obtained from viable subjects is 0·49 μg/g. This adjusted value is in accordance with the mean value of 0·05 μg/g for hepatic B_{12} reported elsewhere[10,11]. Whether the markedly low concentrations of hepatic B_{12} that were found in stillborn infants (and in neonates) reflect some aspect of undeveloped liver function or a low requirement for the vitamin in these age groups remains to be investigated.

The effect of various diseases on hepatic vitamin B_{12} content is shown in Table 3. These results indicate that the vitamin B_{12} level of a human liver can vary to some degree with the type of disease encountered. In a disease where the liver is most directly concerned, as in cirrhosis, B_{12} concentration varied the most from the general level observed in corresponding age groups. However, considerable additional anamnestic data would be required in order to draw meaningful conclusions from the data shown for the other diseases in Table 3. The possibility that factors other than age may be important is emphasized by the hepatic B_{12} concentrations observed in two subjects who died accidentally. Their hepatic vitamin B_{12} concentrations of 0·245 μg/g were somewhat lower than might be expected from their chronological age, but by comparison they agree well with a recent investigation of twelve other individuals who suffered sudden, violent deaths, where the average hepatic B_{12} concentration was 0·280 μg/g (ref. 12).

Table 3. LIVER B_{12} CONCENTRATIONS IN DISEASE STATES

Cause of death	No. of cases	Average age	Vitamin B_{12} (μg/g wet tissues)
Pneumonia	2	1·5	0·383 ± 0·089*
Accident†	2	37	0·245 ± 0·003
Cerebral thrombosis	1	50	0·348
Coronary occlusion	3	53	0·542 ± 0·142
Myocardial infarction	2	55	0·698 ± 0·120
Leukaemia	2	61	0·885 ± 0·157
Cirrhosis	1	63	0·262
Carcinoma	4	63	0·481 ± 0·088
Atherosclerosis	3	68	0·936 ± 0·075

* Range estimate of standard deviation.
† One was killed in a car accident, the other died of a gunshot wound.

Table 4. AVERAGES OF VITAMIN B_{12} CONCENTRATIONS MEASURED IN REPRESENTATIVE LIVER AREAS

Cause of death	No. of samples/liver	Vitamin B_{12} (μg/g wet tissue)
Car accident	6	0·251 ± 0·006*
Coronary occlusion	6	0·481 ± 0·022
Cirrhosis	5	0·262 ± 0·071
Leukaemia	5	0·537 ± 0·039
Cancer of pancreas	5	0·506 ± 0·124

* Range estimate of standard deviation.

Table 4 compares the uniformity of concentrations of vitamin B_{12} localized in various lobes of single livers. The small standard deviations reflect the relatively small

interareal differences detected. However, concentration differences were greater in the cirrhotic liver studied than in all but the carcinomatous liver tissue, where areas that contained cancer cells had a higher B_{12} concentration than other adjoining, but normal, liver tissue obtained from the same subject. Without additional investigations, an exact meaning cannot be assigned to this observation. It is worth mentioning in this connexion, however, that it has been reported that mouse tumour cells are able to synthesize vitamin B_{12} (ref. 13).

Effects of Thiols on *Escherichia coli* β-Galactosidases

IN the extensive experimentation that has involved the assay of β-galactosidase activity during the past 5 years it has been common practice to use thiols, and particularly β-mercaptoethanol. In our method of preparing this enzyme[1] we use thioglycolate for the primary purpose of reducing large aggregates to a minimum. The substitution of β-mercaptoethanol in the preparative procedure, using strain *ML*308 as a source of β-galactosidase, has resulted in a variety of effects, one of which is a progressive inactivation.

In exploring the action of β-mercaptoethanol on β-galactosidase we have verified the observation that, under assay conditions, the addition of this thiol (at concentrations greater than 10^{-3} M) increases the apparent activity by about 50 per cent. However, the thiol effect on our enzyme preparations is a function of the Mg^{++} (or Mn^{++}) concentration as well as *p*H. A typical example is shown in Fig. 1. At *p*H 7, both inactivation and activation by thiols may be seen, depending on the presence of Mg^{++} or Mn^{++}. At a *p*H value of 8·6 these effects are greatly diminished and the rates are reduced.

Highly purified preparations of β-galactosidase from *ML*308 lose activity readily but may be stabilized either by storing in 50 per cent glycerol or by removing Mg^{++} by dialysis against ethylenediamine tetraacetic acid (EDTA). The latter technique is successful only for dilute solutions of protein. However, changes occur in more concentrated solutions due to the fact that such a protein preparation cannot be eluted off DEAE columns even at high salt concentration.

We interpret these results as indicating that β-galactosidase has several conformational and association modes and that the most active form enzymatically is not the most stable thermodynamically. In the presence of β-mercaptoethanol and Mg^{++} the structure is permitted more possibilities to associate with the substrate. In the absence of Mg^{++} other associations occur which are enzymatically inactive. Numerous ultracentrifuge investigations have failed to show readily reproducible differences between active and thiol-inactivated enzyme. In gel-electrophoresis, the latter moves at about 0·9 times the rate of the former.

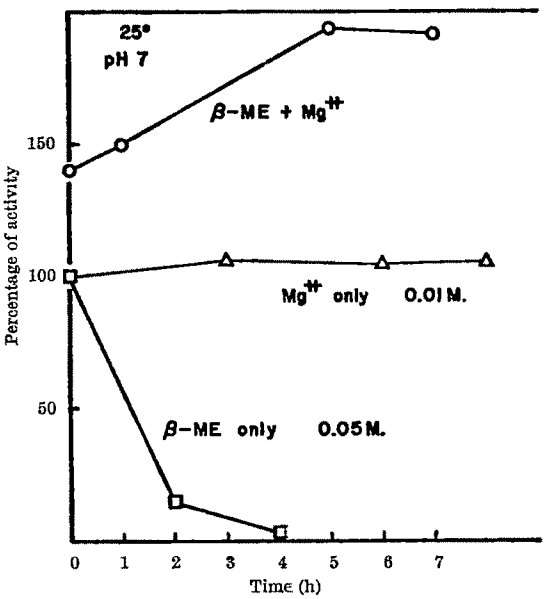

Fig. 1. The effect of β-mercaptoethanol on β-galactosidase activity when under assay conditions. Substrate solution. 9 ml. 0·05 M sodium phosphate buffer *p*H 7 plus 1 ml. *o*-nitrophenyl β-D-galactoside (30 mg in 10 ml.). The release of *o*-nitrophenol from the substrate by enzymatic action was plotted (420 mμ) by a 'Cary' spectrophotometer. Points on the graph correspond to slopes, linear under assay conditions

Beta-galactosidase isolated from strain *K*12 does not behave toward thiols as described here. Rather they seem necessary for retention of activity[2]. Presumably this is due to conformational and sequential differences in the two proteins.

Effects of β-mercaptoethanol such as we have observed in the enzyme isolation process have also been noted in the case of fatty acid synthetase[3]. The phenomenon of superactivity, or the marked enhancement of activity by β-mercaptoethanol, has been seen recently in experiments on lactate dehydrogenase[4]. The interrelation of divalent ions to β-mercaptoethanol activation has been recorded for histidinol dehydrogenase[5]. Whether or not all these effects have the same chemical basis remains to be determined.

Progesterone Biosynthesis by Equine Granulosa Cells growing in Tissue Culture

OUR knowledge of the pathways of steroid biosynthesis in the ovary has been gained mainly by incubations of ovaries *in vitro*[1,2]. The tissues incubated have contained numerous cell types: granulosa cells, theca interna cells, stromal cells, interstitial cells, and sometimes luteal cells. Possibly such mixtures of two or more different cell types are able to secrete hormones that one cell type cannot secrete by itself[3–9]. Furthermore, during such incubations *in vitro* an exchange of precursors and products between different cell types may be facilitated because of breakdown of naturally occurring barriers, such as the basement membrane between the granulosa layer and the theca interna of the follicle.

Thus there is clearly a need for more information on the steroidogenic potential of individual cell types studied in isolation. The purpose of the present experiments was to explore the possibility of growing a corpus luteum in tissue culture from a pure cell line, namely the granulosa cells, and to determine whether or not such a tissue is capable of steroid synthesis.

Graafian follicles, 2–6 cm in diameter, were dissected out of equine ovaries which had been collected at various stages of the oestrous cycle, by a method previously described[3]. The granulosa cells were scraped out under aseptic conditions. Vital staining with eosin *Y* (ref. 10) and nigrosin[11] demonstrated that only 10–20 per cent of the granulosa cells were alive. The cells were grown at 37° C as stationary monolayers, either on glass coverslips placed in test-tubes or in 50-ml. glass bottles. Microscopically, the cultures appeared to consist of one cell-type only. The growth medium used consisted of 10 per cent horse serum, 30 per cent medium 199 (ref. 12), and 60 per cent Hanks's balanced salt solution[12]. After various incubation times the coverslip preparations were washed with warm Hanks's solution, fixed in Bouin's solution, and stained with haematoxylin and eosin. For some experiments, various radioactive steroid hormones in propylene glycol were added to the medium The old medium together with any dead cells was discarded before addition of fresh medium containing the steroids.

Regardless of the stage of the oestrous cycle of the mare, granulosa cells removed from vascular follicles were found to adhere to the glass forming monolayers, and to take on within 2–4 days many of the morphological features which are characteristic of luteal cells. The cytoplasm of these cells increased in amount and became more densely stained and granular in appearance; the nucleus increased in size, and the chromatin material became more distinct and abundant. Some mitoses were also to be seen. This luteinization process occurred irrespective of whether gonadotrophin was added to the medium.

It has been possible to show that these cultured granulosa cells are capable of steroid synthesis. Thirty-two vessels, sixteen with gonadotrophin added (5 I.U./ml. of a mixture of pregnant mares' serum and human chorionic gonadotrophin) and sixteen without gonadotrophin, were incubated for an average of 7 days. The media were pooled, a small amount of 7-^{3}H-progesterone added as an internal recovery standard, and a 224-ml. sample extracted with ether in the presence of alkali; the ether extract was chromatographed on paper in a ligroin/80 per cent methanol system[13].

The paper chromatogram revealed a large amount of progesterone, which was further characterized by the following criteria: (i) same R_F value on paper and same gas chromatographic retention time on 3·8 per cent *S.E.* 30 as authentic progesterone; (ii) absence of acetylable hydroxyl groups; (iii) infra-red spectrum identical to that of authentic progesterone; (iv) formation, on treatment with 20β-hydroxysteroid dehydrogenase[14], of a compound with paper and gas chromatographic properties identical with those of authentic 20β-hydroxypregn-4-en-3-one; the sulphuric acid: 80 per cent ethanol chromogen[15] of this compound showed the expected peak at 478 mμ; its acetylation product had the same paper and gas chromatographic properties as that of 20β-acetoxypregn-4-en-3-one. Control medium in which cells were not grown contained no detectable steroids.

It was calculated that the 340 μg of progesterone isolated from the medium had been formed by 20,000–40,000 live cells in the course of the 7-day culture period. In addition the medium also contained appreciable amounts of 20α-hydroxypregn-4-en-3-one (89 μg), 17α-hydroxyprogesterone (35 μg), androstenedione (35 μg), and a trace of oestradiol (> 2 μg). Contrary to Falck's observations in the rat[7,8] and Short's observations in the horse[3,4,6], it appears that equine granulosa cells by themselves are capable of some androgen and oestrogen biosynthesis in tissue culture when gonadotrophin is present.

When the 7- or 14-day-old cultures were incubated for 24 h with 10 μc. 16-^{3}H-pregnenolone (15 μc./μg), more than 90 per cent of the steroid was metabolized—the major product being progesterone. The specific activity of the progesterone so formed was only half that of the starting material, which can be taken as further evidence for the *de novo* synthesis of progesterone by these cells.

The pattern of pregnenolone metabolism by the luteinized granulosa cells was similar to that obtained with cultures of equine corpora lutea. Thus it seems as if equine granulosa cells really can develop into a corpus luteum in tissue culture. Surprisingly, they can do so regardless of the stage of the follicle from which they were obtained, and quite irrespective of the presence of gonadotrophin in the culture medium. It remains to be seen whether gonadotrophins can augment the secretory activity or prolong the life-span of such a test-tube corpus luteum.

I thank the National Institutes of Health and the Agricultural Research Council for financial aid. I also thank Dr. R. Short for providing laboratory space and helpful advice, and Dr. T. Mann for his co-operation and Mr. J. Stansfield of Unicam for carrying out the infra-red analysis.

Trimethylamine-N-oxide Biosynthesis in the Bullfrog

THE comparative aspects of the mechanism of oxygenations dependent on molecular oxygen have recently been investigated using the biosynthesis of trimethylamine-N-oxide as a model[1]. That investigation raised a number of questions beyond the presence of the enzymatic activity in a given organism. In the case of the bullfrog, *Rana catesbeiana*, questions which remained were: the intra-

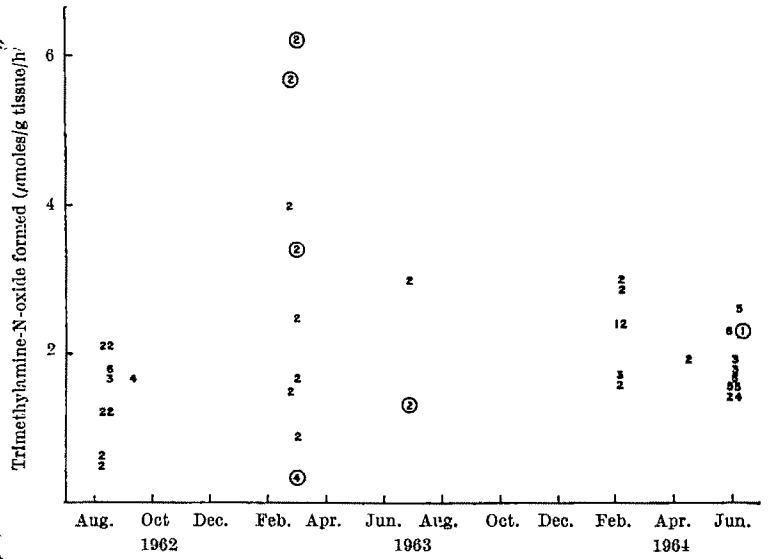

Fig. 1. Variation in trimethylamine oxidation activity with season and stage of tadpole development. The numbers on this figure refer to the stage of tadpole development. Circled numbers refer to tadpoles maintained in the laboratory for at least five months before assay. 1, Small tadpole, 2, large tadpole; 3, rudimentary hind legs; 4, well-developed hind legs; 5, rudimentary forelimbs, 6, well-developed forelimbs (tail not as yet resorbed)

cellular location of the enzyme, the reason for the apparent lack of trimethylamine-N-oxide synthesis in the tadpole and the nature of the developmental processes involved in the ultimate production in frog cells of high levels of activity. Continued investigation of trimethylamine-N-oxide synthesis in the bullfrog system has provided some answers to these questions.

In the present investigation assay conditions were the same as those adopted earlier[2]. Tadpole and frog liver microsomes were isolated according to the classical procedure of Hogeboom[3] and electron microscope techniques were essentially those of Palade[4].

In contrast to the lack of demonstrable trimethylamine oxidation in early experiments[1], in the most recent ones trimethylamine oxidation by tadpole livers was clearly detectable (0·3–6·2 μmole/g tissue/h). The activity was, however, lower than that exhibited by homogenates of adult bullfrog livers (8–11 μmoles/g tissue/h). Although no special importance was attributed to it at the time, the first tadpoles were taken in the later winter and were therefore in hibernation or had recently arisen from hibernation. In later experiments, tadpoles taken in the summer were used. The possibility then presented itself that there might be seasonal effects on the levels of activity, or that the levels of activity were a function of tadpole age. The latter was a possibility because bullfrog tadpoles very often do not undergo metamorphosis until one to three years after they hatch. Since all of the tadpoles used in these experiments were taken in nature, they varied considerably in age. The data presented in Fig. 1 clearly indicate that neither the season of the year nor the stage of development of the tadpoles used significantly affected the results obtained. Included in the group were small tadpoles (less than a year old); tadpoles at least a year old, which had been allowed to winter either in the laboratory or in their natural habitat; and tadpoles at all stages of metamorphosis, including those with forelimbs. In the period between the appearance of forelimbs and the completion of metamorphosis the animal's liver acquires the adult levels of trimethylamine-oxidation activity. These results are quite similar to those obtained by Cohen *et al.*[5], who found in the bullfrog that the liver enzymes associated with the biosynthesis of urea also show precipitous increases in activity during the late stages of metamorphosis. Thus the original tadpole data[1] were in error, and resulted from sampling at the lower end of the wide range of possible trimethylamine oxidation activities.

Table 1. TRIMETHYLAMINE OXIDATION BY SUBCELLULAR FRACTIONS

Subcellular fraction	μmoles/g liver (wet weight)/h Tadpole	Adult
Nuclei + cell debris	1·4	2 5
Mitochondria	< 0 2	1·1
Microsomes	1 4	3·7
Supernatant	0 2	2·6

Since, in hog liver, trimethylamine oxidation previously had proved to be a microsomal activity[6], it was of interest to verify that this activity in the bullfrog tadpole and adult was similarly located. The data presented in Table 1 verify that in the bullfrog trimethylamine oxidation occurs in the centrifugal fraction which in mammalian systems contains microsomes. That this is also a microsomal fraction in both the bullfrog tadpole and adult was verified by electron microscopy. The spread of activity among the various fractions was to be expected, due to the difficulty of preventing association of the microsomes, on the one hand, and excessive fragmentation during homogenization, on the other. It was for this reason that the specific activities of the various subcellular fractions of the adult liver were also determined. They were as follows (mμmoles/mg protein/h): nuclei mitochondria, 149; microsomes, 710; and supernatant, 48. Thus, in the bullfrog tadpole, trimethylamine oxidation appears to be a microsomal activity which undergoes the same metamorphic increase in activity as was previously shown to be true of a number of soluble enzyme activities[7].

Triplet Nucleotide–Amino-acid Pairing; a Stereochemical Basis for the Division between Protein and Non-protein Amino-acids

Pelc and Welton have recently proposed[1] a stereochemical relationship between protein amino-acids and the codon triplet of nucleotides. I wish to propose a rather different possible relationship between nucleotide triplets and amino-acids which has emerged as a result of preliminary investigations aimed at understanding the usual exclusion and the occasional intrusion of the so-called non-protein amino-acids into protein.

It is unlikely that the non-protein amino-acids were excluded when life began to evolve because of lack of availability. A number of them, ornithine and homoserine, for example, are intermediates in the production of other amino-acids. Is there some stereochemical relationship between the four nucleotides and the protein amino-acids which favoured their aggregation—a relationship not involving enzymes which originally could not have been available? Theories concerning direct stereochemical relationships between DNA or RNA and amino-acids were popular some years ago in relation to the apparent

coding problem of sixty-four base permutations to twenty amino-acids, but a direct binding of amino-acids on to nucleotides implied an overlapping code which was shown to be unacceptable[2]. The discovery of transfer RNA appeared to solve the amino-acid–nucleic acid linkage problem but in reality shelved it. The existence in *t*RNA, however, of an isolated triplet allows a direct linkage of an amino-acid to the bases without requiring an overlapping code.

I propose that the anti-codon triplet for an amino-acid in a transfer RNA molecule provides a cage which will bind amino-acids (as their acyladenosine-monophosphates) in differing degrees so that they are made to lie in a position suitable for coupling to the non-specific-cytosine-cytosine-adenosine end of the *t*RNA chain. One must ask what incentive the amino-acid has to enter such a cage and what forces between the bases could create a precisely defined cage. Interaction between the free $-NH_+$ group of the amino acyl-AMP, ($>NH_2^+$ of proline) and some feature of the triplet common to all nucleotide triplets could provide the incentive and hydrogen bonding between the neighbouring bases the specific defining force for the cage. The importance of planar A—U and C—G base binding tends to overshadow the possibility of out-of-plane hydrogen bonding, but the existence of $-NH_2$ groups in three out of four bases allows great flexibility of such bonding. Out-of-plane hydrogen bonding between bases is expected to be weaker, but this is necessary, since the presence of messenger RNA must cause refolding of the anti-codon triplet to form planar bonds with its codon and release of the —CCA amino-acid end for peptide condensation.

I suggest that, just as chance causes the hydrogen bonding of C and G or U and A bases to be of a unique kind, so the fit between amino-acids and the triplet cages selects twenty chemically quite dissimilar amino-acids from the possible 100 found in Nature (there are more chemical species, but the 100 are biologically available).

First it is interesting to note that if the second base of the *t*RNA triplet is guanosine (anti-codons in Table 1)[3] the coding depends only on the first two bases. In this case, the last base acts only to seal off the end of the cage and its character is immaterial. Guanosine as the first base is almost as powerful in this respect, and cytosine as the first or second base is next to guanosine in its influence. Between them they control all the amino-acids which are stereochemically determined by only two bases. On the other hand, when the second base is uracil the first and last base are critical in determining the amino-acid which is bound. Cytosine and guanosine are the bases with both hydroxyl and amino groups projecting from their six-membered rings and are therefore better able to form hydrogen bonds than uracil with two hydroxyl groups (which can only hydrogen-bond with $-NH_2$ for stereochemical reasons) and adenosine with only one amino group. All other features of the six-membered rings are common to all bases. The possession by guanosine of two extra nitrogen atoms in its five-membered ring provides an explanation for dominance over cytosine

Table 1. THE GENETIC CODE

1st base	2nd base				3rd base
	U(A)	C(G)	A(U)	G(C)	
U	Phe	Ser	Tyr	Cys	A
(A)	Phe	Ser	Tyr	Cys	G
	Leu	Ser	'ochre'	?	U
	Leu	Ser	'amber'	Try	C
C	Leu	Pro	His	Arg	A
(G)	Leu	Pro	His	Arg	G
	?	Pro	GIN	Arg	U
	(Leu)	Pro	GIN	Arg	C
A	Ileu	Thr	AsN	Ser	A
(U)	Ileu	Thr	AsN	(Ser)	G
	Ileu	Thr	Lys	Arg	U
	Met	Thr	Lys	?	C
G	Val	Ala	Asp	Gly	A
(C)	Val	Ala	Asp	Gly	G
	Val	Ala	Glu	Gly	U
	Val	Ala	Glu	Gly	C

The anti-codons of the *t*RNA are shown in parentheses.

in hydrogen bonding and thereby in influence on the geometry of the cage.

Detailed testing with models of this hypothesis even of those amino-acids defined by two bases is a major undertaking. Proline was selected for examination since its side chain has no freedom of movement and its anti-codon is G.G.-3rd base, the most powerful hydrogen-bonding combination. Furthermore, several of its naturally occurring analogues have been studied in detail. A 'Courtauld' model of the triplet G.G.-3rd base was made and it was found possible to form three hydrogen bonds. C60-NH_2C2′,N1-N1′, C2NH_2-OC6′, between the guanosines. This left a narrow cleft into which the proline ring could fit and the NH_2^+ of the proline apparently could bond to the oxygen of the phosphorus between the second and third base. This is the only free phosphorus-bound oxygen (P=O); that of the phosphorus between the first and second base is on the outside of the cage. The naturally occurring ring-substituted proline molecules and pipecolic acid, a six-membered ring analogue, do not permit free access of the NH_2^+ group to the same point. The four-membered ring analogue azetidine-2-carboxylic acid does permit such access but makes fewer stabilizing van der Waals hydrogen contacts. The foregoing results are consistent with biochemical investigations which indicate that of the aforementioned analogues only azetidine-2-carboxylic acid is incorporated into protein[4,5]. The levels of azetidine-2-carboxylic acid used suggest that it reaches the amino-acid pool at a much higher level than that of the endogenous proline[4]. Experiments with isolated activating enzyme and *t*RNA are not conclusive, but an incorporation of azetidine-2-carboxylic acid at 3 per cent of the level of proline was indicated[5].

The present hypothesis differs from that of Pelc's in that it seeks to find some relationship between the anti-codon trinucleotides and amino-acids. With the limited examination so far made it would be premature to put this hypothesis forward as a general one; rather, it is claimed that it appears to provide an explanation in the case of a protein amino-acid and its non-protein analogues. The difficulty Pelc encountered with the many hydrocarbon side chains caused him to invoke bonds between methyl groups and bases, and hydrogen bonds between sulphur and bases, which are chemically rather unusual. These difficulties are removed if one maintains that it is hydrogen van der Waal's contacts which stabilize the amino-acids in the trinucleotide pocket. Certainly such contacts seem to be of particular importance in the stabilization of protein conformation[6]. By this approach the interaction of anti-codon and amino-acid is seen much more as a selection by steric restriction rather than as the formation of a chemical complex with the trinucleotide. At the present-day level of organization an aminoacyl-*t*RNA-synthetase attempts to put the amino-acid key into the anti-codon lock and if it succeeds binding to the —CCA terminal end occurs. Before the existence of enzymes the fit of lock and key would merely have been much slower.

Significance of Sub-bands of Lactic Dehydrogenase Isozymes

THE five isozymes of lactic dehydrogenase (LDH) usually observed after electrophoresis of vertebrate tissue homogenates are generally considered to result from the five possible combinations of two basic sub-units, *A* and

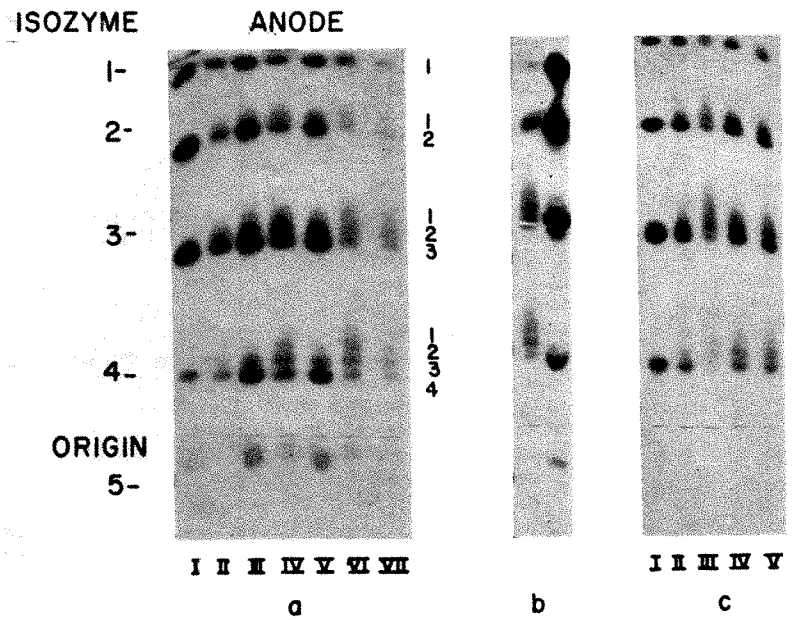

Fig. 1. Production of sub-bands by formaldehyde treatment. (*a*) Testis, I was not treated; the storage time between treatment and homogenization was 1 day for II and III, 3 days for IV and V, and 7 days for VI and VII. The concentration of formaldehyde used was 0·4 per cent for II, IV, and VI and 0·8 per cent for III, V, and VII. (*b*) A testis, exhibiting sub-bands without treatment, is on the left; kidney from the same cadaver is on the right. (*c*) Kidney, I was not treated; the storage time between treatment and homogenization was 1 day for II and III, and 7 days for IV and V. The formaldehyde concentration was 1·0 per cent for II and IV, and 2·5 per cent for III and V

B, combined into tetramer units[1,2]. The synthesis of each of the two sub-units is believed to be under the control of separate genes, which together account for the total isozyme composition[1,2].

Two sub-units arranged as tetramers cannot account for more than five isozymes. Some tissues, however, exhibit isozymes composed of a number of discrete sub-bands[3–5]. Conflicting hypotheses have been proposed in order to account for them.

This communication describes experiments that demonstrate that the isozymes of human testis, which originally show single isozyme bands, can be made to exhibit a number of distinct sub-bands after treatment with formaldehyde. Similar results have also been obtained with other human tissues investigated. The exhibition of LDH sub-bands, after appropriate treatment, may therefore be a general characteristic of human tissues.

Tissues were obtained at autopsy. The tissues were homogenized in distilled water (2 ml./g of tissue). Starch-gel electrophoresis and detection of LDH activity were carried out as previously described[6]. The electrophoretic buffer used was either the potassium phosphate–citric acid buffer, *p*H 7·0 (ref. 7), or a *tris*–citric acid buffer[7]. In the latter case, the gel buffer was prepared by adding 0·01 M citric acid to 0·01 M *tris* until the *p*H reached 7·0, and the electrode buffer was prepared by adding 0·03 M citric acid to 0·03 M *tris* until the *p*H reached 7·0. Both buffers produced comparable results.

Samples were treated with formaldehyde by dipping about 0·5 g of tissue, for 5 sec, in a solution of formaldehyde, which had been prepared by dilution with water. The tissue was then lightly blotted, wrapped in 'Saran Wrap', and stored at 3° C. The number of days the tissue was stored before being homogenized, and the concentration of formaldehyde used, are specified below.

Results obtained with a sample of testis, with and without formaldehyde treatment, are presented in Fig. 1*a*. The treated tissue had been divided into three portions, and each was stored for different periods of time before being homogenized. The isozymes of the untreated sample consisted of five single bands (the *X*-band is not easily discerned with the buffers used). The treated tissue, which had been stored for seven days after the formaldehyde treatment, before being homogenized, exhibited a single isozyme 1, two bands in the isozyme 2 position, three in the isozyme 3 position, and four bands in the isozyme 4 position. The portions of the tissues stored for shorter periods of time between the treatment and homogenization also exhibited sub-bands, but not always as many. In some cases, the number of sub-bands do not increase with longer periods of storage, but the amount of formaldehyde which penetrated different areas of the tissue may have varied, depending on the shape of the tissue and other possible factors. After the samples were homogenized, the isozyme patterns did not change over a period of several days (the samples were stored at 3° C).

Fig. 1*b* presents an isozyme pattern of a homogenate of testis which exhibited sub-bands without being treated with formaldehyde. It could not be determined with certainty whether or not this tissue had inadvertently been brought into contact with formaldehyde during the autopsy. The isozyme pattern of a homogenate of kidney tissue obtained from the same cadaver is also presented. Isozyme 3 exhibits some sub-bands, but the other isozymes are singlets.

A sample of kidney homogenate, with and without formaldehyde treatment, is shown in Fig. 1*c*. The kidney requires a higher concentration of formaldehyde for the demonstration of sub-bands than the testis does, but the distribution of the sub-bands is similar. The treatment of liver and heart tissues with formaldehyde also resulted in similar sub-bands.

The electrophoresis of treated samples of testis, conducted with the phosphate–citrate buffer, and with the discontinuous buffer described by Poulik[8], is compared in Fig. 2. The testis *X*-band is more sharp and distinct when the latter buffer is used. However, the regular increase in the number of sub-bands with decrease in isozyme mobility, after formaldehyde treatment, is not clearly demonstrated with this buffer. The formaldehyde causes the intensity of the *X*-band and isozyme 4 to decrease, and the intensity of isozymes 2 and 3 to increase.

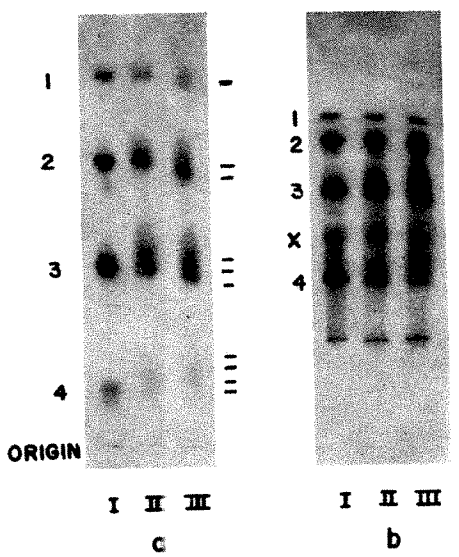

Fig. 2. Effect of buffer on separation of sub-bands. The buffer used was (*a*) phosphate-citrate, and (*b*) discontinuous buffer of Poulik. Testis samples were the same in each case: I was not treated. The formaldehyde concentration was 0·4 per cent for II and 0·8 per cent for III. Storage time between treatment and homogenization was 4 days.

This phenomenon is being investigated by treatment of purified isozymes with formaldehyde.

Costello and Kaplan demonstrated LDH sub-bands in untreated mouse tissue, which increase in number from isozymes 1 to 5 (ref. 9). They suggested that the sub-bands may be due to the synthesis of two types of *A* sub-units by separate genes. Two slightly different forms of *A* sub-units would account for sub-bands which correspond in number to the order of the isozymes. Koen and Shaw, who also investigated isozyme sub-bands in mouse tissues, have observed that in some cases the number of sub-bands is too great to be explained by this hypothesis[3].

Fritz and Jacobson found that sub-bands exhibited by homogenates of mouse muscle could be accentuated by the addition of β-mercaptoethanol to polyacrylamide gels[5]. They proposed, as a tentative explanation, that the mobility of the *A* sub-unit may be slightly different when it is combined with NAD, and that an equilibrium is produced by the mercaptoethanol between *A* sub-units with and without NAD. The validity of this explanation has been questioned by investigators, who could not confirm any difference in the isozyme patterns after the addition of NAD to the gels[3,10,11].

In addition to mouse tissues, regularly increasing sub-bands have been observed by various investigators in haemolysates of untreated human erythrocytes of small portions of populations sampled[4,10–13]. In some instances (ref. 4, for example), the sub-bands appear almost identical to those previously mentioned in testis and kidney tissues. The erythrocyte sub-bands have generally been explained by the hypothesis of mutant genes, which lead to the synthesis of two types of *A* or *B* sub-units.

The LDH sub-bands do not appear to be due to an equilibrium resulting from polymerization[3,13], and they retain their original mobility when isolated and submitted to a second electrophoretic separation[3].

The consistent production of regularly ordered, distinct sub-bands by formaldehyde treatment in various tissues suggests that the ability to exhibit such sub-bands under these conditions is a general characteristic of human tissues, rather than a result of genetic mutation. Two alternate explanations which would appear most likely are: (1) the sub-bands were originally present, but not demonstrated, until the formaldehyde treatment; (2) formaldehyde caused an alteration of some of the sub-units.

In the latter case, it is possible that detection of sub-bands in untreated tissues or haemolysates, already referred to, was due to sub-unit alterations, which occurred before or during processing, without formaldehyde treatment. Resistance of sub-units to alteration may be indirectly affected by other metabolic variations which are inherited.

Effect of Age on the Composition of Bovine Nasal Cartilage

Malawista and Schubert[1] showed that 80 per cent of the chondroitin sulphate present in bovine nasal cartilage could be extracted from the tissue by homogenization in distilled water. Further purification of the extracted material indicated that 15 per cent of the dry weight was protein[2] which appeared to be covalently bound to the polysaccharide moiety. Small amounts of keratan sulphate have recently been found in the complex[3], and work in this laboratory has indicated that both mucopolysaccharides behave as though they are part of a single complex molecule[4].

Kaplan and Meyer[5] showed that the proportion of keratan sulphate in the total acid mucopolysaccharide fraction of human costal cartilage increased linearly with age. It seems possible that these changes reflect alterations in the chemical composition of the mucopolysaccharide protein complex in the tissue. In this communication the composition of the extracted mucopolysaccharide protein complex from bovine nasal cartilage is investigated as a function of the age of the animal.

Nasal cartilage was obtained from embryonic (23 in. crown to rump), young (2 years), and old (14 years) steers within 1 h of death. The loose fascia was dissected away and the cartilage minced at 0° C and then homogenized in distilled water as described by Malawista and Schubert[1]. The homogenates were first centrifuged for 60 min at 20,000 r.p.m. (Spinco, model *L* ultracentrifuge, No. 21 rotor) to remove collagen residues and then for 150 min at 45,000 r.p.m. (No. 50 rotor) to remove a heavy gel fraction[2]. The residues were extracted a further three times and the supernatants pooled and the mucopolysaccharide protein complex precipitated with cetyl trimethylammonium bromide (CTAB) and washed with distilled water. The quaternary ammonium ion was then removed by shaking the precipitate with a saturated solution of potassium thiocyanate in ethyl alcohol. After washing the precipitate with alcohol the crude preparation was dissolved in distilled water and passed through a jacketed column of 'Ecteola' ion exchange resin in the chloride form at 2° C. The eluate was again treated with CTAB and the quaternary ammonium ion removed from the precipitated complex as before. The passage of the crude preparation through the 'Ecteola' resin removed nucleic acid, free acid mucopolysaccharide and any unbound protein. The resin did not retain more than 2 mg of the protein polysaccharide complex per gram of dry resin.

An examination of the sedimentation velocity pattern in the analytical ultracentrifuge showed the presence of a single boundary in each preparation (Fig. 1).

The protein content of the preparations was between 15 per cent and 20 per cent of the dry weight and was not altered by reprecipitation with CTAB. This protein could be removed by digestion with papain and the acid mucopolysaccharide fraction isolated as described by

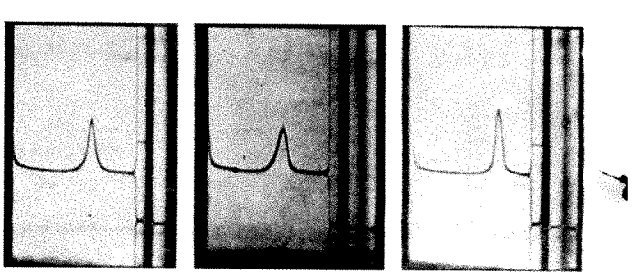

Fig. 1. Sedimentation velocity patterns of mucopolysaccharide protein complexes of cartilage isolated from: (1) embryonic steer; (2) young steer; (3) old steer. Sedimentation in 0·15 M KCl at a sample concentration of 0·3 g/100 ml.

Table 1. CHANGES WITH AGE IN THE POLYSACCHARIDE COMPOSITION OF THE MUCOPOLYSACCHARIDE–PROTEIN COMPLEXES EXTRACTED FROM BOVINE NASAL CARTILAGE

* The values are calculated using total hexosamine as 1·00.

Scott[6]. Analysis of this fraction for uronic acid, hexosamine and hexose is shown in Table 1. The molar equivalence of (1) glucosamine and hexose and (2) of galactosamine and uronic acid indicated the presence of keratan sulphate and chondroitin sulphate in all three preparations. This was confirmed by the separation of the two mucopolysaccharides on cellulose columns as described by Gardell[7].

The ratio of keratan sulphate to chondroitin sulphate as indicated by the proportion of glucosamine to galactosamine in Table 1 varied according to the age of the animal, while the total acid mucopolysaccharide content of the complexes remained relatively constant. The keratan sulphate content of the total mucopolysaccharide increased from 9·0 per cent in the embryonic preparation to 29 per cent in that of the old steer. These results suggest that the changes in the ratio of keratan sulphate to total mucopolysaccharide observed by Kaplan and Meyer[5] in human costal cartilage with increasing age are probably due to changes in the composition of the acid mucopolysaccharide complex present in this tissue.

Premature Birth in Rats induced by Ethionine Injection

THE injection of pregnant rats with certain antimetabolites, such as ethionine, in sub-lethal doses, may result in resorption or stillbirth[1–4]. We wish to report the effect of smaller, repeated doses of ethionine on the course and outcome of pregnancy in rats. Daily subcutaneous injections, in the doses listed in Table 1, were given from the twelfth day of pregnancy until delivery. Control animals received saline injections. All injections were in a volume of 1 ml. The date of conception was established by the first appearance of sperm on vaginal smears.

Most of the litters from females receiving ethionine were born prematurely. The degree of prematurity was, in general, directly related to dose. These findings are outlined in Table 1. The birth weight deficits of the pups were no longer evident after ninety days.

We subsequently injected a group of non-pregnant female rats with single doses of ethionine in the lethal range. When the survivors were mated with normal males fertility was not impaired and young were delivered after a normal gestation period. The birth weights and growth rates of the pups were normal.

It is interesting to contrast the premature pups born to ethionine-treated mothers with those born at term to mothers whose dietary intake was restricted during pregnancy. Both types of pups result from a nutritional stress and both are underweight at birth. Their subsequent progress is, however, quite different. The premature pups attain full adult weight; the pups of restricted mothers remain underweight throughout their lives and also show other evidence of permanent damage[5].

Relationship between Age and Haemoglobin-splitting Activity in Chicken Muscle

CATHEPTIC activity towards proteins has been found in extracts of kidney, spleen, liver, lung, muscle, brain and erythrocytes[1–5]; therefore, the cathepsins may be considered to be part of the general enzymatic apparatus of animal cells. The action of the cathepsins is evident during the autolysis of animal tissues at acid *p*H. Recently, considerable interest has been shown in the catheptic activity of beef and chicken muscle because of their suggested role in meat tenderization, preservation and flavour[6–10].

The function of the cathepsins in living tissue is not clearly known. Sylven and Malmgren[11] have shown that the haemoglobin-splitting activity of young rapidly growing tumour cells is much greater than that of older tumour cell generations, and Ross and Ely[12] found higher activity in young rats than in adult and older rats. These investigations suggest that cathepsins may play a part in protein turnover and synthesis.

The investigation reported here was undertaken to determine whether haemoglobin-splitting activity (protease activity at *p*H 3·8) in broiler chicken breast and thigh muscles changes during maturation. Such information is important in elucidating the physiological role of the haemoglobin-splitting cathepsins and can be of value as a means of determining maturity.

Six sets of broilers, 4, 5, 8, 10, 12 and 14 weeks of age, were slaughtered by cutting the neck veins. The animals were bled and the breast and thigh muscles were removed. The tissue was immediately ground and then blended with distilled water. Haemoglobin-splitting activity was determined in tissue extracts by a modification[13] of Anson's[14] method. The amount of tyrosine and tyrosine-containing peptides liberated from denatured haemoglobin

* Live births.

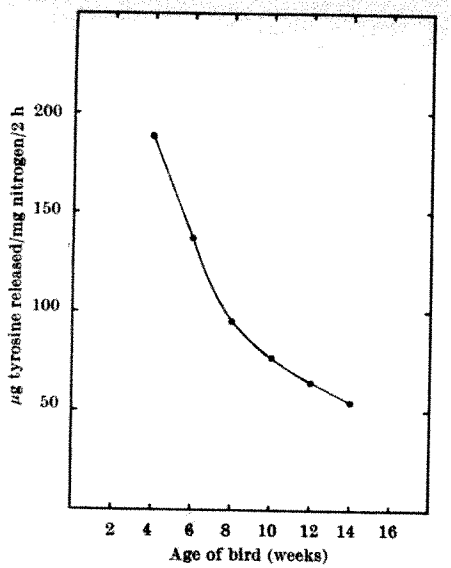

Fig. 1. Haemoglobin-splitting activity of breast muscle versus age of bird

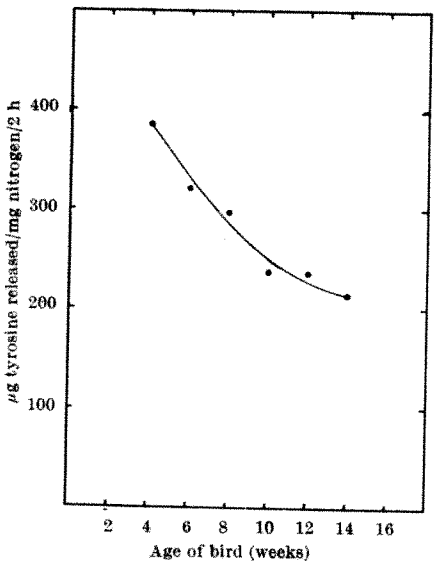

Fig. 2. Haemoglobin-splitting activity of thigh muscle versus age of bird

was used as a measure of haemoglobin-splitting activity Moisture and total nitrogen were determined as described in the *A.O.A.C. 1960 Official Methods of Analysis*[15].

Tables 1 and 2 show the average amount of tyrosine liberated from haemoglobin and the average moisture and nitrogen contents of six sets of breast muscle and three sets of thigh muscle. Moisture and nitrogen content changes little with age. The amount of tyrosine liberated decreased substantially with age in both breast and thigh muscle. Figs. 1 and 2 show the average tyrosine liberated (per mg of nitrogen) of six sets of breast muscle and three sets of thigh muscle as a function of age. The results show that haemoglobin-splitting activity was directly related to bird age.

Table 1. AVERAGE (6 BIRDS) BREAST MUSCLE COMPOSITION AND TYROSINE RELEASED FROM HAEMOGLOBIN (MG/G MEAT)

Age (weeks)	Moisture	Nitrogen	Tyrosine
4	750	37·8	7·13
6	744	39·3	5·41
8	744	39·9	3·81
10	739	39·9	3·08
12	735	40·4	2·58
14	735	40·5	2·21

Table 2. AVERAGE (3 BIRDS) THIGH MUSCLE COMPOSITION AND TYROSINE RELEASED FROM HAEMOGLOBIN (MG/G MEAT)

Age (weeks)	Moisture	Nitrogen	Tyrosine
4	762	32·6	12·55
6	760	32·9	10·58
8	758	32·8	9·72
10	765	32·7	7·75
12	763	33·3	7·87
14	761	33·9	7·26

We have undertaken to obtain information on the role of the haemoglobin-splitting cathepsin of chicken muscle. The results show that haemoglobin-splitting activity was high in young rapidly growing birds and decreased with maturity. This direct relationship is consistent with the proposal that the haemoglobin-splitting catheptic activity is related or involved in protein turnover and/or synthesis. However, the specific role of the cathepsins in muscle is unknown and remains a subject of considerable interest.

Glycolytic and Dehydrogenase Activities of Dwarf Colony Mutants *Salmonella typhi* and *Salmonella typhimurium*

MUTANTS producing dwarf colonies occur in many species of micro-organisms. The delayed rate of multiplication of these mutants is sometimes related to disturbances in the metabolism of amino-acids and vitamins[1-3] and sometimes to respiratory deficiency[4,5].

Mutants of *Salmonella typhi* and *S. typhimurium* which produce dwarf colonies have been obtained by treatment with antibiotics and trypaflavine. (The mutant *Bc4M* is resistant to 200,000 U./ml. of streptomycin, the mutant *N20* is resistant to 800 μg/ml. of myecrine.) All strains used and their mutants have a typical antigenic structure —with the exception of the 'trypaflavine' mutant, which is without Vi-antigen. The idiosyncrasies of amino-acid metabolism, and of the oxidative and glycolytic processes of these mutants, were investigated. Two out of three mutants were auxotrophs (*Bc4M* and *N20*). The former required one of the amino-acids containing sulphur in addition to tryptophan, and the latter required isoleucine. The respiration of the mutants in the same phase of growth was as sensitive to cyanide in the presence of glucose as the respiration of the initial cultures, and thus our mutants differed from those described by Gause[4].

Mutants resistant to antibiotics were characterized by a disturbed Pasteur effect. They showed an intensive aerobic glycolysis twice as high as that of the initial forms (Table 1); the rate of lactate utilization by mutants and the parental strains was the same. Under anaerobic conditions (in the presence of cyanide and in an atmosphere of nitrogen) there was a similar accumulation of lactic acid by the mutants and the initial cultures. Such a disturbance of the Pasteur effect was not found with the third 'trypaflavine' mutant. There was a small decrease of glycolytic activity under anaerobic conditions as compared with the initial strain.

Table 1. GLYCOLYTIC AND DEHYDROGENASE ACTIVITIES OF MUTANTS OF *S. typhi* AND *S. typhimurium*

Strain	Lactic acid* (μg/mg of protein) Without KCN	Lactic acid* (μg/mg of protein) With KCN (10^{-2} M)	Formazan* (μg/mg of protein) in the presence of substrates: Glucose	Pyruvate	Lactate	Glutamate	Acetate	Succinate	Malate
S. typhi B (wild)	225	700	90	75	43	19	10	13	10
mutant *Bc4M*	500	800	62	33	24	10	2	0	0
S. typhimurium NI (wild)	159	654	75	72	75	58	19	38	42
mutant *N20*	319	806	34	28	38	20	4	16	22
S. typhi ty2 'trypaflavine' mutant	186	633	88	82	53	24	16	6	0
	155	479	54	41	38	14	14	10	6

* Lactic acid was estimated after the bacteria had been incubated for 1·5 h in the presence of glucose (25 μM). Formazan was estimated after the bacteria had been incubated for 45 min.

The dehydrogenase activity of the bacteria was also investigated, using for assay the reduction of triphenyl tetrazolium chloride to formazan. Dehydrogenase activity was far more intense in the presence of glucose, pyruvate and lactate than with succinate, malate, acetate, and glutamate as substrates.

Mutants resistant to antibiotics were characterized by a decreased dehydrogenase activity in the presence of all substances studied. The mutant cells (*Bc4M*) also lost their capacity to dehydrogenate in the presence of succinate and malate. The 'trypaflavine' mutant exhibited decreased dehydrogenation activity in the presence of glucose, pyruvate, lactate and glutamate, but it showed slightly increased dehydrogenation of succinate and malate (Table 1). As was demonstrated previously, the latter phenomenon is a typical feature of rough strains of bacteria[6]. Thus, in this communication, we are dealing with phenotypically similar mutants of *Salmonella* which produce dwarf colonies which differ only in the disturbances they effect in oxidative and glycolytic processes.

The common property shared by the mutants described here is a decreased dehydrogenase activity in the presence of certain substrates; however, the increase in aerobic glycolysis was not a feature common to the mutants studied. Two mutants were characterized by simultaneous disturbance of both amino-acid metabolism and oxidative and glycolytic processes.

From the data reported it can be seen that the morphological expression of the delayed multiplication of microorganisms (dwarf colonies) is probably a consequence of different metabolic processes.

HAEMATOLOGY

Inhibitors of Fibrin Cross-linking : Relevance for Thrombolysis

THE terminal stages of vertebrate blood clotting have been shown[1-4] to proceed by the following steps:

Reactions (I) and (II) can be seen when purified fibrinogen is clotted by thrombin. A gel forms which readily dissolves in a number of solvents such as 1 per cent monochloroacetic acid, 5 M urea or 1 M sodium bromide which would not disrupt covalent bonds. In whole blood or plasma reactions (III) and (IV) are also operating and, due to the functioning of the thrombin-activated fibrin stabilizing factor (FSF*), the aggregated fibrin molecules are immediately cross-linked. The gel thus becomes insoluble in the solvents mentioned and also acquires a greater mechanical strength. It was shown earlier that the chemistry of fibrin cross-linking is based on a transpeptidation (that is, transamidation) mechanism[1,3,5]. Amino groups of one fibrin molecule react with carbonyl functions of another to yield peptide-type of intermolecular bonds. As predicted from such a mechanism, certain amines[1,3-6] inhibit the cross-linking process by becoming incorporated into fibrin and thereby terminating the chain of polymerization. It is important to emphasize that these compounds do not interfere with the gelation (that is, aggregation) of fibrin; they specifically affect only the subsequent cross-linking step (that is, reaction IV). Accordingly, a very specific tool is available for modifying the chemical structure of clots and thrombi without affecting the 'clotting time' of blood itself. The extent of cross-linking will clearly depend on the concentration of inhibitor. Sufficiently high concentrations of the latter will reduce the size of cross-linked units so that they remain completely soluble in 1 per cent monochloroacetic acid. Nevertheless, even in low concentrations, the inhibitor might still be expected to loosen the chemical structure of clots (and thrombi) which, while perhaps no longer soluble in the acid, might be a more digestible substrate for fibrinolytic enzymes. In fact, it was shown[7] that whole human blood, clotted in the presence of 20 mM glycineamide, lysed far more rapidly and more completely than control blood which was clotted in saline of identical ionic strength. The plasmin system in these experiments was activated by urokinase added to the blood before clotting occurred.

This communication describes further experiments designed to extend these findings to the more complex system of using artificial thrombi made from human blood[8]. Glycine methyl ester and aminoacetonitrile, both of which mimic the end amino portions of fibrin molecules, were selected as cross-linking inhibitors for these initial studies.

Blood was obtained from healthy volunteers by venipuncture using 18-gauge needles and plastic syringes. It was immediately emptied into a plastic tube, cooled in ice and then distributed into 26 cm long 'Tygon' tubings (internal diameter 3/16 in.). In the experimental series, 1 ml. blood was mixed with 1 ml. of the inhibitor (that is glycine methyl ester or aminoacetonitrile at various concentrations). Stock solution of 0·1 M inhibitor was prepared in a *p*H 7·4, 0·05 M *tris* (hydroxymethylaminomethane)–hydrochloric acid buffer; in order to keep the ionic strength constant, further dilutions of the inhibitor were prepared with use of 0·05 M *tris* buffer containing 0·1 M saline. In the control series, 1 ml. of this *tris*-saline buffer alone was mixed with 1 ml. of blood. Each tube was bent to form a loop with the ends connected by a sleeve of tubing (internal diameter 5/16 in.). Thrombi were produced by rotating the loops on a turntable with a 40 degree tilt, at 33⅓ r.p.m. for 2 h at room temperature (about 24° C). At the end of this time, contents

of the loops were transferred to glass test-tubes and 1,100 CTA units of urokinase, dissolved in 0·3 ml. of 0·15 M saline, was admixed to each. (For definition of CTA units, see ref. 10; urokinase was a gift from Abbott Laboratories, North Chicago, Illinois.) Furthermore, to eliminate the possibility that glycine methyl ester or aminoacetonitrile might have acted by accelerating the action of the fibrinolytic enzymes *per se*, 1 ml. of 0·1 M inhibitor was now added to all tubes of the control series and 1 ml. of *tris*-saline buffer to those of the experimental one. Thus, final urokinase concentration was about 335 CTA units per ml. The test-tubes were gently shaken in a water bath at 37° C for 5 h. Their contents were then poured into sufficiently large volumes of 0·15 M saline to make visual examination of remnants of thrombi possible.

Some thrombi, not exposed to urokinase, were tested for solubility in 1 per cent monochloroacetic acid and were also selected for light microscopic studies.

The results (ten series of experiments involving five blood donors) were remarkably reproducible and may be summarized as follows.

Morphological characteristics of the thrombi, both in regard to consistency and histological appearance, were unaffected by the presence of cross-linking inhibitor. This was true even for as high as 50 mM glycine methyl ester which inhibited cross-linking to such an extent that the thrombus could be fully dissolved in 1 per cent monochloroacetic acid. Clearly, such inhibitors do not interfere with thrombus formation, and aggregation of fibrin without covalent cross-linking is apparently sufficient to hold the formed elements of blood together in a tight thrombus.

Thrombi formed in the presence of 25 and 12·5 mM glycine methyl ester were partially soluble in 1 per cent monochloroacetic acid, whereas the control ones were totally insoluble.

The main purpose of this work was to study the enzymatic lysis of experimental thrombi and, in particular, to see what effect chemical modification of their structure would have on this process. Thrombi produced in the presence of at least 1 mM glycine methyl ester were always completely lysed in 5 h following the addition of urokinase. Partial but appreciable lysis was observed down to 0·25 mM glycine methyl ester concentration: sometimes 0·5 mM of the latter enabled complete lysis to occur (Fig. 1). All thrombi formed in the absence of cross-linking inhibitor remained unaffected by the urokinase used in the experiments.

Aminoacetonitrile, another fibrin cross-linking inhibitor, gave results entirely analogous to those obtained with glycine methyl ester. In fact, it proved to be even more effective, for complete lysis ensued with thrombi formed in the presence of 0·2 mM aminoacetonitrile. The greater efficacy of this compound can probably be rationalized partly in terms of its rather low pK_a (ref. 9), which means that, in contrast to about a 10 per cent fraction of glycine methyl ester, almost all the added aminoacetonitrile would exist in the inhibitory unprotonated form. Furthermore, under the conditions of the experiments, aminoacetonitrile is chemically more stable than glycine methyl ester.

The experiments clearly demonstrate that the chemical structure of thrombi may be modified with the use of specific inhibitors of fibrin cross-linking so that they can be lysed much more rapidly. Possible pharmacological planning in this instance is an interesting and direct outgrowth of studies on the molecular mechanism of transpeptidation in the physiological polymerization of fibrin[1,3–6].

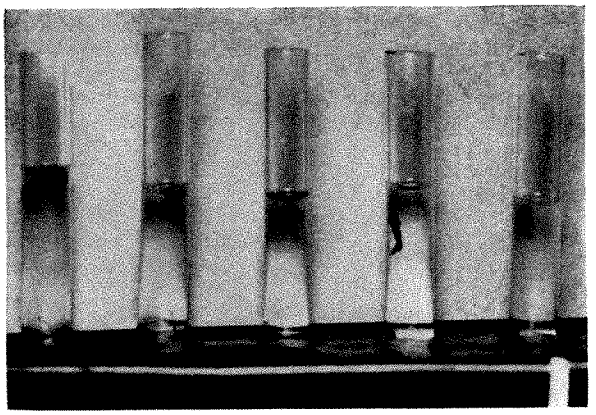

Fig. 1. Urokinase-induced lysis of thrombi. For experimental details see text. Approximate concentration of glycine methyl ester present during formation of thrombi (from left to right): 0; 0·06; 0·12; 0·25 and 0·5 mM

New Genetic Variants of Transferrins and Haptoglobins in Pigs

POLYMORPHISM of transferrins in pigs was first shown by Ashton[1] and Kristjansson[2,3]. The alleles which control the synthesis of the three protein fractions were designated Tf^A and Tf^B; King[4] identified another allele Tf^C in animals of the Landrace breed. In the breeds so far investigated the frequency of this latter is very low[5,6], but transferrin *C* has been recently detected in the homozygous state in some Chinese pigs (*Sus vitatus*) inbred since 1958 at the Zoological Gardens, Prague[6] (Fig. 1).

By means of starch-gel electrophoresis[7] it was possible to detect a new variant of transferrins, controlled by the allele Tf^D, which has so far been found only in heterozygotes Tf^A/Tf^D and Tf^B/Tf^D of Bohemian large white pigs (Fig. 1). Proof of genetic control of the new transferrin was obtained by analysing the progeny of those animals in the serum of which Tf^D had been detected (Tables 1 and 2). The calculated gene frequency is $0{\cdot}004 \pm 0{\cdot}002$, $N = 457$.

Table 1. SEGREGATION OF THE Tf^D ALLELE IN THE LITTER OF SOW NO. 48

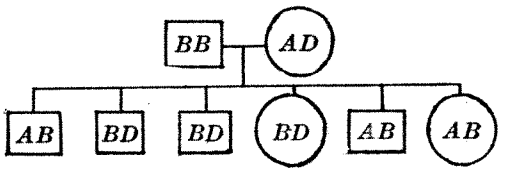

Table 2. OBSERVED AND EXPECTED DISTRIBUTION OF TRANSFERRIN TYPES IN OFFSPRING FROM MATINGS, INCLUDING THE ALLELE Tf^D

Matings	No. of Litters	No. of Offsprings	Transferrin type *AB*	*BB*	*BD*
$AD \times BB$	1	6	3/3·00		3/3·00
$BD \times BB$	2	7		2/3·50	5/3·50

* Litters of Chinese pigs.

The transferrin fractions *D* are easy to identify, and difficulties arise only during the simultaneous determination of transferrin and haptoglobin types from a serum sample to which haemoglobin has been added. The haptoglobin–haemoglobin complex then covers to a certain extent the transferrin fractions *D*.

In the haptoglobins of pigs[8], an unusual variant was also observed (Fig. 2). It is represented by a fraction, migrating a little faster than the zone controlled by the allele Hp^1, and is undoubtedly of genetic character (Table 3). It was also found in the aforementioned Chinese pigs and later also in other breeds.

Since a similar variant, but with a slightly slower migration than the Hp^1 zone, is known from literature, we suggest for the three fractions the nomenclature 1*F*, 1 and 1*S* in the order of decreasing electrophoretic motility and with a corresponding designation of alleles Hp^1F, Hp^1 and Hp^1S. The fraction 1 is identical with the present zone Hp^1. A reciprocal comparison was carried out with Canadian standard sera forwarded by F. K. Kristjansson. The type Hp^1S has not yet been observed in our laboratory.

It has lately been suggested that the haptoglobins in pigs[8] are not in reality true haptoglobins because they do not bind fresh haemoglobin, but only haemoglobin which has been stored and alkaline haematin or methaemoglobin[5,9,10]. That is why the above proteins are called haematin-binding proteins[9] or haem-binding proteins[5].

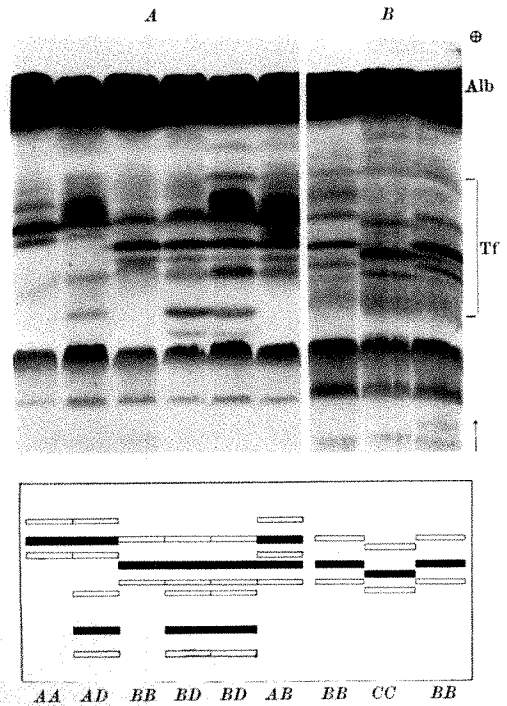

Fig. 1. Photograph and corresponding diagram of a starch gel with nine serum samples, showing (from left to right) the transferrin types in pigs: *AA*, *AD*, *BB*, *BD*, *BD*, *AB*, *BB*, *CC* and *BB*. Part *A* represents samples without haemoglobin, part *B* samples with an addition of chicken haemoglobin. Alb, albumin; Tf, transferrins. Buffer system: *tris*-citrate-borate (ref. 7), starch concentration 12·35 g/100 ml., stained in amido black

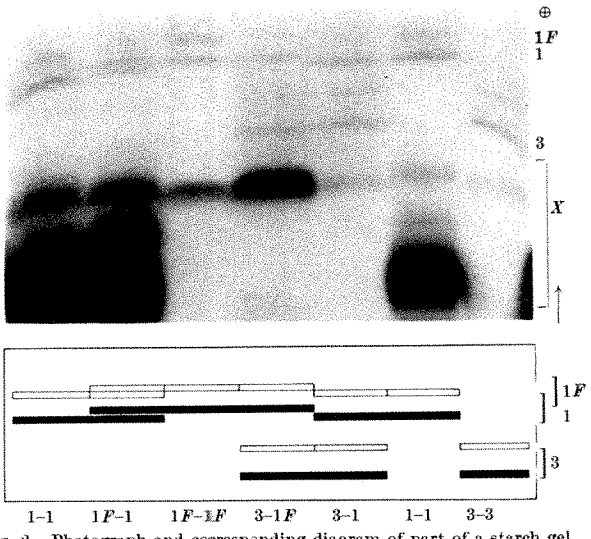

Fig. 2. Photograph and corresponding diagram of part of a starch gel with seven serum samples, showing (from left to right) haptoglobin types of pigs: 1–1, 1*F*–1, 1*F*–1*F*, 3–1*F*, 3–1, 1–1 and 3–3. Chicken haemoglobin (stored) 150–300 mg/100 ml. was added to the samples. Stained in benzidine. *X*, probably true haptoglobins of pigs

However, the acknowledged genetic hypothesis of control of their synthesis remains unchanged.

I thank Dr. F. K. Kristjansson, Animal Research Institute, Department of Agriculture, Ottawa, Canada, for sending standard sera, and the management of the Zoological Gardens, Prague, for the facilities given for collecting blood samples.

HISTOCHEMISTRY

Ferritin-labelled Enzyme: a Tool for Electron Microscopy

THE labelling of immune globulins with electron-dense substances has been used, by various investigators, as a means of localizing sites of antibody–antigen interaction *in situ*[1,2]. Singer[3] conjugated ferritin and Pressman and Sternberg[4] iodine to gamma globulin with the view of subsequent interaction with antigen.

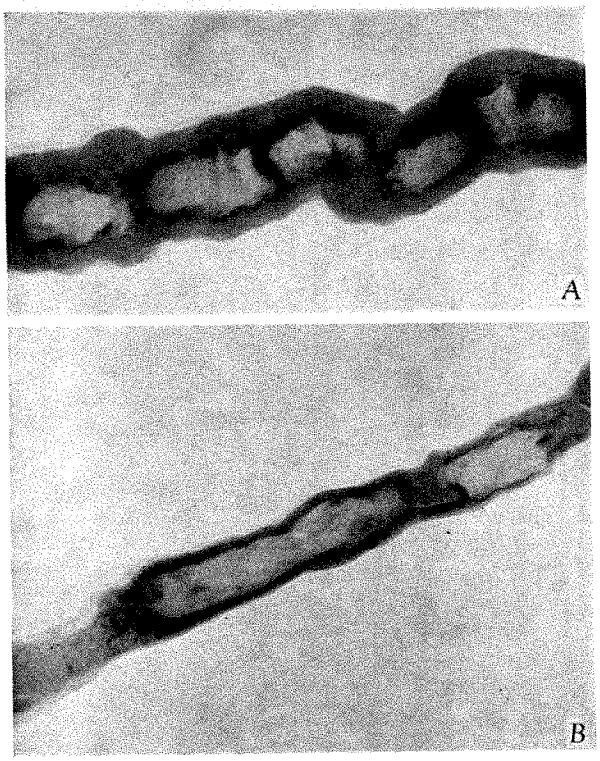

Fig. 1. Hypha of *Aspergillus niger*. *A*, Treated with ferritin-labelled chitinase. *B*, Treated with unconjugated ferritin. (× *c.* 82,750)

This led us to explore the possibility of using a similar technique in conjugating an enzyme rather than a globulin with ferritin. That enzymes such as lipase[5], lysozyme[6] and chitinase can be labelled with fluorochromes has been shown. In our investigation, chitinase was the enzyme chosen.

Chitinase, 20 mg/ml. (Nutritional Biochemicals, Cleveland, Ohio), was coupled with horse spleen ferritin (Pentex, Inc., Kankakee, Ill.) using the method outlined by Singer[3]. Following the final dialysis, a soluble and an insoluble fraction were recovered by centrifugation at 28,500*g* for 10 min. In our investigations, only the soluble fraction was used. In order to demonstrate that conjugation had actually occurred, chitin (Calbiochem, Los Angeles) was first reacted for 18 h with the soluble fraction buffered at *p*H 5·7 with 0·2 M phosphate buffer. Portions of the mixture (one drop) were placed on glass slides and heat fixed. The smears were then examined microscopically with tungsten illumination. The chitin particles appeared stippled with brown. Afterwards, the slide was thoroughly washed and treated with fluoroscein isothiocyanate-labelled chitinase[7]. Controls were prepared which had not previously been treated with the soluble fraction, but which were reacted with fluoroscein isothiocyanate-labelled chitinase alone. All preparations were examined with ultra-violet, bright field illumination (Zetopan microscope, Reichert, Vienna).

Control preparations showed uniform, bright, specific fluorescence. Conversely, those smears which had been previously treated with the soluble fraction revealed complete inhibition of fluorescence in the smaller chitin particles; while in the larger ones, fluorescence was limited to occasional areas. This indicated that the ferritin-labelled chitinase (FLC) had 'tied up' a larger percentage of the combining sites on the substrate.

Electron micrographs (RCA, *EMU* 2*A*) of chitin particles, both reacted with FLC and unreacted, revealed extensive deposition of electron-dense material in the former. That an enzyme-substrate reaction was occurring was demonstrated by a decrease in optical density in the FLC-chitin reaction mixtures over a period of 45 min. The rate of reaction is slow, which is characteristic of this enzyme system. The presence of a small amount of amino sugar (a product of the enzymatic hydrolysis of chitin) was detected by its characteristic colour reaction with ninhydrin. Later, FLC was tested against fungal material prepared by disruption with glass beads of a mycelial suspension of *Aspergillus niger* from which the lipids had been previously extracted.

Electron microscope investigations (RCA, *EMU* 3*H*) were carried out on FLC-treated and unconjugated ferritin-treated fungal preparations, both of which had been vigorously washed following a 2-h incubation period. Typical results are shown in Fig. 1. Note the heavy deposition of electron-dense material on the walls of the FLC-treated specimen. This deposition is evidently so heavy that structural detail is partially obscured.

We feel that the value of this method will become more evident as our work progresses and with the utilization of thin-sectioning techniques. Eventually, it should be possible to pinpoint the location of specific enzymatic substrates *in situ*. Additional investigative work is planned on all aspects of this technique with the view of extending it to other enzyme systems.

Histochemical Demonstration of Oxytocinase in the Human Placenta

Serum of pregnant women inactivates oxytocin due to the presence of oxytocinase. Serum of men and non-pregnant women does not inactivate oxytocin. Oxytocinase is thought to be produced by the placenta. This enzyme (*E.C.* 3.4.1.2) hydrolyses L-cystine-di-β-naphthylamide and has been termed 'cystine aminopeptidase'.

The determination of serum oxytocinase activity is carried out by incubation in the presence of L-cystine-di-β-naphthylamide. The β-naphthylamine released is afterwards measured.

L-Cystine-di-β-naphthylamide may also be used as a histochemical substrate for the demonstration of oxytocinase activity. The use of this substrate in histochemistry has already been suggested[1]. No account seems to be available, however, of its use in the histochemical demonstration of oxytocinase activity. Incubation of tissue sections from placentae with L-cystine-di-β-naphthylamide results in the release of β-naphthylamine at the site of enzyme activity[2]. The β-naphthylamine undergoes a simultaneous coupling reaction with a suitable chromogen in the incubating medium which results in the deposition of a coloured final reaction product at the enzyme site. The only chromogen used so far is diazotized 3-chloro-4-nitro-aniline ('Echtrot 3*GL*' salt). The more familiar chromogens, fast blue *B* or garnet *GBC*, have not yet been used.

The following procedure has been evolved for the histochemical demonstration of oxytocinase activity: Frozen tissue sections are cut at 10μ from human placentae fixed in 70 per cent alcohol for 24 h. The sections were incubated in 40 ml. 0·15 M phosphate buffer to which 1 ml. of substrate solution and 20 mg 'Echtrot 3*GL*' salt have been added. The substrate solution is prepared by

dissolving 25 mg L-cystine-di-β-naphthylamide in 10 ml. hot 0·012 N hydrochloric acid and adding 10 ml. distilled water. The substrate is stable and may be stored at 4° C. The incubation period lasts 1 h at room temperature. The final reaction product is diffusely and evenly deposited along the outer margin of the syncytium. Background staining does not occur and sections incubated in the presence of trichloroacetic acid do not show enzyme activity.

The distribution of enzyme activity may reflect oxytocinase activity. Alternatively, another enzyme may be hydrolysing L-cystine-di-β-naphthylamide and the final reaction product represents the localization of this enzyme. Therefore, the trivial name cystine aminopeptidase should not be applied to histochemical activity observed with this substrate, as confusion may result. A similar situation already exists with leucine aminopeptidase (*E.C.* 3.4.1.1). Leucine aminopeptidase hydrolyses leucineamide more rapidly than L-leucine-di-β-naphthylamide. At least one other enzyme, however, hydrolyses L-leucine-β-naphthylamide more rapidly than leucineamide[3]. The histochemical activity with respect to leucine-β-naphthylamide represents a system of enzymes and does not reflect leucine aminopeptidase activity. In addition, the present biochemical nomenclature covering peptide hydrolases is inadequate due to overlapping specificities, and it has been suggested that the trivial names based on particular substrates should be abandoned[4]. The enzyme that hydrolyses the histochemical substrate L-cystine-di-β-naphthylamide is a cystine-di-β-naphthylamide hydrolase. If it is shown, however, that this enzyme specifically hydrolyses the cystine–tyrosine bond of oxytocin, then the term oxytocinase may be retained for histochemical use.

Thanks are due to Prof. J. Chassar Moir and Dr. A. H. T. Robb-Smith for the facilities provided for this work.

Preferential Staining of Collagen by Acid Dyes in Methanol

THE effects of dye solvents on the selectivity of histological staining have not been extensively investigated. Robards and Purvis[1] have reported preferential staining of the gelatinous fibres of tension wood by chlorazol black *E* when dissolved in methyl cellosolve. Earlier the influence of solvents on the staining reactions of this dye was discussed by Cannon[2]. Puchtler and Sweat[3] reported a method for selectively staining haemoglobin in sections with amido black in a methanol solution, but not in water. Investigation of phospholipid staining by Luxol fast blue *G* revealed a changing selectivity dependent on the solvent used[4]. This dye in methanol solution was later found to stain only collagen and elastin[5].

When other sulphonated acid dyes were later used as methanolic solutions they preferentially stained connective tissue elements. This selective staining did not occur with aqueous solutions of the dyes. Among the dyes successfully used in this manner were acid fuchsin, aniline blue, methyl blue, fast green *FCF*, chlorazol black *E*, and pontamine fast turquoise 8*GLS*. Most of these dyes also selectively stain collagen when used as mixtures in saturated picric solutions, such as the Van Gieson stain.

Methylation, nitrosation and acetylation of tissue sections did not prevent the selective staining[5]. The staining was reduced by tanning with tannic acid, which affects the physical nature of collagen by the introduction of cross-linkages. Although the mechanism of this collagen staining has not been finally elucidated, it would seem to be of a physical nature rather than an affinity for specific chemical groupings in the collagen macromolecule.

It was considered that the most likely explanation for the preferential staining was a difference in the type of micelle or molecular arrangement of the dyes in methanol and water. The molecular form of the dye in methanol might conceivably have a greater affinity for collagen. However, as the molecular arrangement of the dyes in the two solutions appears to be comparable when examined in the analytical ultracentrifuge[6], this explanation is unlikely. It may be that methanol affects the permeability of the various proteins present in tissue sections, allowing only the collagen to stain. Collagen has a maximum solvation coefficient of 218 g/g, which is much higher than that for other non-globular protein polymers likely to be present in mammalian tissue sections, such as myosin (49 g/g) and tropomyosin (23 g/g)[7]; possibly this particular property of collagen is associated in some manner with its preferential staining.

As the collagen-staining reaction can be used after other histochemical and staining procedures in which the dyes used are not removable by methanol, it may be of value in histochemical investigations of connective tissue.

I thank Dr. Joel Kirschbaum of this Institute for examining the dye solutions in the analytical ultracentrifuge.

Histochemical Distribution of Alcohol Dehydrogenases in Endocrine Tissue

HISTOCHEMICAL investigations of alcohol dehydrogenase in rodents using various alcohols[1] revealed no obvious differences in the sites of alcohol utilization. Primary and secondary alcohols in general tissues were utilized at the same sites; the present communication deals with the histochemical variations in sites of utilization of different alcohols in steroid-producing endocrine glands.

Human term placenta, obtained at Caesarean section, and rat (Royal Wistar) adrenal glands, testes and ovaries were frozen on solid carbon dioxide and the tissues were prepared and incubated as described by Ferguson[1], using the following alcohols (final concentration 2·5 per cent): methanol, ethanol, propanol, butanol, pentanol, hexanol, heptanol, octanol, nonanol, decanol, undecanol, dodecanol, tridecanol, phenol, hydroquinone, 2-ethoxyethanol, allyl alcohol, 2-methyl-butan-1-ol, 3-methyl-butan-1-ol, nonyl alcohol, tertiary butanol, tertiary butyl carbinol, *iso*-propanol, secondary butanol, pentan-2-ol, pentan-3-ol, octan-2-ol, *cyclo*hexanol, ethylene glycol, propylene glycol, glycerol, butan-1 : 3-diol, butan-1 : 4-diol, pinacol and furfuryl alcohol.

Control sections were concurrently incubated in the buffered medium containing no alcohol.

The results are summarized in Table 1.

Since Bonnichsen[2] isolated alcohol dehydrogenase from horse liver, the biochemical properties and mechanism of action of this enzyme have been widely described[3–14].

The reactions catalysed by alcohol dehydrogenase, namely, (I) primary alcohols:

$$R.CH_2OH + NAD^+ \rightleftharpoons R.CHO + NADH + H^+$$

and (II) secondary alcohols:

$$R.CHO.R + NAD^+ \rightleftharpoons R.CO.R + NADH + H^+$$

tend to move farther to the right as the *p*H is increased and to the left when the *p*H is decreased. *p*H 7·4 was chosen for the medium in this investigation, due to aqueous solubility of nitro B.T. at this value.

Utilization of alcohols by endocrine tissues can be classified according to the alcohol structure[1].

(1) Utilization of straight-chain alcohols (methanol-tridecanol) improved with increasing chain-length to an optimum of six carbon atoms, and thereafter the longer-chained alcohols were progressively less satisfactory substrates, perhaps because of their decreased solubility in the medium.

(2) Aromatic alcohols (phenol and hydroquinone). These two substrates are not usually dehydrogenated in tissues but are instead conjugated with glucuronic acid prior to excretion.

(3) 'Cellosolve' (2-ethoxy ethanol) was moderately used by the tissues; however, straight-chain alcohols of a corresponding length appeared to be more suitable substrates. Thus the ethereal oxygen atom appears to exert some effect on the terminal hydroxyl group, impeding its dehydrogenation.

(4) The unsaturated alcohol (allyl alcohol) was fairly well utilized, but the double bond seemed to impede dehydrogenation to a slight extent in comparison to straight-chain alcohols.

(5) Branched alcohols (isobutanol, 2-methyl-butan-1-ol, 3-methyl-butan-1-ol, nonyl alcohol, tertiary butanol, tertiary butyl-carbinol). The two tertiary alcohols were not used and the remaining branched alcohols were not as well utilized as were the corresponding straight-chain alcohols. 3-Methyl-butan-1-ol tended to be a more suitable substrate than 2-methyl-butan-1-ol, presumably due to the increased steric hindrance of the methyl group the nearer it is to the hydroxyl group.

Secondary alcohols (isopropanol, sec. butanol, pentan-2-ol, pentan-3-ol, octan-2-ol). Alcohol dehydrogenase has been shown to utilize various alcohols biochemically, but there do not as yet appear to be any references to different alcohol dehydrogenases. The present findings suggest that primary alcohol dehydrogenase and secondary alcohol dehydrogenase are two separate enzymes. With the primary alcohols, activity was demonstrable in all components of the ovary to an approximately equal extent but not at all in placenta. With secondary alcohols the corpora lutea were extremely active, whereas the rest of the ovarian tissues were only very slightly reactive. The placenta could also utilize some of the secondary alcohols although the primary alcohols were not suitable substrates.

(6) *Cyclo*hexanol was not utilized to any significant extent by the endocrine tissues examined under the conditions of the experiment.

(7) Polyhydric alcohols (ethylene glycol, propylene glycol, glycerol, butan-1 : 3-diol, butan-1 : 4-diol, pinacol) did not appear to be utilized as avidly as were the monohydric alcohols.

(8) Furfuryl alcohol. Pentose metabolism involves the formation of furfuryl alcohol as a by-product, and as the most notable metabolism of pentoses is connected with nucleic acids it is not surprising that furfuryl alcohol dehydrogenase was observed in all the tissues examined.

From this investigation it emerges that in any future histochemical investigations into alcohol dehydrogenases at least three substrates would be required: first, a straight-chain primary alcohol such as hexanol, in preference to ethanol, which is the substrate quoted for demonstration of this enzyme[15,16]; secondly, a secondary

IMMUNOLOGY

Mucolipids of the Brain in the Process of Formation of Post-vaccinal Antirabic Immunity

THE biochemical changes which develop in the brain during the process of forming post-vaccinal antirabic immunity are of considerable importance.

We have recently investigated the mucolipids of the brain. Neuraminic acid is a characteristic compound of these substances and, as has been shown by some investigators, can provide protection against certain infections[1-3].

White mice were used in the experiments. The animals were immunized with live rabies virus fixe ($L.D._{50}$ $10^{-6.5}$). The virus was injected intraperitoneally six times on alternate days (0·25 ml. suspension per injection). The concentration of the virus was gradually increased by decreasing the dilution factor from 10^{-6} to 10^{-3}. Groups of animals (with corresponding controls) were killed on the eighth, fourteenth, thirtieth and fortieth day after the beginning of immunization. Mucolipids in the brain were determined by Klenk's[4] and Svennerholm's[5] method using Promyslov's[6] modification. The antibodies present in the sera were determined by means of ordinary neutralization tests (Table 1).

The results presented in Table 1 show that on the eighth day after immunization the amount of mucolipids in the brain had not increased significantly. On the fourteenth day the quantity of mucolipids reached a maximal level. It remained high until the thirtieth day and then decreased, reaching normal levels by the fortieth day.

Table 1

Length of test (days)	Antibodies in serum (neutralization index)	Mucolipids in the brain of immunized animals (μg/g wet wt.)	Mucolipids in the brain of control animals (μg/g wet wt.)
8	0	177·71 ± 1·775	
14	0	236·46 ± 4·303	161·01 ± 5·423
30	1,047	218·89 ± 17·67	
40	4,571	159·84 ± 16·03	

It is of considerable interest that under the immunization scheme described here the antibodies in the serum were found comparatively late.

Thus, in the process of forming the post-vaccinal antirabic immunity, a stable increase in the contents of mucolipids in the brain was observed over a certain period, which preceded the accumulation of specific antibodies in the serum. This shows that the reaction of the organism after the inoculation of a vaccine preparation proceeds not only in the so-called 'organs of immunogenesis', but also in the systems mainly affected in the course of the disease.

PATHOLOGY

Intracellular Plasma Protein: a Manifestation of Cell Injury in Myocardial Ischaemia

THE recognition of early cell injury poses an important problem in the study of disease, namely, the certain diagnosis of early myocardial infarcts. A variety of chemical and histochemical techniques have been tested for use in the identification of early myocardial ischaemia in experimental animals as well as in man[1,2]. The search has been only partially successful.

The interstitial fluid that surrounds cells *in vivo* contains plasma proteins of varying size and shape[3]. Thus the permeability of cell membranes is constantly being tested by a spectrum of protein molecules ranging from β_1-lipoproteins (molecular weight 1,300,000) to albumin (molecular weight 69,000). Under normal conditions the concentration of plasma proteins in interstitial fluid is low as compared with plasma. This is particularly true for large molecules such as β_1-lipoprotein and fibrinogen. Increased capillary permeability, which is common to many pathological conditions, including ischaemia, may result in a concentration of intercellular fluid protein comparable to that of plasma[3]. Cell injury associated with increased permeability of cell membranes may be marked by the intracellular diffusion of one or more types of plasma proteins. Labelled antibody to plasma proteins which are either commercially available or readily produced provides a sensitive way of specifically identifying these proteins in interstitial tissue and within cells.

The anterior descending branch of the left coronary artery of eight mongrel dogs was ligated as previously described[2]. The animals were killed from 1 to 24 h after the onset of ischaemia (Table 1). Blocks of myocardium were taken from the ischaemic anterior wall and from the normal myocardium of the posterior wall of the left ventricle. The tissue was fixed in 95 per cent ethanol at 4° C and processed for paraffin embedding as described by Sainte-Marie[4]. Serial sections were cut at 4μ. Slides of the ischaemic and control tissue from each animal were stained by the haematoxylin and eosin, periodic acid–Schiff (PAS) and diastase–periodic acid–Schiff (D-PAS) methods[5].

Table 1. INTRACELLULAR PLASMA PROTEINS AND D-PAS MATERIAL IN EXPERIMENTALLY PRODUCED MYOCARDIAL ISCHAEMIA IN THE DOG AS A FUNCTION OF TIME*

No. of animals	Period of ischaemia (h)	D-PAS material	Albumin	γ-Globulin	Fibrinogen
2	1	0	+ +	+	0
2	3	+	+ +	+	0
2	6	+ +	+ + +	+ + +	+ + +
1	12	+ + + +	+ + + +	+ + + +	+ + + +
1	24	+ + + +	+ + + +	+ + + +	+ + + +
8	0	0	0	0	0

* The maximum staining observed by the D-PAS and fluorescent antibody methods was designated + + + +. + + +, + + and + indicate approximately 75, 50 and 25 per cent of the maximum staining.

Other sections were incubated with fluorescein-labelled rabbit anti-dog albumin, rabbit anti-dog IgA globulin and rabbit anti-dog fibrinogen (obtained from Antibodies, Inc., Davis, California). These sections were examined with a large Zeiss fluorescence unit using a '*UG*1' excitor filter and a Kodak '2*B*' barrier filter. The specificity of the observed reactions was evaluated by exposing normal tissue from each animal to the labelled specific anti-sera and ischaemic tissue to labelled normal rabbit serum, labelled anti-sera absorbed with specific antigen and labelled anti-sera mixed with unlabelled anti-sera[6].

Cytoplasmic and nuclear changes sufficient to identify the ischaemic area were evident in the 12- and 24-h animals, but were equivocal in the 6-h animals and absent in the 1- and 3-h animals. The glycogen present normally in the dog myocardium was lost from the ischaemic areas of all animals (Table 1). By 3 h after the onset of ischaemia a D-PAS staining material was noted in the sarcoplasm but was very faint[1,2]. This reaction became more prominent as the infarcts developed (Table 1).

In normal portions of myocardium the fluorescent antibody technique showed albumin and IgA globulin in the blood vessels and interstitial spaces. Only auto-fluorescence was seen in the sarcoplasm. Fibrinogen was identified in the lumen of blood vessels but not in interstitial spaces or sarcoplasm.

Albumin and IgA globulin was seen in the ischaemic sarcoplasm of all animals. Although the ischaemic fibres in the 1- and 3-h animals could clearly be distinguished from adjacent normal fibres by the specific fluorescence for albumin or IgA globulin, the intensity of the specific fluorescence was greater in the 6-, 12- and 24-h animals (Figs. 1 and 2). In the 1- and 3-h animals the intensity of specific fluorescence for albumin was greater than for IgA globulin. In the 6-, 12- and 24-h animals the specific fluorescence for albumin and IgA globulin was about the same (Table 1). Fibrinogen was not found within muscle fibres until 6 h after the onset of ischaemia. The intensity of this specific fluorescence was greater in the 12- and 24-h animals.

The relationship between the intracellular plasma proteins and the D-PAS material was evaluated by comparing the distribution and intensity of staining of the plasma proteins by the fluorescent antibody technique with the

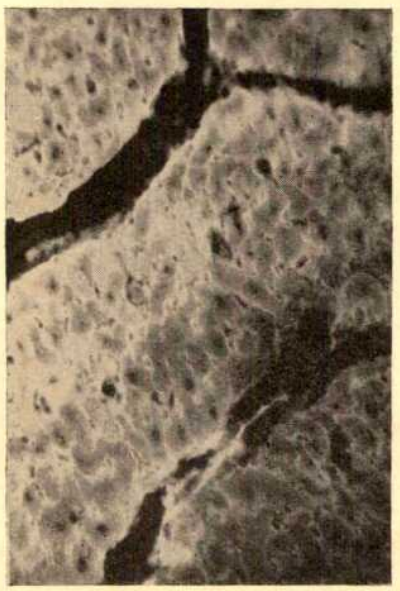

Fig. 1. Dog myocardium 1 h after ligation of a coronary artery incubated with fluorescein-labelled rabbit anti-dog albumin for 1 h. Adjacent normal muscle fibres are seen in the upper left. The sarcoplasm does not fluoresce. The sarcoplasm in the other areas was a bright yellow-green (bright area in the print) (×688)

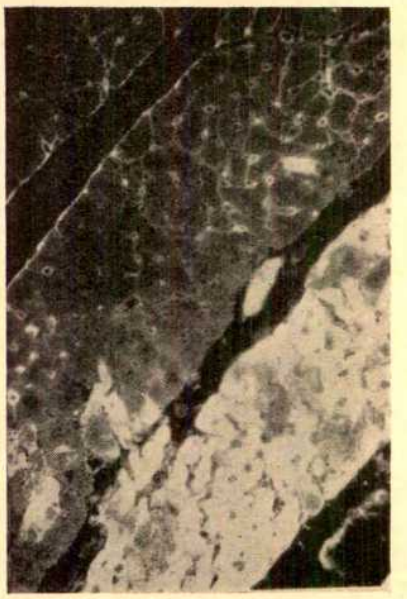

Fig. 2. Dog myocardium 12 h after ligation of a coronary artery incubated with labelled rabbit anti-dog IgA globulin for 1 h. The sarcoplasm of the normal muscle fibres (upper) does not show specific fluorescence in contrast to the sarcolemma and the ischaemic muscle fibres in the lower right (×688)

D-PAS material in alternate sections. Also, both reactions were performed on the same section. That is, a section was incubated with one of the labelled specific anti-sera and selected areas marked and photographed. Afterwards the section was digested with diastase and stained by the PAS method. The previously marked areas were photographed and compared with the staining by the fluorescent antibody technique. The distribution and intensity of staining by the two methods were quite comparable. That is, the muscle fibres showing D-PAS staining in the sarcoplasm also stained for plasma proteins; the greater the intensity of staining by the D-PAS method, the greater the specific fluorescence observed.

These data suggest that albumin and IgA globulin, normally present in intracelllular fluid, diffuse into muscle fibres quite soon after the onset of ischaemic injury. The albumin, presumably because of its smaller size and higher concentration in extracellular fluid, diffuses earlier than IgA globulin. Fibrinogen, being a much larger molecule, is not normally present in interstitial fluid in sufficient concentration to be demonstrated by the method used. However, by 6 h, the capillary permeability in the ischaemic area was such that fibrinogen had passed into the interstitial fluid and into the sarcoplasm of muscle fibres. Correlation between the distribution and intensity of staining by the D-PAS method and the influx of plasma protein indicates that the carbohydrate-rich (PAS positive) plasma proteins account for the D-PAS material found in ischaemic muscle fibres.

Myocardial ischaemia in man is accompanied by a similar intracellular diffusion of plasma proteins[7]. The possibility of using plasma proteins as an indicator of cell injury of a variety of types is supported by the finding that plasma proteins enter the cytoplasm of cells injured with arsenic[8].

Further, the finding of plasma proteins as described here, in cells injured by anoxia under circumstances which indicate that they are the result rather than the cause of the injury, necessitates a re-evaluation of the significance previously attached to the presence of certain plasma proteins in a variety of lesions. One of the criteria for the classification of disease as autoimmune has been the demonstration of immune globulins in the lesions[9]. The finding of an abundance of IgA globulin in ischaemic muscle fibres under conditions suggesting that the

globulin could not logically be considered an aetiological factor emphasizes the need for caution in using these criteria to designate a disease as autoimmune. The accumulation of fibrinogen in the renal glomerular cells of Masugi-type nephritis has been suggested as the cause of the observed cell injury[10]. The possibility that the fibrinogen accumulates as a result of the cell injury must be seriously considered.

This work was supported in part by a grant from the U.S. Public Health Service. I thank Clerence Forest, Gayle Roden and Carol Cross for technical assistance, and Robert W. Mowry for help in preparing the manuscript.

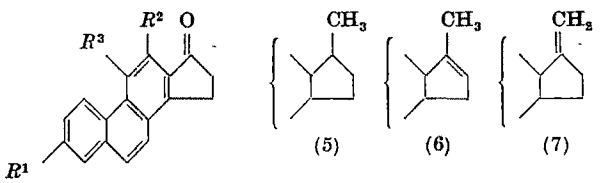
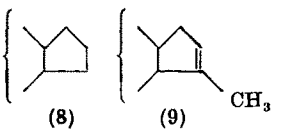
Carcinogenic Derivatives of *Cyclo*penta[a]phenanthrene



ALTHOUGH much is known concerning the relationship between carcinogenic activity and structure in hydrocarbons containing four or more condensed aromatic rings, comparatively little work has been reported on derivatives of 16,17-dihydro-15*H*-*cyclo*penta[*a*]phenanthrene (8) which have the same carbon ring structure as the natural steroid hormones. Butenandt and Dannenberg[1] have shown that of the methyl derivatives of this hydrocarbon, which is itself inactive, only the 7- and 11-monomethyl and 11,12-dimethyl compounds showed any carcinogenic activity, and even then the activity was very weak in skin painting experiments and non-existent by subcutaneous injection. It is noteworthy that 1,2,3,4-tetramethylphenanthrene exhibited activity of this order[2,3]. Later, in an investigation of the nature of the carcinogenic products formed from cholesterol during dehydrogenation with chloranil, Dannenberg[2] found that the *D*-ring unsaturated compounds (9) and (6) both possessed weak activity. Since these compounds were oxidized, by osmium tetroxide, at the *D*-ring double bond rather than at the "phenanthrene" double bond, the former was designated the *K*-region in these hydrocarbons.

With a view to preparing the phenanthrene analogue of 18-noroestrone, a new method for the synthesis of 15,16-dihydro-17-oxo*cyclo*penta[*a*]phenanthrenes was devised[4] in which the ketones (1)–(4) were readily accessible. These compounds were tested for carcinogenic activity together with the hydrocarbons (5)–(7).



T.O. albino mice were randomly bred in these laboratories in a closed colony. They were fed on diet *GR*25 with water *ad libitum*, and were 3 months old at the start of the experiment. Ninety males and the same number of females were divided by a formal randomization process into nine groups each consisting of ten mice of each sex. The dorsal hair was removed from each animal by electric clippers. The chemicals were dissolved in redistilled 'AnalaR' benzene at a concentration of 0·5 per cent. One drop (6 μl.) of each solution was applied to the clipped skin of each mouse of the appropriate group twice a week for 52 weeks. One control group received the solvent (benzene) only, another was clipped but otherwise untreated. During the course of the experiment it was necessary to reclip the animals at regular intervals and when this was done the clipper blades were washed in acetone after clipping each group.

The size, appearance and position of all skin tumours were recorded at fortnightly intervals and those which appeared malignant were removed under ether anaesthesia, for histological examination. The mice which bore them were returned to the experiment. The results are shown in Tables 1 and 2. The histological classification refers to the first tumour removed from each animal only.

Of the hydrocarbons (5), (6), (7), Diel's hydrocarbon (5) was inactive as previously found by several groups of workers[5]. The production of one tumour after a long latent period by the dehydro-derivative (6) was consistent with the weak carcinogenic activity of this compound reported by Dannenberg[2]. In addition, the new exocyclic isomer (7) produced two tumours with similarly long latent periods.

	R^1	R^2	R^3
(1)	H	H	H
(2)	H	H	CH_3
(3)	H	CH_3	H
(4)	OCH_3	H	H

$R^1 = R^2 = R^3 = H$

Table 1. NUMBER OF TUMOURS PRODUCED BY COMPOUNDS UNDER TEST

Compound tested	No. of survivors at: 6 months	12 months	18 months	No. of animals with tumours at the site of application
1	18	9	6	0
2	19	4	1	15
3	18	7	6	0
4	20	15	4	0
5	20	13	7	0
6	19	13	10	1
7	17	11	5	2
Benzene control	17	13	10	0
Clip control	20	18	10	0

Table 2. TYPES OF TUMOURS PRODUCED BY THREE ACTIVE COMPOUNDS

Compounds	Histology	No. of mice with tumour	Latent period range (days)
2	Squamous carcinoma	10	130–305
	Spindle cell sarcoma	2	306–340
	Squamous papilloma	3	240–330
6	Squamous carcinoma	1	482
7	Squamous carcinoma	2	467–576

Marked carcinogenicity was shown by 11-methyl-15,16-dihydro-17-oxo*cyclo*penta[*a*]phenanthrene (2) which produced tumours in the majority of treated animals. The latent periods of these were shorter than those of the hydrocarbons (6) and (7). The carcinogenicity has been confirmed by two further skin painting experiments still in progress. The other ketones (1), (3), (4) were completely inactive, thus indicating the importance of a methyl substituent at the 11-position.

In view of the very weak carcinogenicity of 11-methyl-16,17-dihydro-15*H*-*cyclo*penta[*a*]phenanthrene [the deoxo derivative of (2)] found by Dannenberg, it appears that the presence of a carbonyl group at C-17 has greatly augmented the activity. This is surprising, because Shear *et al.*[6] found that the 15-oxo derivative of methylcholanthrene was much less carcinogenic than methylcholanthrene itself.

Further work with these and a number of related compounds is in progress and will be reported later. We thank

Dr. G. F. Marrian and Dr. S. Young for advice, and Mr. T. S. Bhatt and Mr. J. A. Smith for technical assistance.

RADIOBIOLOGY

Production of Carrier-free Iron-52 for Medical Use

IRON-52 has been used in this hospital since 1957[1]. As it is a positron emitter, coincidence counting techniques are used to investigate the distribution of erythropoietic tissue in patients with a variety of haematological disorders. In addition, its short half-life (8·2 h) has made it possible to investigate the effect of cytotoxic agents and ionizing radiation on marrow function by serial measurements at various intervals. It has also proved of value in the study of the kinetics of iron in animals. In some of the disorders studied, the iron-binding capacity of the serum may be low, and iron-52 of the highest specific activity is therefore desirable.

A recent paper by Yano and Anger[2] described a method for preparing samples of iron-52 for medical use, based, essentially, on the extraction of iron from a solution in hydrochloric acid of an alpha-bombarded chromium target. We have used a similar approach, but prepare "carrier-free" samples, and have developed the special technique described here to handle the initial stages of the separation, where the activity involved is at its height.

The Medical Research Council cyclotron has an α-beam of only 30 MeV, but targets can be placed inside the "dee-box" where beam currents of up to about 300 μamp are readily available. The targets consist of high-purity chromium, plated (by Fescol Ltd., London) to a thickness of 0·05 mm, over an area approximately 20 cm by 5 cm, on iron-free aluminium backing plates. They are placed at grazing incidence to the beam, which makes them effectively "infinitely thick" chromium targets.

After bombardment for 1 h, the chromium layer is dissolved by clamping the target plate in such a way that it becomes the base of a 'Perspex' etching chamber, into which is pumped 5 ml. of concentrated hydrochloric acid, microanalytical grade. The dissolution is completed within about 5 min, and carrier-free iron-52 is then extracted from the resulting solution, adjusted to about 8 M hydrochloric acid, into di-isopropyl ether. These steps are carried out by remote control inside a 4-in. lead-shielded enclosure.

The central feature of the apparatus used is the proportioning pump (supplied by Technicon Instruments Co, Ltd.) which transports the various aqueous and organic solutions as shown in the flow diagram (Fig. 1). Mixing of organic and aqueous phases takes place in a spiral of glass tubing, 125 cm long × 0·2 cm internal diameter, packed with glass beads of about 1·5 mm diameter, and is aided by the entrainment of air bubbles in the stream of liquid. The efficiency of this extraction procedure has been determined by tracer experiments, using iron-59, to be better than 85 per cent. The phases are afterwards separated in an open-ended U-tube, the organic phase being collected from the top of one limb and the aqueous from the top of the other; air bubbles, of course, escape at this point.

Note that the ethereal solution does not pass through the pump but is collected by displacement of air from the receiving vessel. This is because the carrier-free isotope is retained on the walls of the flexible pumping tubing (even fluorinated-silicone rubber tubing has been found unsatisfactory for this purpose), although it can be transported without loss through polythene tubing. Because of its rigidity, polythene tubing cannot be used in the proportioning pump itself.

When carrier iron can be tolerated in the final sample and, say, 100 μg are added at the start of the separation, further extraction steps can be carried out using the proportioning pump, as shown in Fig. 2. We normally take great care to exclude carrier iron, and all steps beyond the first extraction into di-isopropyl ether, together with the preparation of the iron-52 ferric citrate samples for clinical use, are carried out in more conventional apparatus by methods similar to those described by Yano and Anger. However, the use of the proportioning pump in the target etching and first extraction steps reduces the level of the activity which has afterwards to be handled from the equivalent of about 100 mc. of radium to about 150 μc. of iron-52.

After chemical separation we find that the yield of iron-52, corrected to the end of the bombardment, averages about 50 μc./100 μamp/h. Some iron-55, an X-ray emitting isotope with a half-life of 2·6 years, is also made during bombardment, and, in order to keep the iron-55/iron-52 ratio in the administered sample down to a minimum, the time elapsing between bombardment and clinical use is kept as short as possible: in fact, not more than 3 h are required for the chemical processing.

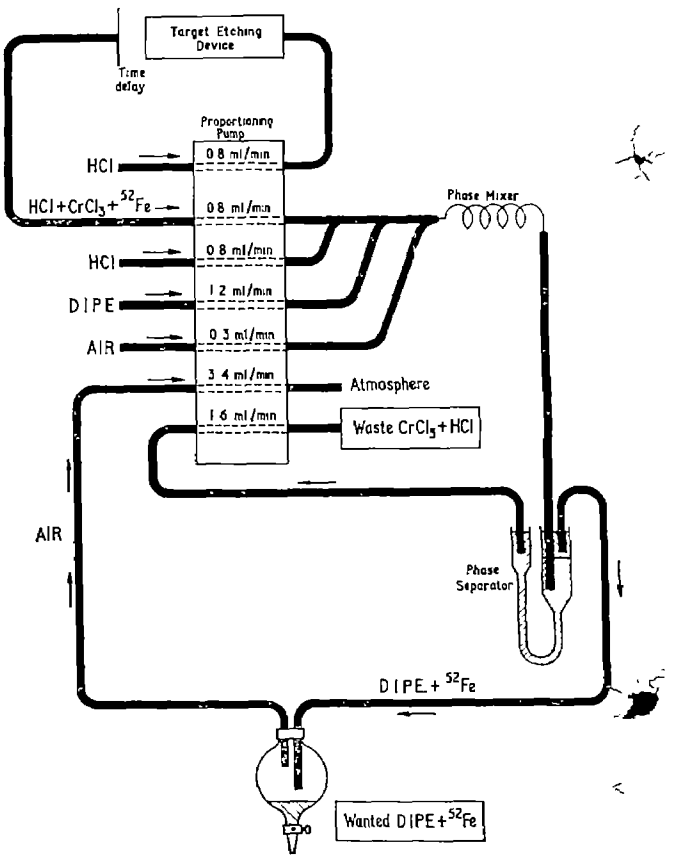

Fig 1. Flow diagram for the initial separation of carrier-free iron-52 from chromium targets

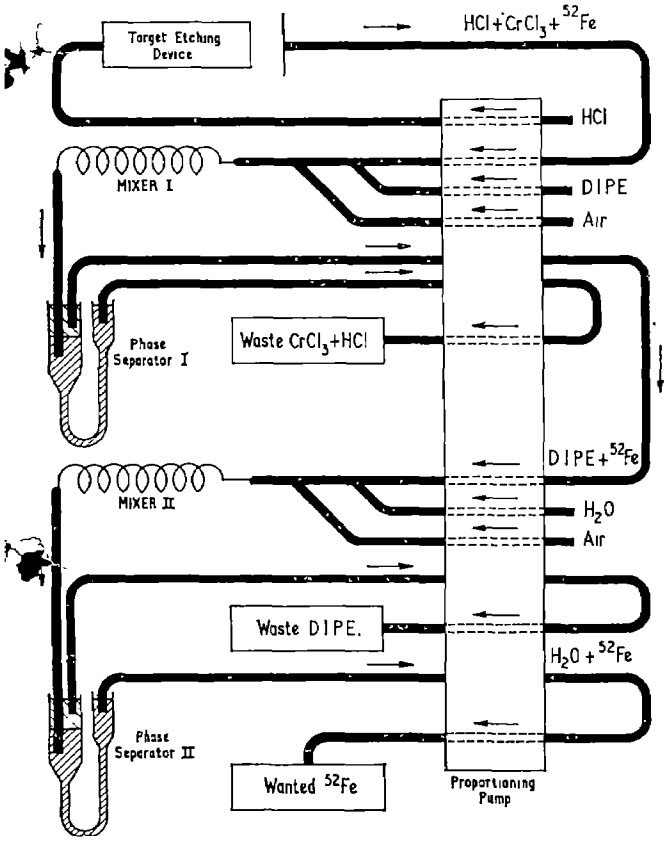

Fig 2. Flow diagram for the initial separation of iron-52 with carrier from chromium targets

The purity of a small fraction of the final product is checked while the main part is being sterilized by autoclaving; γ-spectrometry ensures that the sample is free from 5·7-d manganese-52 and other γ-emitting contamination (we find it unnecessary to add manganese carrier to achieve this), and microanalysis by the ring-oven technique shows that the content of inactive chromium, aluminium and iron is below the limit of detection —which for each element is equivalent to less than 5 μg in an entire 5-ml. sample.

In vitro Distribution of Americium in Human Blood Serum Proteins

The distribution of plutonium in blood serum proteins has been investigated previously[1–3]. Normally, americium-241 is present in plutonium samples, and is produced there by the β-decay of plutonium-241. Accordingly it is of interest to compare the distribution of americium in blood serum proteins with that of plutonium.

Human blood was allowed to clot at room temperature for 2 h, stood overnight at 4° C, and then centrifuged. The supernate was dialysed for 16 h at 5°–8° C in Visking dialysis tubing against several changes of 0·1 M 2-amino 2-hydroxymethylpropane 1:3 diol (*tris*) and its hydrochloride in 1 M sodium chloride at *p*H 8·0. 10–20 μl. of a mixture of americium-241 and plutonium in 0·3 M nitric acid were added to about 6 ml. of the dialysed serum. The mixture of isotopes and serum was stored at about 8° C for 1 h and then resolved by gel-filtration through a column (93 cm × 2·5 cm) of 'Sephadex *G*-200' (ref. 4). The plutonium distribution in the various protein eluates was determined by measuring the delayed neutron emission following neutron irradiation[5]. The fission cross-section and delayed neutron yield for americium are much lower than the values for plutonium, thus the delayed neutron emission was specific for the plutonium present. The amount of americium-241 in equal portions was measured by γ-spectrometry. Plutonium and americium were found predominantly in the fraction containing albumin and transferrin. This fraction was further resolved by ion-exchange chromatography using diethylaminoethyl 'Sephadex *A*-50' (ref. 4).

The distribution of americium and plutonium in the 'Sephadex *G*-200' resolution of the proteins was very similar. However, in the ion-exchange stage, attempts to resolve the americium distribution failed to identify eluate americium radioactivity with any particular protein fraction. The difference between americium and plutonium in their distribution between albumin and transferrin is illustrated in Fig. 1. Since the methods of measurement of the plutonium and americium activities are quite different, no significance is attached to the relative peak heights. Two further experiments on the americium distribution in serum proteins showed similar qualitative behaviour but dissimilar quantitative behaviour. When americium species alone are subjected to elution through the ion-exchanger under conditions otherwise identical with the experiment depicted in Fig. 1, the americium elutes at a stage greater than the elution volume corresponding to the protein elution volume. This indicates that the americium in serum is chemically bound to protein—at least initially. It seems likely that americium forms protein complexes weaker than those of plutonium, and they do not survive the ion-exchange processes.

Filtration through 'Sephadex *G*-50' has been used for studies of the binding between proteins and iron[6]. Similar experiments were carried out to measure the distribution of americium and of plutonium between the protein fraction and the low molecular weight non-protein fraction. About 90–95 per cent of the americium and the plutonium were distributed in the protein fraction, and the remainder in the low molecular weight fraction. Experiments performed with added citrate ions produced the inverse effect; practically no actinide was found in the protein portions.

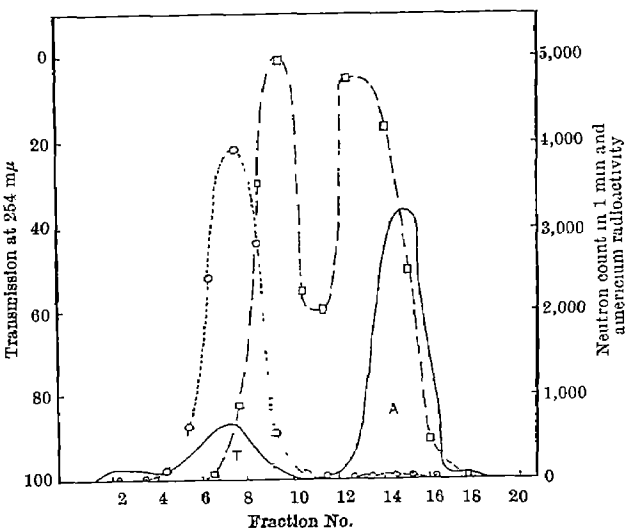

Fig 1. Resolution of the transferrin/albumin fraction by chromatography on DEAE-'Sephadex *A*-50'. Elution was started with 0 1 M *tris* and its hydrochloride in 0 1 M sodium chloride, followed by a gradient of 0 1 M–2 0 M sodium chloride in 0·1 M *tris*-hydrochloric acid. ——, Optical transmission; · · · ○ · · ·, radioactivity due to plutonium; — — □ — —, radioactivity due to americium-241; *T*, transferrin; *A*, albumin

From the point of view of physico-chemical equilibria, citrate appears to be very effective in removing americium and plutonium from their serum protein complexes.

Further investigations are being carried out to identify more precisely the americium complexes present in blood serum.

Increased Proliferation of Transplanted Mouse Bone Marrow Cells by Pre-irradiation of the Recipient

THE transplantation of bone marrow cells from normal donor animals into heavily irradiated recipients rapidly restores haemopoiesis to normal. For example, we find that erythropoiesis in a heavily irradiated mouse is restored to normal within 7 days of the injection of 4×10^6 bone marrow cells, although this is only 1 per cent of the normal number of bone marrow cells in a mouse. This very considerable capacity for restoration of erythropoiesis suggests that before transplantation the progenitor cells responsible for recovery of erythropoiesis are proliferating slowly, either all the cells dividing slowly or a small proportion of them dividing more rapidly. This has recently been confirmed by Becker *et al.*[1] by incubating bone marrow cells *in vitro* with tritiated thymidine of sufficient activity so that all the cells synthesizing DNA and incorporating the isotope are killed by the subsequent β-irradiation. For bone marrow cells from normal animals, they found less than 10 per cent of the cells in DNA synthesis, while for rapidly dividing cells (6 days after 900 r. whole-body irradiation with bone marrow transplantation) 65 per cent were in DNA synthesis.

Because of the low proliferation rate of the progenitor cells in normal animals the stimulus for proliferation in the recipient animals will be low until some time after whole-body irradiation. It was therefore decided to determine whether pre-irradiation of the recipient animals would lead to the earlier stimulation of transplanted bone marrow cells.

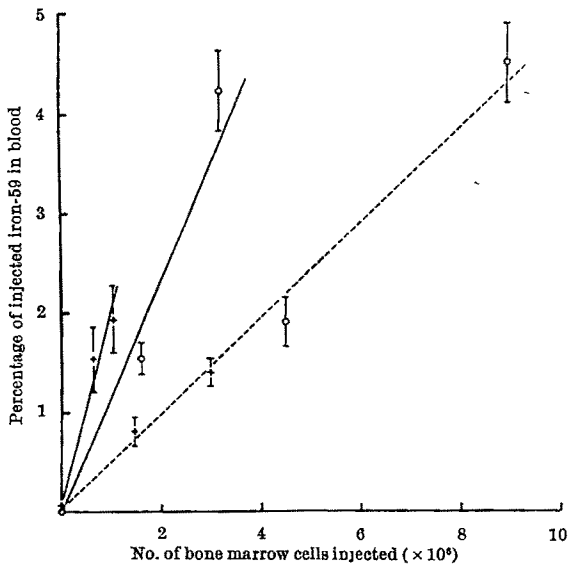

Fig. 1. Incorporation of iron-59 into red blood cells as a function of the number of bone marrow cells injected. ——, Bone marrow cells from unirradiated animals; – – – –, bone marrow cells from mice given 160 r whole-body irradiation 6 days previously, transplanted into: O, mice given 650 r. whole-body irradiation; and +, mice given 650 r. whole-body irradiation and 160 r. 6 days previously

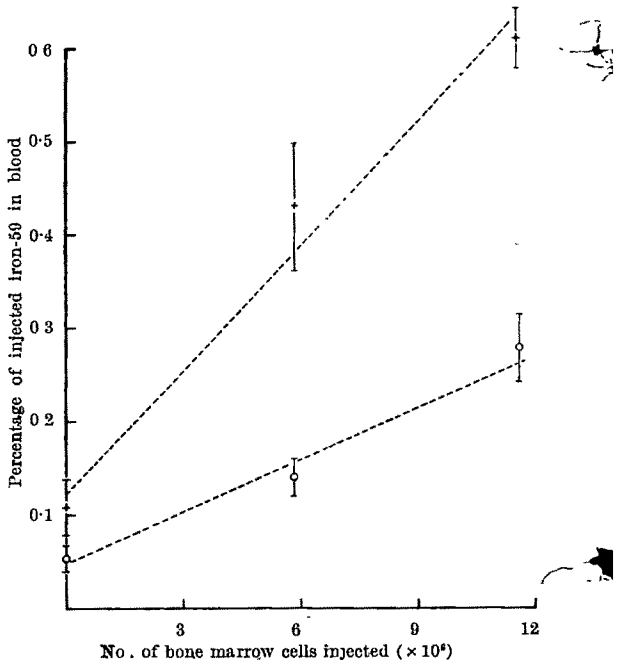

Fig. 2. Incorporation of iron-59 into red blood cells as a function of the number of injected bone marrow cells taken from donor animals directly after 160 r. whole-body irradiation. O, Mice given 650 r. whole-body irradiation; +, mice given 650 r whole-body irradiation and 160 r. 6 days previously

Bone marrow cells from unirradiated *C57BL* mice were injected into groups of recipient mice that had received 650 r. whole-body X-irradiation a few hours previously —some of these animals having also received 160 r. whole-body irradiation 6 days earlier. Five days after the 650 r. and transplantation, iron-59 was injected and 2 days later the activity of this isotope in the circulation was determined according to the method of Blackett *et al.*[2], to give a measure of the incorporation into the red blood cell precursors. Fig. 1 shows that to give the same incorporation of iron-59 only about half the number of normal bone marrow cells is required in the pre-irradiated animals than in the mice not pre-irradiated (change in slope significant at $P = 0{\cdot}05$ level).

To determine whether this increased proliferation also occurred with bone marrow cells from irradiated donors, cells were transplanted from animals that had received 160 r. 6 days previously (Fig. 1). No increased proliferation in the pre-irradiated recipients was observed. This absence of increased proliferation is not due to an inhibition of the effect by irradiation, since an increased response is observed if bone marrow cells are taken from animals directly after 160 r. irradiation, Fig. 2 (change in slope significant at $P = 0{\cdot}05$ level).

At present it is not known at what stage of erythropoiesis this increased proliferation occurs; whether it is an effect on the most primitive progenitor cell, or on the recognizable differentiating red blood cell precursors, or simply due to an increased transplantation efficiency of the cells.

It is suggested that these observations may be explained by the state of proliferation of the transplanted cells and the physiological state of the recipient at the time of the cell injection. The level of cell proliferation will be low in bone marrow cells taken from normal animals or from animals directly after 160 r. whole-body irradiation. On transplantation, the cells will start to proliferate earlier in the pre-irradiated recipients because they are still recovering from the 160 r. pre-irradiation, and so

already have a greater than normal stimulus for proliferation. The absence of any increased proliferation of bone marrow cells if they are taken from donor animals given 160 r. 6 days previously would be explained by the fact that these cells are already actively proliferating and continue to do so irrespective of whether the recipient animals have been pre-irradiated. The conclusion that cells responsible for transplantation are actively proliferating 6 days after 160 r. is based on the fact that the incorporation of iron-59 per 10^6 cells has not regained normal values at this time (Fig. 1). At later time intervals after 160 r., when recovery of the bone marrow is complete and cell division is again at the normal low level, it would be expected that the bone marrow cells would again show increased proliferation in pre-irradiated recipients.

Further studies are being undertaken to investigate this effect in more detail and to determine whether it provides a means for improving the grafting of bone marrow cells.

RADIATION CHEMISTRY

A Correlation between Electron Affinity and Protection in the Radiation Chemistry of Hydrocarbons

It has been known for some time[1,2] that the presence of aromatic compounds in solutions of saturated hydrocarbons can protect the solvent against radiation-induced decomposition. Since the aromatic solute plays a mainly 'non-sacrificial' part, scavenging of chemical intermediates (atoms, radicals, or ions) cannot be the major process in the observed protection[3–5]. Rather, it has been proposed[2] that some sort of efficient energy transfer from the solvent, which absorbs the primary radiation, to the solute must operate. The recent observations of thermal electrons produced in relatively high yield in the radiolysis of aliphatic hydrocarbons in the glassy[6] and liquid[7] states indicated that it would be interesting to investigate whether there is a link between radiation protection by aromatic compounds and their electron affinity as it is known that these compounds are electron acceptors.

Lovelock *et al.*[8] have measured in the gas phase the electron absorption coefficients relative to chlorobenzene, χ, of a number of aromatic hydrocarbons. These electron absorption coefficients are related to the relative electron affinities, EA_{PhCl} by the expression $EA_{PhCl} = \log \chi$. Dilute solutions (5×10^{-3} M) of several of these aromatic compounds in *cyclo*hexane were deaerated and irradiated with cobalt-60 γ-rays (total dose $6{\cdot}0 \times 10^{18}$ eV ml.$^{-1}$), and the hydrogen yields, $G(H_2)$, were measured; the yield from pure *cyclo*hexane, $G(H_2)_0$, was 5·56 molecules per 100 eV. Because hydrogen is the major product of the radiolysis of *cyclo*hexane the $\Delta G(H_2)$ values, where $\Delta G(H_2) = 5{\cdot}56 - G(H_2)$, are a measure of the protective effect. In Fig. 1, $\Delta G(H_2)$ values have been plotted against the electron affinities, EA_{PhCl}. It can be seen that there is a satisfactory linear correlation between the protective effect of the aromatic compounds and their electron affinities. Only in the case of the halobenzenes is there a significant deviation.

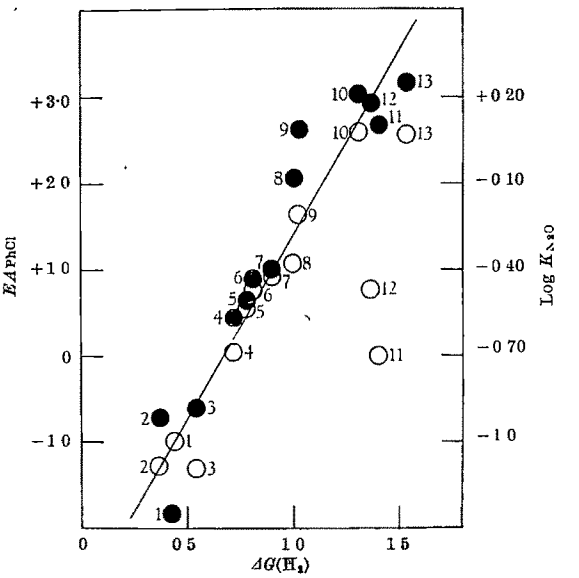

Fig. 1 Electron affinity, EA_{PhCl}, versus $\Delta G(H_2)$, open circles, log K_{N_2O} versus $\Delta G(H_2)$, closed circles (1) Aniline, (2) benzyl alcohol, (3) phenanthrene, (4) *cis*-stilbene; (5) *trans*-stilbene; (6) pyrene; (7) azobenzene, (8) anthracene, (9) benzaldehyde; (10) nitrobenzene; (11) chlorobenzene, (12) bromobenzene, (13) iodobenzene

It has been shown[7] that nitrous oxide scavenges thermal electrons produced in the radiolysis of *cyclo*hexane according to the stoichiometric equation:

$$e^- + N_2O \longrightarrow N_2 + O^- \qquad (1)$$

To test the foregoing contention that the aromatic solutes behave as electron acceptors in the radiolysis of *cyclo*hexane solutions, solutions containing both nitrous oxide and an aromatic compound were irradiated. The presence of the aromatic compound was found to depress the nitrogen yield, indicating competition for thermal electrons. From the depression in the nitrogen yield the relative electron affinities of the aromatic compounds, EA_{N_2O}, were calculated using the relation $EA_{N_2O} = \log K_{N_2O}$, where K_{N_2O} is the relative rate constant for the electron-capture process. The electron affinities obtained by this method have also been plotted against the $\Delta G(H_2)$ values in Fig. 1. Again, a satisfactory linear correlation exists.

From the foregoing it is evident that thermal electrons are a precursor of a significant part of the hydrogen yield in the radiolysis of *cyclo*hexane (reactions 2 and 3).

$$RH_2 \rightsquigarrow RH_2^+ + e^- \qquad (2)$$

$$e^- + RH_2^+ \longrightarrow R\dot{H} + H\cdot \qquad (3a)$$

and/or:

$$e^- + RH_2^+ \longrightarrow R + H_2 \qquad (3b)$$

Aromatic hydrocarbons present in low concentration provide an alternate path to the hydrogen-forming reaction of the thermal electrons (reaction 3) by a non-dissociative electron-capture process giving an aromatic anion (reaction 4). In an aliphatic hydrocarbon solvent these aromatic anions would be expected to be relatively unreactive and have a long life, possibly reacting finally with the primary cations, RH_2^+, of the solvent (reaction 5):

$$e^- + ArX \rightleftharpoons ArX^- \qquad (4)$$

$$ArX^- + RH_2^+ \longrightarrow ArX + RH_2 \qquad (5)$$

Thus, by the intermediacy of the aromatic solute a route is provided for the return of the electron formed in the primary process (2) to a solvent cation, RH_2^+, resulting in no net chemical change in the system.

Of the aromatic solutes investigated, only the halobenzenes are capable of dissociative electron capture (reaction 6) in addition to the non-dissociative process (reaction 4).

$$e^- + ArX \longrightarrow Ar + X^- \qquad (6)$$

Since the breaking of the Ar—X bond is very fast (the order of a molecular vibration, $\sim 10^{-13}$ sec) it would occur before the back reaction of the equilibrium (4). The observed deviation of the halobenzenes from the linear $\Delta G(H_a)$ versus EA_{PhCl} plot would indicate that the dissociation process (reaction 6) is more important in the liquid phase than under the gas-phase conditions[8] where the EA_{PhCl} values were obtained.

Ultra-violet Absorption Spectrum of Thymine in Ice

WANG[1-3] has found that the production of photodimers is much greater when frozen aqueous solutions of thymine are irradiated with ultra-violet light than when liquid solutions of thymine are similarly irradiated. Adding alcohol to the solution before freezing or using thymidine, thymidylic acid, or uracil compounds instead of thymine all markedly reduce the formation of photodimer. He believes that the dimer formation in ice is facilitated by aggregation of the molecules. We have measured the absorption spectrum of various frozen solutions and have thus been able to obtain direct evidence of aggregation.

Samples were frozen on to a quartz plate to give a specimen about 1 mm thick and then immersed in liquid nitrogen in a quartz Dewar flask. The samples used were either pure water or an aqueous solution at a concentration of about 1 mg/ml. The apparent absorption of the pure ice was subtracted from that of each frozen solution. The absorption spectrum was measured with a Cary 14 spectrophotometer and a 2-in. diameter photo-multiplier placed 2 in. from the sample (model 1462 light scattering attachment). This apparatus detects a large fraction of the forward scattered light in addition to the transmitted light and thus more nearly gives an accurate absorption spectrum.

The absorption of thymine in ice is shown as the solid line in Fig. 1. A room temperature aqueous spectrum of

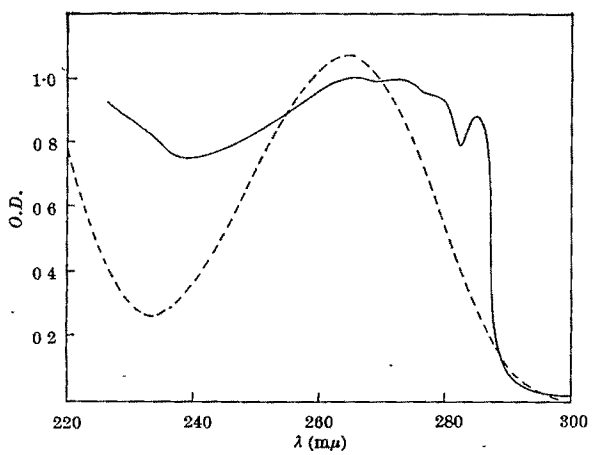

Fig. 1. Ultra-violet absorption spectrum of thymine frozen in ice at liquid nitrogen temperature (solid line) compared with a sample in liquid aqueous solution (dashed line)

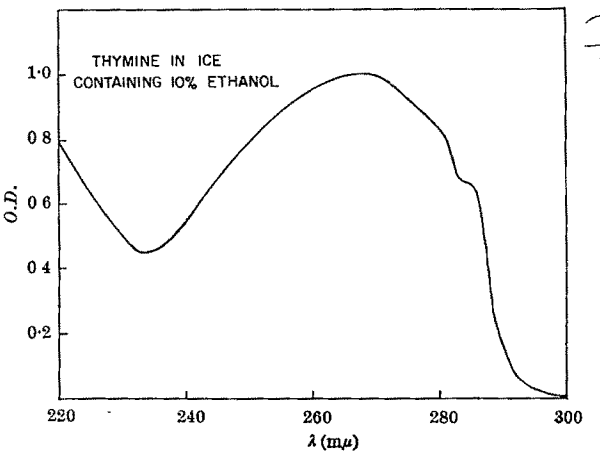

Fig. 2. Spectrum of thymine frozen in a 10 per cent (v/v) aqueous ethanol solution

thymine is also shown for comparison. The change in absorption is quite pronounced. In a frozen 10 per cent (v/v) solution of ethanol (Fig. 2) the thymine spectrum is more nearly like that in the liquid solution. The spectra of frozen solutions of thymidylic acid (5′), uracil, uridine and uridylic acid (5′) were also measured. Although they all gave broadened spectra in the frozen solutions relative to their liquid solution spectra, none showed the striking differences found in thymine.

The spectrum of the thymine in ice at liquid nitrogen temperature is essentially identical to that found by Sinsheimer *et al.*[4] for dry, sublimed films of thymine at this temperature. The four maxima seen in the ice spectrum agree with those in the dry film to ± 1 mμ. This is strong evidence that aggregates of thymine occur in the ice similar to those present in the sublimed film. Furthermore, the fact that alcohol partially restores the liquid solution spectrum strengthens the conclusion that the frozen solution spectrum indicates interaction between thymine molecules. Apparently, for thymine in ethanol or for thymidylic acid, uracil, uridine and uridylic acid, the solute–solute attraction is less (or the solute–solvent repulsion is less) than for thymine in water.

These conclusions are in accordance with Wang's photochemical experiments and his interpretation of them in terms of aggregation. However, the spectral evidence is a more direct measure of this aggregation.

PHYSIOLOGY

Heparin-induced Hypocalcaemia in Rabbits

IT has been reported[1] that heparin contains certain mineral substances of the alkaline earth series, among them calcium. The amounts of these minerals vary with the batch of heparin and the quantities of these impurities are sufficient to cause error in the analysis of plasma calcium, barium and strontium if heparin is added *in vitro* to blood samples. We have found a much more serious

source of error in the estimation of plasma calcium when heparin is injected intravenously into rabbits.

Two groups of animals were used. In one group, thirty rabbits were anaesthetized with 25 per cent urethane at a rate of 6 ml./kg body wt Blood samples were removed via a jugular catheter. In the other group, forty rabbits were maintained conscious in a rabbit box, blood samples being collected from an ear vein. In both groups of animals 25 mg of heparin (Boots or Evans Medical Ltd.), dissolved in 5 ml. of physiological saline, was injected intravenously. Estimation of plasma calcium was carried out by titrating against EDTA with murexide as an indicator at a *p*H of 12, using an EEL titrator. Plasma samples were prepared by collecting blood into centrifuge tubes in ice and centrifuging at 1,500*g* in a refrigerated centrifuge.

In both groups of animals we found that the estimated plasma calcium fell rapidly when the samples were stored at 20° or 37° C, but not at 0° C (Fig. 1) (55 experiments out of 70). If heparin is added to blood after removal from the animal, no such fall occurs.

Fig. 2 indicates that the maximum rate of fall of plasma calcium occurs very rapidly after injection of heparin. However, 3 h after injection, while blood is still uncoagulable, the fall in plasma calcium on storage is very small. In this experiment, plasma calcium was determined within 20 min of sampling, and then determined again 24 h later, the samples being stored at room temperature (18–22° C).

In those samples which show the greatest fall, a precipitate forms which is considerably more dense than plasma.

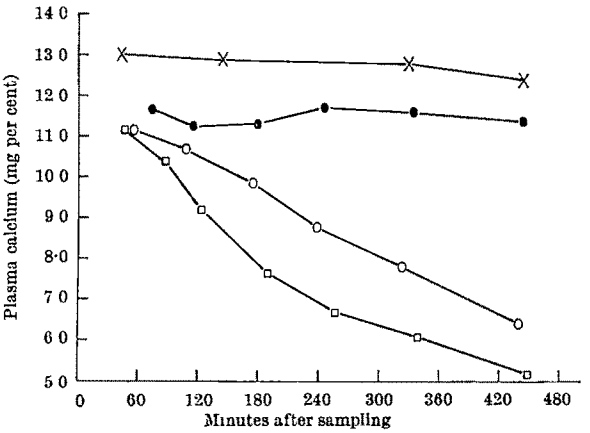

Fig. 1. The effect of temperature on the fall of plasma calcium *in vitro*. ×, Pre-heparin sample with heparin added *in vitro*, incubated at 37° C, ●, post-heparin plasma incubated at 0° C; ○, post-heparin plasma incubated at 20° C; □, post-heparin plasma incubated at 37° C. Each line represents the estimated plasma calcium from a single sample at a particular temperature, analysed at intervals

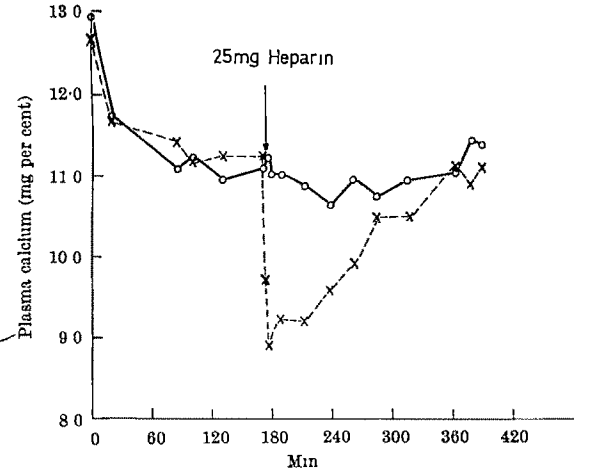

Fig. 2. Effect of intravenous heparin on plasma calcium over 24 h (rabbit). ○, Plasma calcium analysed 20 min after withdrawing the samples at different periods after the beginning of the experiment, ×, the same samples analysed 24 h later

Examination of this precipitate indicated that it is poorly soluble in saline and fat solvents, chloroform dissolving more than ether. Acid hydrolysis of the precipitate with boiling 8 N hydrochloric acid changes the nature of the precipitate so that it is now soluble in fat solvents. Analysis of this acid extract showed that calcium was now present, the ratio of calcium to total precipitate being 1·5 : 34 w/w.

The observation that heparin, injected intravenously, appears to cause an *in vitro* fall in plasma calcium on subsequent sampling of blood and storage, while *in vitro* addition of heparin to blood does not produce this phenomenon, suggests that the injection of heparin causes the release of some factor from the vascular bed. This factor subsequently appears to cause the build-up in the blood sample of a substance which can combine with calcium. We considered that the phenomenon is related to the release of lipoprotein lipase which follows the injection of heparin[2]. This releases free fatty acids from lipoproteins including chylomicra. In the animal these released free fatty acids are carried on proteins for eventual utilization by the animal's tissues. In plasma samples the enzyme will still be active, but the free fatty acids can no longer be cleared from plasma, and so accumulate to saturate plasma proteins. As this occurs the excess free fatty acids will form insoluble calcium soaps, which appear to be no longer capable of estimation by EDTA.

We have examined cats and rats to see if other species show the same phenomenon. We have been unable to detect it in cats, except in special circumstances involving the addition of chyle to plasma samples after heparin injection. We have found it in rats but less readily than in rabbits. Examination of the literature revealed that Heidland *et al.*[3] reported a heparin-induced hypocalcaemia in dogs. They attributed this to formation of a heparin–calcium complex. Other workers, Spitzer and Spitzer[4], French *et al.*[5] and Brown *et al.*[6], all mention the appearance of a precipitate when studying the clearing of chylomicra from plasma by heparin released lipoprotein lipase. However, they do not report having carried out calcium analyses on their samples as they were concerned principally with the action of lipoprotein lipase on the clearing of chylomicra.

An Anovulatory Bilateral Hermaphroditic Rat

Any discussion of mechanisms in mammalian sex differentiation must consider two classes of chemical mediators: embryonic inductors and androgenic steroid hormones. The inductors, the chemical nature of which is unknown, play a vital part in differentiating the gonad and probably the secondary sex ducts[1], while the steroids are credited with influencing behaviour and brain–pituitary functions[2]. However, the definitive experiment obligating androgen as the organizer of the male type brain–pituitary axis has not been carried out. This communication describes a bilateral hermaphrodite occurring in Nature, which casts doubt on the indispensability of androgen for determining a male type of hypophysial-hypothalamic axis.

During a routine laparotomy of 30-day-old male Holtzman strain rats, an animal was found which had a scrotal testis of about normal size on the right side and a follicular

ovary on the left. A well-developed oviduct and uterus was present on the left along with a small rudimentary nephric (Wolffian) duct. On the right side a thread-like uterus was closely attached to an apparently normal deferens duct. Two small seminal vesicles were attached to the utero-vaginal rudiment, which had no external opening.

At 60 days of age the testis was removed and serially sectioned. Histological examination disclosed a small lateral area of ovarian tissue containing six large follicles, as well as a few smaller ones. The seminal tubules contained abundant sustentacular (Sertoli) cells, but very few germ cells. Interstitial cells were large and numerous.

Sixty days after removal of the testis (total age 120 days) the animal was killed. The body weight was 255 g, which is the normal weight of a female of this strain at 4 months of age. The reproductive tract was dissected *in toto*, fixed in Bouin's solution, and sectioned in paraffin. The adrenals and pituitary were large, weighing 74·7 mg and 20·0 mg respectively.

The ovary did not appear to undergo significant compensatory hypertrophy during the 60 days following removal of the testis. The follicles were of varying size, several being fully mature, but no corpora lutea were found. A few small seminal tubules surrounded by several interstitial cells were seen in the region of the hilus as well as in a portion of the cortex.

The uterus on the left side was filled with fluid and lined by tall columnar epithelium. The left uterus was atrophic. The utero-vaginal rudiment showed oestrogenic stimulation in the form of a heavily cornified epithelium. Small prostatic buds, with atrophic acinar epithelial linings, were found attached to the wall of the rudiment. The epithelium of the small seminal vesicles was also unstimulated.

While the testis was capable of causing differentiation of the nephric duct into a ductus deferens on both sides, it did not cause regression of the oviducts (Müllerian ducts). Furthermore, androgen production was insufficient to cause complete differentiation of prostatic lobes or to produce functional prostatic or seminal vesicle epithelium. In spite of this apparent lack of androgen, the hypothalamic-pituitary function resembled that of the androgenized female[3], that is, follicles in the ovary were well developed as were those in the small ovarian remnant attached to the testis, but failed to undergo luteinization. The well-developed theca and interstitial cells further contribute to the interpretation that gonadotropins were present, but no cyclic surge of luteinizing hormone, necessary for ovulation and formation of corpora lutea, occurred.

The original experiments involving alteration of pituitary function in female rats used testicular implants[4]. More recently, testosterone propionate has completely replaced this method of 'masculinizing' females[2] and is thought to duplicate the action of the testis. However, the lack of development of secondary sex organs seen in the above-described rat suggests a very low level of androgen during the so-called critical period for sex differentiation of the brain–pituitary system. Hollander *et al.*[5] reported that in mouse intersexes, in which the testes develop poorly, ovulation or follicular luteinization was always lacking. Therefore, the possibility that an embryonic inductor, responsible for testicular differentiation, also influences the brain–pituitary axis cannot be overlooked. Certainly, such a concept appears worthy of further examination.

Disappearance of Iodine-131-labelled Human Growth Hormone from the Plasma of Diabetic, non-Diabetic and Acromegalic Subjects

THE disappearance of iodine-131-labelled human growth hormone (HGH) from plasma has been investigated as part of a study designed to measure the secretion rate of the hormone. This was undertaken because plasma levels alone may not be indicative of the secretion rate of the hormone. Twenty-six adult patients consented to the procedure. Seventeen were diabetics (six required insulin and seven had never been given insulin). Eight were acromegalic (four with diabetes), and five were normal. Thyroidal uptake of radio-iodine was blocked with Lugol's iodine. HGH prepared by the Raben[1] technique and purified[2] was iodinated by the method of Hunter and Greenwood[3]. Material of specific activity 30–150 μc./μg was used. It was diluted at once and stored in a diluent containing 0·3 per cent human serum albumin. Each batch was used within 14 days of preparation. The subjects were studied resting, fasting and after 12 h without food or drugs. Care was taken to ensure that where possible each member of the various groups of patients was studied with a different batch of ^{131}I-HGH, and this meant that each batch was used in several types of patients. A weighed dose of 2–5 μc. was given intravenously at about 9 a.m. Blood samples were collected at intervals during the next 2–4 h, cooled, and the plasma radioactivity counted in a well-type scintillation counter to give >95 per cent accuracy. The plasma proteins were then precipitated with cold 20 per cent trichloroacetic acid (TCA) and the supernatant counted. The protein-bound ^{131}I could then be calculated and was expressed as a percentage of the dose injected and plotted semi-logarithmically against time. In each of the five normals a disappearance curve similar to Fig. 1*A* was found. Equilibrium was reached in 10 min and a straight-line exponential curve thereafter gave half-times of from 23 to 45 min (see Fig. 2). All seven non-insulin-requiring diabetics gave curves similar to Fig. 1*B*, reaching equilibrium by 20–60 min and giving final straight-line curves with half-times of from 60 to 185 min (see Fig. 2).

All eight acromegalics showed a similar slow final phase in their disappearance curves (see Fig. 2). The six insulin-requiring diabetics gave curves the final straight-line portions of which gave half-times of from 23 to 185 min. Fractional turnover rates were calculated from these curves by the method of Matthews[4] (fractional turnover rate = fraction of intravascular HGH metabolized per minute). Table 1 shows that the fractional turnover rates follow the half-times approximately, being 0·03–0·06 in the normals, 0·01–0·028 in the diabetics not requiring insulin and 0·015–0·05 in those usually on insulin. The

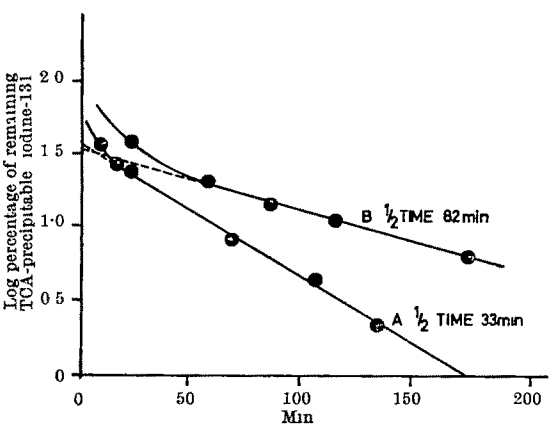

Fig. 1 Plasma disappearance curves of iodine-131-labelled human growth hormone in man. Protein-bound iodine-131 is plotted semi-logarithmically with time. *A*, Curve in normal subject W. R.; *B* curve in diabetic subject J. S

Table 1. RANGE OF THE CALCULATED FRACTIONAL TURNOVER RATES (F.T.R. = FRACTION OF INTRA-VASCULAR HGH REMOVED PER MINUTE) WITH THE MEAN AND THE STANDARD DEVIATION OF EACH GROUP

Group	Non-diabetics (5)	Diabetics on insulin (6)	Diabetics not on insulin (7)	Acromegalics + diabetes (4)	Acromegalics − diabetes (4)
F.T.R.	0·0322–0·0604 Mean = 0·0453 *S.D.* ± 0·01	0·0184–0·0474 Mean = 0·0346 *S.D.* ± 0·0115	0·007–0·0261 Mean = 0·0178 *S.D.* ± 0·007	0·009–0·019 Mean = 0·0157 *S.D* ± 0·0062	0·0133–0·0233 Mean = 0·0133 *S.D.* ± 0·0078

The non-diabetic values are significantly different from those of non-insulin requiring diabetics ($P < 0·01$) and from both groups of acromegalics ($0·001 > P < 0·01$), but not from the values for diabetics requiring insulin ($0·2 < P > 0·1$).

Table 2. BLOOD GLUCOSE-LEVELS AND FRACTIONAL TURNOVER RATES PER MINUTE OF HGH IN DIABETICS REQUIRING INSULIN

Blood glucose	50	116	270	336	380	554	660
Fractional turnover rate	0·0187	0·0211	0·038	0·0184	0·04	0·0368	0·0474

acromegalics all had fractional turnover rates of less than 0·03. It was noted that in the insulin-requiring diabetics the curves usually gave normal fractional turnover rates when the blood glucose was high (see Table 2), and these values show significant correlation ($r = 0·83$, $0·01 > P < 0·02$).

Laron *et al.*[5], using similar preparations of ^{131}I-HGH in adolescents, recently reported slow disappearance of their material which they suggest might be due to radiation damage to the HGH. In view of the absence of the slow phase in the normal subjects reported here it is believed that this is not the whole explanation in the present investigation. In addition, it was possible to precipitate almost identical amounts of iodine-131 by TCA and by anti-HGH sera from standard solutions and from the plasma of two normal and two diabetic subjects (both early and late in the procedure), so that immunological activity was not lost during the observations. Autoradiograms of electrophoreses in agar gel, of the labelled hormone, after incubation with various plasmas, have not as yet indicated that any differences occur in the 'binding' of the label between diabetics or acromegalics and normals. The patterns obtained from these investigations were similar to those reported by Hadden and Prout[6].

The explanation of the delayed disappearance of ^{131}I-HGH in acromegalics and in diabetics whose blood glucose is not greatly raised is uncertain. It could be accounted for by the presence of a large pool of HGH in the acromegalics—certainly it would be interesting to know if the adolescents studied by Laron *et al.*[5] had high plasma levels of HGH. The apparent correlation between the blood glucose-levels and the fractional turnover rates of HGH in the insulin-dependent diabetics may mean that there is some change in the peripheral uptake of the hormone with alteration of the blood glucose-level; alternatively it may mean that a high HGH turnover is associated with more severe diabetes. The fact that marked differences were found in the disappearance rates of ^{131}I-HGH between the normal and most other subjects in this study means that it may not be possible to deduce secretion rates from the blood-levels alone.

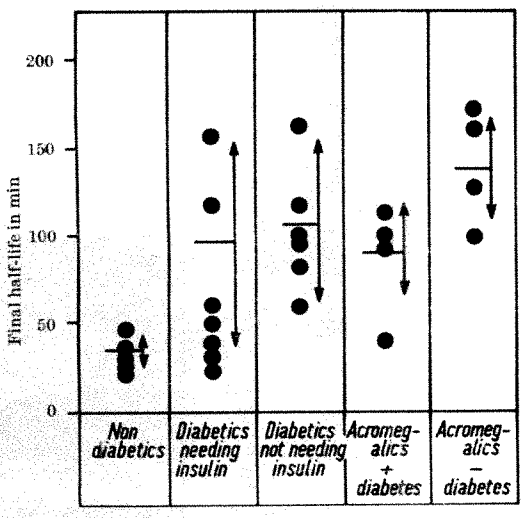

Fig. 2. Half-times of the final straight-line portions of the disappearance curves of ^{131}I-HGH in man. Both groups of diabetics give values significantly different from those of the normals ($P < 0·01$ and $P < 0·05$), as do both groups of acromegalics ($P < 0·01$ and $P < 0·001$). The means are shown by horizontal lines and ± one standard deviation by the arrowed vertical lines

The ^{131}I-HGH was kindly made available to me by Dr. F. C. Greenwood (Imperial Cancer Research Fund), whom I also thank for much helpful discussion. I also thank Dr. Bomford, Dr. Stuart Mason, Dr. Picton Thomas and Dr. A. Bloom for permission to study their patients.

ANATOMY

Synaptic Contacts on Axons in the Cerebral Cortex

AXO-AXONAL contacts have been described in various areas of the nervous system, including the retina[1], spinal cord[2], lateral geniculate nucleus[3], olfactory bulb[4], superior colliculus[5] and the vertical lobes of *Octopus*[6]. In the spinal cord these junctions have been postulated as a basis for presynaptic inhibition[2,7]. In addition, axonal endings of basket cells have been described forming synapses with the initial segment of Purkinje cell axons[8,9], and physiological evidence for inhibition is found in this area[10]. Until now, axo-axonal contacts have not been seen in the cerebral cortex.

During the course of an ultrastructural investigation of the synaptic organization of the prepyriform cortex in the rat, I have seen presynaptic bags contacting unmyelinated axons. The stratified and uniform orientation of neurones in this area[11] of the cerebral cortex permits the investigation of different components of the neuropil with some degree of reliability, in contrast to the neocortex, for example, where the arrangement is much more complex.

The tissue was fixed by perfusion with a buffered paraformaldehyde solution[12] post-fixed in osmium tetroxide[13], and the preparations were double-stained with uranyl and lead solutions for electron microscopy[14]. A Siemens 'Elmiskop 1b' electron microscope was used for studying and photographing the preparations.

In the region immediately beneath the perikaryal or pyramidal layer, myelinated axons of 0·5–1·5μ diameter are seen, some of which are oriented towards the overlying somata. Occasionally an unmyelinated segment several micra long (Fig. 1) can be followed from a myelin sheath towards the overlying cell bodies. Such unmyelinated axons have not as yet been traced in continuity with the cell body so it cannot yet be decided whether they are initial segments of the overlying neurones or terminal unmyelinated portions which end on these neurones. The diameter of these unmyelinated axon segments is between 0·4 and 1·0μ and they contain filaments, mito-

chondria, multivesicular bodies, smooth endoplasmic reticulum, tubular structures and sometimes ribosomes. The occurrence of ribosomes in some of these processes suggests that they may be initial segments. All processes identified as unmyelinated axon segments could be directly traced in the same section, and seen to emerge from myelin sheaths. Such an arrangement has not been associated with dendritic processes in this area. Several of the unmyelinated segments, continuous with a myelinated portion, are seen to have one or more presynaptic bags contacting them (Fig. 1). These presynaptic bags are beween 0·5 and 1·2μ in diameter and contain predominantly ellipsoidal or polymorphic vesicles. The contacts are mostly of Gray's type II (ref. 15), but the "thickenings" are of variable density. The largest number of presynaptic bags counted thus far on any one such segment was five and in this case the unmyelinated segment was about 8μ in length. More commonly, short (1–3μ) segments were seen contacted by one or two presynaptic bags. Also, in the material examined so far, the unmyelinated segments of axons containing contacts have shown no branching.

The origin of the fibres which form the synaptic endings on these unmyelinated axons remains to be determined. Among the sources to be considered are the interneurones or inhibitory cells suggested from physiological investigations[16,17]. It is not known whether these endings produce excitation or inhibition of the axons with which they are in contact. Inhibitory phenomena have been described in the prepyriform cortex[18], and synaptic bags containing ellipsoidal vesicles have recently been shown in an inhibitory area of the cerebellar Purkinje cells[19]. If these endings are inhibitory in function their occurrence on the initial or terminal segment of axons (Fig. 2*A* or *B*) seems a more powerful "stop-valve" arrangement for "outgoing" or "incoming" impulses than, say, axo-somatic contacts.

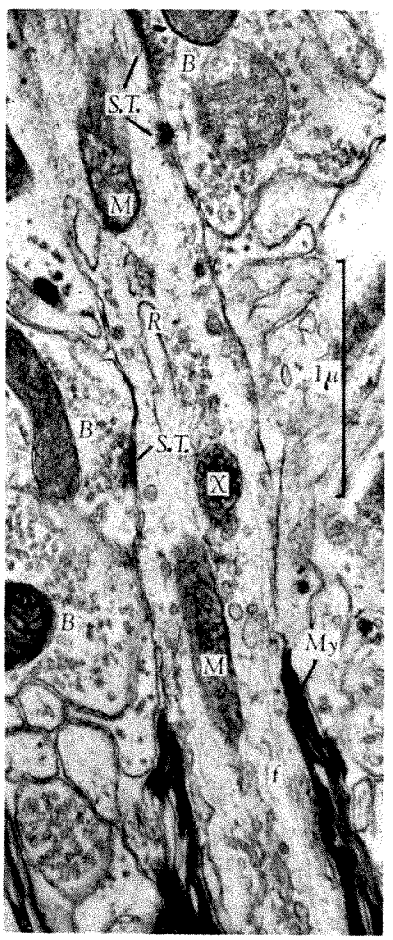

Fig. 1. Electron micrograph of an axon from the deep layer of the prepyriform cortex. Part of the myelin sheath (*My*) is seen below. The unmyelinated continuation is seen to have three presynaptic bags (*B*) contacting it, two of them forming synaptic thickenings (*S.T.*). This axon contains mitochondria (*M*), filaments (*f*), a multivesicular body (*X*) and smooth reticulum (*R*) with ribosomes to the right

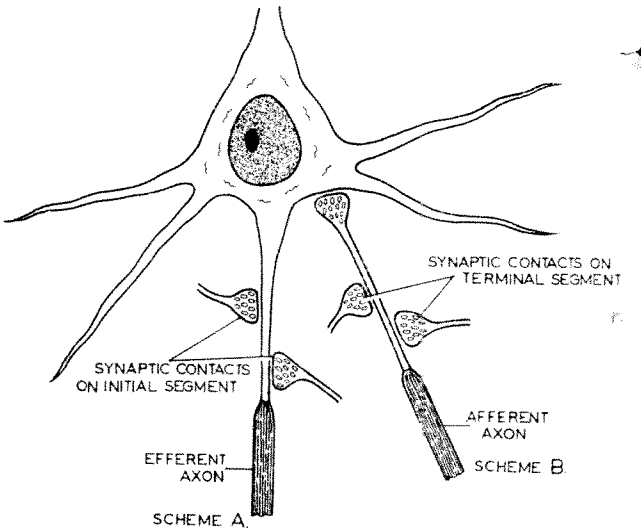

Fig. 2. A diagrammatic representation of a portion of a pyramidal cell from the prepyriform cortex showing possible axo-axonic relationships. The presynaptic bags contact unmyelinated axon segments which may be either the initial segment of the efferent axon (*A*) or the terminal segment of the afferent axon (*B*)

I thank Profs. J. Z. Young and R. Miledi and Drs. E. G. Gray and B. G. Cragg for advice and criticism. Valuable technical assistance was provided by Mrs. J. Astafiev, Miss C. Martin, and Mr. S. Waterman.

PSYCHOLOGY

Tranquillizers in Pregnancy and Behavioural Effects on the Offspring

IN 1964 we[1] reported that we had repeated an experiment "exactly as described by Werboff and Kesner"[2] and had failed to confirm their reports that the administration of meprobamate to pregnant rats had deleterious effects on the offspring. Shortly afterwards, a report by Hoffeld and Webster[3] appeared which also denied that these offspring were deficient in learning ability or bodyweight. Werboff[4] has recently commented on these two papers, emphasizing that alterations in procedure were important in this area of research. In our case, the difference in results was attributed by Werboff to an

alteration in dosing procedure whereby our pregnant rats received far less meprobamate than did his own.

In order to eliminate any misunderstanding, we wish to emphasize that our pregnant rats received exactly the same amount of drug on exactly the same schedule as that described by Werboff, that is, 20 mg/kg per injection (three injections per day), or 60 mg per kg of body-weight per day for 4 consecutive days, a total of 240 mg of meprobamate per kg per rat. Therefore, our failure to reproduce his data cannot be due to any difference in drug doses or procedures used.

In the case of Hoffeld and Webster, who also used the same drug doses and procedures, Werboff attributes their failure to confirm his own report to two factors. Hoffeld and Webster's rats were pregnant at the time that they were shipped and probably suffered severe stress during this shipment. Secondly, the offspring of these rats were exposed to the stresses of colony housing and did not experience the handling and testing of the Werboff rats. But no explanation is offered as to why these rats should be healthier and learn better than Werboff's rats. Werboff's suggestion that the stresses listed above masked the deleterious effects of the drug is more puzzling than enlightening.

The fact remains that the results of Hoffeld and Webster agree completely with our findings. Both our group and theirs followed the procedures and schedules described by Dr. Werboff without difficulty, but failed to confirm his data.

Threshold Regulation and Stimulus Wave-length

IN a repeat of earlier research[1,2] into the relationship between alpha abundance and visual thresholds for emotive words, red and green monochromatic lights were used as the visual stimuli. On the first presentation of each colour, results were in substantial agreement with those obtained in the previous work. Irrespective of stimulus wave-length, high thresholds for emotive words followed on sustained alpha abundance while low thresholds followed reduced alpha. The second presentation under a different colour, however, produced results which diverged somewhat from those previously reported. Irrespective of stimulus wave-length subjects tended to show higher thresholds for emotive than for neutral words, but those with higher thresholds for emotive words in red light showed reduced alpha abundance before reaching the threshold. This result is consistent with the finding[3,4] that a red stimulus in juxtaposition to a potentially emotive subliminal stimulus will evoke emotional disturbance, and the finding[5] that sympathetic activity decreases retinal sensitivity for light of long wave-length. All in all, the results suggest that while a given level of cortical activation may be necessary for awareness of a visual stimulus of low intensity, visual thresholds may also depend on a retinal variable under autonomic control.

BIOLOGY

Allotypy and Eniotypy

INDIVIDUAL animals of a given species show well-defined, genetically controlled differences in the composition of certain isofunctional proteins. This molecular polymorphism is essentially of two types. The first type is one in which an isofunctional protein such as haemoglobin is present in all individuals of the species and the individuals differ from one another by the amino-acid sequence in limited regions of the molecule. The second type of polymorphism is characterized by the presence or absence of a particular protein in different animals of the same species. We wish to propose here a general nomenclature for these two polymorphic states.

Most instances of molecular polymorphism are of the first kind. When such polymorphism in the past has been revealed by the use of isologous antibodies, the phenomenon has been designated as allotypy (Oudin[1]). We propose now to extend this term to include all kinds of polymorphism of the first type, irrespective of the method used to reveal it. Medawar[2] has recently made the same suggestion. For the second type of polymorphism we wish to propose the term 'eniotypy' (that is "a type occurring in some", derived from the Greek ἐνίοτε, 'somewhere'). One can distinguish between these two types of polymorphism by the hetero-specific reactivity of isologous antibody.

Isologous antibodies to a molecule with allotypic polymorphism show a very narrow range of cross-reactivity for, usually, they react only with molecules from animals of the same species as the immunized animal. As an example of this we may quote the failure of isologous antibodies to mouse or rabbit immunoglobulin to react with the sera of other mammals belonging to the same order. Isologous antibodies to a molecule with eniotypic polymorphism, on the other hand, would be expected to show a wide cross-reactivity with the corresponding isofunctional molecules from animals of other species, as was observed in the investigations of murine antibodies to the murine complement factor MuB1 (refs. 3 and 4).

Such experimental findings can readily be accounted for in terms of tolerance to autologous determinants[3,5,6], because the animal completely lacking a particular protein molecule will not be tolerant to any of its determinants. This lack of tolerance provides the animal with the capability of synthesizing antibodies against all the determinants on the injected molecule, including some that are shared by animals of different species and even different natural orders. As a result, a typical eniotype antiserum, such as an antiserum to MuB1, reacts with the isofunctional proteins of a wide range of animal species and not just with proteins from other individuals within the species.

The foregoing classification of molecular polymorphism can be applied to an analysis of deficiency diseases such as various clotting defects (haemophilia, Christmas disease, absence of factors 5, 7, 8, and 10 (refs. 7 and 8) and metabolic deficiencies exemplified by total albinism (tyrosinase), Von Gierke's disease (glucose-6-phosphatase), familial goitrous cretinism (iodotyrosine deshalogenase), phenylketonuria (phenylalanine hydroxylase), Crigler-Najjar syndrome (glucuronyl-transferase)[9,10] and acatalasaemia[11,12]).

The inherited defects in these diseases may be due to a change in amino-acid composition (allotypy) which would affect the biological function of the molecule[13], or might be attributable to a complete deletion of the synthesis of the molecule (eniotypy). In none of the instances enumerated here has it been definitively established whether the deficiencies are due to total failure to synthesize a biologically active molecule (eniotypy), loss of function resulting from amino-acid substitution of the functionally

crucial portion of the molecule (allotypy), or reduction in the quantity of the molecule synthesized. It is even possible in some diseases that, in different individuals, different types of polymorphism might be involved, some allotypic and others eniotypic in nature.

We thank Dr. H. Parry of York University, Toronto, for suggesting the term 'eniotypy'. We also thank the following bodies for support in the experimental work on which the foregoing proposals are based: the Banting Research Foundation, the Canadian Arthritis and Rheumatism Society, the Medical Research Council of Canada, the National Cancer Institute of Canada, and the U.S. National Institutes of Health.

Respiration in Yam Tuber Tissue

YAMS (*Dioscorea* spp.) are major food crops in many tropical countries. Global production of the edible tubers is approximately 20 million tons/year, the most important producer area being West Africa, where they often contribute up to half the total calorific intake of the population[1]. The tubers are frequently stored for periods of several months and, although they are generally said to 'store well', it has been shown[2–4] that appreciable losses in weight, of the order of 10 per cent after 3 months, and 25 per cent or more after 6 months, occur during the storage even of sound tubers. A number of storage rots are known[5], and attack by these organisms can further enhance storage losses. It has been estimated[1] that around a million tons of yams are lost, annually, in storage.

One of us has shown[4] that the weight losses occurring in sound tubers can only partially be accounted for by loss of moisture associated with the desiccation of the tubers during storage, and it was suggested that the remaining dry matter loss is caused by the respiratory metabolism of the dormant tuber. Some preliminary experiments on the evolution of carbon dioxide by yam tubers[6] have yielded results in fair agreement with the weight losses observed in field trials.

The information available indicates that these losses are much greater than those observed in the case of temperate tuber crops, such as the potato[7]. This is partly due to the fact that storage temperatures in tropical countries where yams are grown are higher (25°–30° C) than are normal in potato stores in temperate climates (5°–10° C): but the differences in weight loss are greater than would be expected from this factor alone. Furthermore, the observed rates of weight loss in yams are greater than those corresponding to the respiration rates, measured even at comparable temperatures in potatoes. The present experiments were therefore initiated to investigate the respiratory processes in yam tuber tissue, as the subject is obviously of interest from both theoretical and economic points of view.

The experimental material was purchased in the main yam market in Accra. After preliminary investigations, to develop technique, the main series of experiments was conducted with a single parcel of *D. rotundata* Poir—a species which is widely cultivated in West Africa—of the local variety 'Pasajo'.

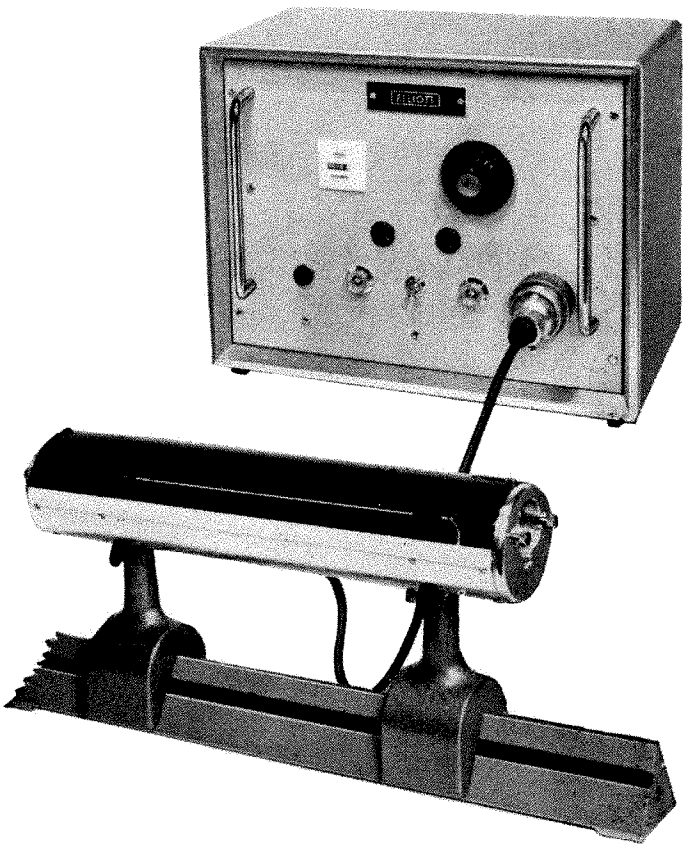
The investigations of respiration were undertaken by means of the Warburg technique[8], using a Braum–Colora refrigerated circular Warburg apparatus. The oxygen uptake of slices of tuber tissue was measured at temperatures at 5° intervals between 5° C and 30° C; some experiments were conducted in the presence of antibiotics (penicillin, streptomycin and tetracycline, either singly or in combination) and some without. The slices were prepared by a modification of a technique developed[9] for other root crops as follows. A section was cut across the middle of a sound tuber with a sharp knife. The section was held under running tap-water, slightly scrubbed to remove all surface dirt and mounted in a commercial bacon slicer set at gauge zero. Thin layers were cut under hand pressure to a number greater by two than the number of small slices required for each experimental flask, and stacks of small slices were stamped from these using a 1-cm diameter cork borer. Before adding each stack of slices to the flask, the top and bottom disks were rejected. They served to reduce dehydration, further bacterial contamination and oxidation while the experiment was being assembled. In certain of these experiments, the slices were cooled to 5° C or 10° C and oxygen uptake was measured over a long period, for example, up to 44 h, before raising the temperature to near ambient (25° C) and continuing the measurements. A stack, usually of five slices, was placed in each Warburg flask in a phosphate buffer isotonic with yam tuber tissue and of the same *p*H value, 6·1; this buffer solution was 0·1 molar in potassium dihydrogen phosphate and 0·01 molar in sodium hydrogen phosphate. Some comparative measurements on slices of potato tubers were also made using a similar technique.

Under asterile conditions, rapid uptake of oxygen occurred at 30° C, and only slightly less rapid uptake at 25° C and at 20° C. At 15° C, however, the rate of oxygen uptake was only about a sixth of the 20° C rate, while at 10° C and 5° C, only very slow uptake occurred. At all temperatures, the rate of uptake of oxygen increased during the course of the experiment (5–6 h) by a factor of about two. A representation of the trend of the results is given in Fig. 1.

The increase in uptake of oxygen with time, after a partial time lag, suggested possible infection with some kind of micro-organism. Further experiments were therefore conducted in the presence of the antibiotics mentioned: penicillin had comparatively little effect, streptomycin rather more, while tetracycline was almost as effective as a combination of the three in reducing the rate of uptake of oxygen. The initial level of respiration was not greatly affected by antibiotics, but the increase with time previously observed was largely eliminated by their use.

After oxygen uptake by slices of tissue had been observed for up to 44 h at 5° C, and the temperature then raised to the near-ambient temperature of 25° C, a rapid increase in uptake of oxygen occurred in the absence of antibiotics; in their presence, the rate of uptake remained

The Perkin-Elmer Model 139 low-cost, direct-reading spectrophotometer with fluorophotometry attachment (there are many other accessories for this versatile instrument)



This Perkin-Elmer UV/Visible spectrophotometer is of modular design; tailor-made versatility is its hallmark. Conversion from one mode of operation to another can be made in a few minutes. With the Fluorophotometry unit shown here, fluorescence arising from radiation by the 365 mμ line of a high-pressure, voltage-stabilised mercury-vapour lamp can be analysed. Four sample cells are mounted on a turntable in the cell compartment, so that you can measure many different samples quickly, reading directly from the scale at specific points or recording over a chosen wavelength range. If preferred, especially for the quantitative analysis of samples of low concentration a non-dispersive fluorophotometry unit can be used, and within minutes you can be making straight absorption measurements, studying diffuse reflectance or using the instrument as a flame photometer. We are keen to send you full details: Perkin-Elmer Limited, Beaconsfield, Bucks. Beaconsfield 5151.

EHI2

constant for a short period, and then declined; after a similar chilling period at 10° C, and return to 25° C, the uptake of oxygen at the higher temperature was similar to that observed at the latter temperature, without previous chilling, whether in the presence or absence of antibiotics.

These results may be interpreted as follows: at temperatures near the normal tropical ambient, the destruction of the dry matter of yam tubers during storage (that is, during the period of dormancy) is caused, in part by the natural respiratory processes, and in part by the activity of micro-organisms within the tissue. This is in accordance with the observation that yam tubers, which become rotten towards the end of the storage period, lose weight rapidly, even while still apparently sound, in contrast to those tubers of the same origin that remain free from rotting for longer periods[3]. It would seem that apparently healthy yam tuber tissue is normally infected with biodeteriogens. These organisms, judging by the relative effects of the various antibiotics used, would appear to be Gram-negative bacteria. Reduction of the temperature to 15° C—well below normal tropical ambients reduces the rate of dry matter destruction (as measured by the uptake of oxygen), whether due to the enzymatic respiration of the tuber tissue or to microbial activity. Cooling to still lower temperatures reduces the rate further. This observation could well have a practical application to the storage of yams at reduced temperatures as a means of reducing storage losses. However, when the tissue is chilled to 5° C, permanent damage of the tissue is observed and rapid destruction by microbiological attack would be expected as soon as the temperature is raised to one at which normal tropical micro-organisms can rapidly proliferate. Chilling to only 10° C produces no such effect. It would thus appear that the lower critical temperature for safe storage lies between these limits (5°–10° C), as it does for several other tropical vegetables, such as sweet potatoes[10]. It is known[3] that chilling of yams to 1° C results in complete breakdown by decay on return to ambient conditions. No effect attributable to such chilling damage was observed in the potato slices.

Further investigations are being carried out on the temperature of the chilling damage, on varietal differences and on the micro-organisms involved in deterioration. Attempts are being made to relate these observations to storage trials on whole yam tubers.

ENTOMOLOGY

Malic Enzyme Activity in the Fat Bodies of the Cockroach, *Leucophaea maderae* (F.)

Malate is reversibly converted to pyruvate through the agency of the malic enzyme. This reaction, which is effected in the presence of $NADP^+$ and Mg^{++} ions, constitutes the only known means whereby the synthesis of dicarboxylic acids is obtained from pyruvate and carbon dioxide. Simultaneous oxidation and decarboxylation are accomplished by the same enzyme, and although free oxalacetate does not appear in the reaction, this acid is decarboxylated. During equilibrium, there is a tendency for malate to become oxidized, and if $NADP^+$ is removed by coupling action, the process is reversed with the resulting fixation of carbon dioxide.

Faulkner[1] first discovered the malic enzyme in the haemolymph of insects. Fenwick[2,3] also discovered it in the fat bodies of the desert locust *Schistocerca*: and Prota[4] demonstrated its presence in the haemolymph of the mealworm, *Tenebrio molitor*. Thus, the purpose of this investigation was to determine whether or not the presence of malic enzyme in the fat bodies of the cockroach, *Leucophaea maderae*, is due to the activity of these tissues, the symbionts, or both.

Cockroaches were reared according to the method of Pierre[5] and the symbionts were isolated and cultivated according to the methods of Begg and Sang[6], Pant, Nayar and Gupta[7] and Pierre[5,8].

Homogenates were prepared from 1 g of the symbionts (48-h-old cultures cultivated in *Neurospora* agar on Petri dishes) and from similar weights of the fat bodies of normal adult and nymphal cockroaches, as well as corresponding aposymbiotic insects. The ages of the nymphs ranged from sixth to eighth instars. Materials were homogenized for 5 min with a hand homogenizer in 2 ml. of 0·03 M phosphate buffer at *p*H 7·4. The homogenates were then diluted with 2 ml. of 1 per cent $NADP^+$; sufficient of the same buffer was added to make a 3·3 per cent concentration. Homogenates were then incubated in a constant-

temperature water bath at 30° C for 30 min to oxidize the endogenous substrates. At the end of incubation, the homogenates were assayed for the enzyme activity.

Spectrophotometric determination of the malic enzyme activity was performed according to the methods of Faulkner[1] and Prota[4]. Assays were conducted with a Beckman *DU* instrument at a wave-length of 340 mμ. The instrument was set at zero optical density with 3 ml. of 0·03 M phosphate buffer at *p*H 7·4, and the reaction cuvettes consisted of the following: 0·2 ml. of substrate (0·25 M sodium malate); 0·25 ml. of 1 per cent $NADP^+$; 0·25 ml. of 0·033 M magnesium sulphate; 0·1 ml. homogenate; and 2 ml. of 0·03 M phosphate buffer at *p*H 7·4. Recordings of the optical density of reaction mixtures were performed at zero time, and then at 1-min intervals until the end of the experiment. The enzyme activity was determined by the change in optical density which occurred between readings at zero time and the end of the experiment.

Assays of the enzyme activity performed according to the method of Thunberg[9] were conducted as follows: 1 ml. of the homogenate was placed in the side arm of the tube; and 0·5 ml. of methylene blue (1 : 10,000), 1 ml. of 0·25 M sodium malate, 0·5 ml. of 1 per cent $NADP^+$, 0·5 ml. of 0·033 M magnesium sulphate, and 0·5 ml. of 0·03 M phosphate buffer at *p*H 7·4 were placed in the main portion of the tube. Two standards were prepared: (1) a standard which contained all the ingredients of the reaction tube except the substrate (sodium malate); (2) a similar standard the homogenate of which was inactivated by boiling, and in which 0·05 ml. of the methylene blue was used instead of 0·5 ml. All the tubes were sealed and evacuated for 5 min after which the homogenates in the side arms were tipped over into the main portions of the tubes. The latter were then immersed in a constant-temperature water bath at 30° C and the time for 90 per cent decoloration of the methylene blue was determined visually. Accordingly, the enzyme activity was expressed as the reciprocal of the time in minutes required for 90 per cent decoloration of the indicator. In all cases, twenty determinations of the enzyme activity were performed by each method used. This necessitated the use of different insects at each trial, and fresh cultures of the symbionts.

Spectrophotometric determination of the activity of the malic enzyme in materials of the symbionts and those of the normal adult and nymphal cockroaches of *L. maderae* showed the following results: 0·013; 0·343; 0·350, respectively. Corresponding values for the aposymbiotic adult and nymphal fat bodies were 0·340 and 0·327, respectively. Graphic representations of these activities are shown in Fig. 1, which shows the change in optical density of malate as the latter is converted to pyruvate in the presence of the enzyme. Except for the materials of the symbionts (the activity of which was negligible), results of the enzyme activity determined by the Thunberg technique[9] were 0·034 and 0·028 for the normal adult and nymphal fat bodies, and 0·028 and 0·030 for those of corresponding aposymbiotic insects, respectively.

As the results of the activity of the malic enzyme obtained in all the materials (except those of the symbionts) are comparable, it would seem that the symbionts play a negligible part in the activity of the enzyme. This observation seems obvious for the following reasons: (1) Tarver[10] demonstrated high activity for malic dehydrogenase in the symbionts and normal fat bodies of the cockroach, *L. maderae*, but found little activity in the aposymbiotic fat bodies; (2) Epstein[11] also demonstrated low activity of lactic dehydrogenase in the fat bodies of the same insect, but high activity was obtained in the materials of the symbionts; (3) Faulkner[1] obtained high activity for the malic enzyme in the fat bodies of insects, but saw no trace of lactate in the tissues. Thus, the latter worker attributed this to the reversible conversion of pyruvate to malate by the enzyme; (4) Zebe and McShan[12]

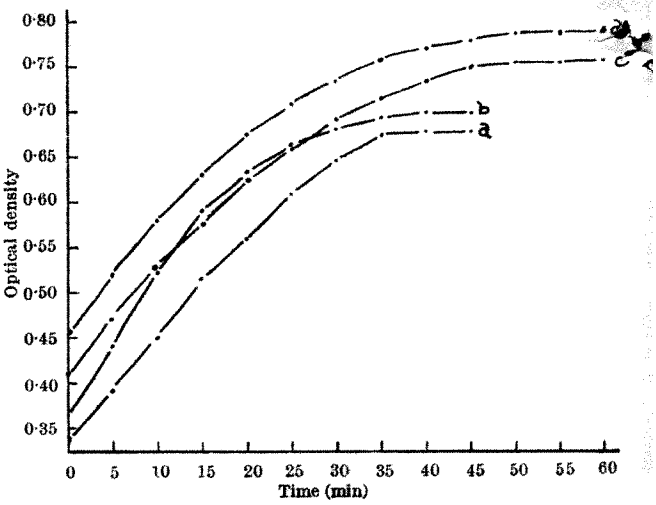

Fig. 1. Showing the activity of malic enzyme in the fat bodies of: *a*, aposymbiotic adult; *b*, normal adult; *c*, normal nymph; *d*, aposymbiotic nymph

reported that the absence of lactate in insect tissues is due to the continual presence of oxygen. It would thus seem that the fat bodies of insects convert malate to pyruvate through the agency of malic enzyme; and the subsequent conversion of malate to oxalacetate is effected through the agency of the symbionts which instead contain malic dehydrogenase.

GENETICS

Induction of Cross-overs, Autosomal Recessive Lethal Mutations, and Reciprocal Translocations in *Drosophila* after Treatment with Diethyl Sulphate

ALTHOUGH crossing-over does not normally occur in the male *Drosophila*, it has been shown[1,2] that chemical induction of crossing-over in the male *Drosophila* is possible using chemical mutagenic agents, such as formaldehyde, dihydroxymethyl-peroxide, and mustard gas.

The present communication reports our findings on the induction of crossing-over in the male *Drosophila* after larval feeding of the mutagen[3], diethyl sulphate, and describes a further experiment designed to detect a possible association between the induction of crossing-over and the induction of autosomal recessive lethal mutations after larval feeding of diethyl sulphate. Tests are also included which show that diethyl sulphate does not induce reciprocal translocations between the second and third chromosome after feeding diethyl sulphate to

either male or female larvae, and after feeding diethyl sulphate to adult male *Drosophila*.

Larvae were cultured on an aseptic yeast–glucose medium[4] of the following composition:

Glucose	10 g
Dried killed yeast (Distillers Co., Ltd.)	10 g
Agar	3 g
Distilled water to 100 ml.	

After autoclaving, 0·5 per cent diethyl sulphate (British Drug Houses 1·177–1·18 g/ml. at 20° C) was added at 60° C. At 55° C the medium was dispensed as 25-ml. portions into four sterile bottles. Eggs, sterilized by Sang's[5] method, were transferred as newly emerged larvae to the treatment medium at a density of one hundred larvae per 25 ml. of medium, and treated over the entire larval life. Emerging males were individually mated to two virgin females of the appropriate test stock for 3 days.

For detection of induced cross-overs on the second chromosome larvae of the genotype *+ + +/dp cn bw* (dumpy, cinnabar, brown) were raised on a diethyl sulphate treatment medium, and cross-overs scored in the F_1 after mating the emergent males to female homozygous for *dp cn bw*.

Table 1. INDUCED CROSS-OVERS IN *Drosophila* MALES TREATED THROUGHOUT LARVAL LIFE WITH DIETHYL SULPHATE

Concentration of diethyl sulphate (per cent)	No. of males treated	No. of gametes tested	Cross-overs Single	Cross-overs Double	Total No. of cross-overs	Cross-overs (per cent)	Treated males which yielded cross-overs (per cent)
Control	70	3,004	None	None	None	0·00	0·00
0·5	47	2,581	* { 1 *dp* 1 *dp cn* 2 *dp cn* 1 *dp*	3 *cn*	8	0·31	14·9

* Recombinants in the progeny of the same male are bracketed together, all other recombinants occurred independently of one another in the progeny of different males.

Table 1 illustrates the cross-over types detected after larval feeding of male *Drosophila* with 0·5 per cent diethyl sulphate; 14·9 per cent of the males examined were found to yield a recombinant class(es).

Table 2. INDUCED CROSS-OVERS IN *Drosophila* MALES ARISING IN THE F_1 PROGENY OF THE AUTOSOMAL RECESSIVE LETHAL TEST

Concentration of diethyl sulphate	No. of males treated	No. of flies examined	Cross-overs	Total No. of cross-overs	Cross-overs (per cent)	Treated males which yielded cross-overs (per cent)
Control	82	5·024	None	None	0·00	0·00
0·5	131	4·149	3 *cn bw*	11	0·27	7·63
			* { 3 *dp* 2 *dp cn* 3 *dp cn*			

* Recombinants in the progeny of the same male are bracketed together; all other recombinants occurred independently of one another on the progeny of different males.

Table 2 illustrates a further larval feeding experiment, where diethyl-sulphate-induced cross-overs were detected by mating males of the genotype *+ + +/dp cn bw* to *CyL*[4]*/dp cn bw* virgin females to detect cross-overs in the F_1 and autosomal recessive lethal mutations[6] in the F_3. The results show that 7·6 per cent of treated males yielded cross-overs. The frequency of autosomal recessive lethal mutations was 22 per cent (total number of chromosomes 464, lethal chromosomes 102, percentage of treated males which yielded lethals 53·1).

To test for an association in the origin of induced cross-overs and autosomal recessive lethal mutations, a male from each F_3 lethal culture was crossed to females homozygous for the *dp cn bw* chromosome to detect which lethal chromosomes were cross-overs; Table 3 shows that three out of ninety-six lethals were associated with a cross-over event.

Table 2 shows an induced cross-over frequency of 0·27 per cent (11/4149), and a corresponding autosomal recessive lethal frequency of 22 per cent.

Assuming that the cross-overs and autosomal recessive lethals arose by independent events, a probability of $0{\cdot}22 \times 0{\cdot}0027 \times 100 = 0{\cdot}59$ per cent is expected for the association of a cross-over and a lethal mutation. However, the observed frequency is three in ninety-six, which is twelve times greater than the number expected if the events were independent ($96 \times 0{\cdot}27 = 0{\cdot}26$).

Table 3. TEST FOR THE ASSOCIATION OF DIETHYL-SULPHATE-INDUCED CROSS-OVERS WITH DIETHYL-SULPHATE-INDUCED AUTOSOMAL RECESSIVE LETHALS IN *Drosophila* MALES

Lethals tested	Cross-overs associated with a lethal	Total No. of cross-overs detected	Lethals which were associated with a cross-over (per cent)
96	1 *dp cn* 1 *dp* 1 *cn bw*	3	3·12

Thus, the data suggest there may be an association between the origin of induced cross-overs and autosomal recessive lethal mutations. However, this association, even if real, might be nothing more than a reflexion of the fact that certain males received a larger amount of diethyl sulphate and therefore responded more to both recombination and mutation induction. Alternatively, the chromosomes used may have been capable of generating synthetic lethals by recombination.

To test for the induction of reciprocal translocations by diethyl sulphate (0·5 per cent) between the second and third chromosome, treated male and female larvae, and male adults treated by an adult feeding method[3], were mated to flies homozygous for the second and third chromosome markers *bw* (brown) and *st* (scarlet), respectively.

The male and female larval treatments yielded no translocations in samples of 838 and 902 gametes, respectively, and the adult males yielded no translocations in a sample of 775 gametes.

Part of this work was carried out at the Department of Genetics, University of Cambridge. I thank Prof. J. M. Thoday, Department of Genetics, University of Cambridge, and Prof. A. C. Kanellis, Department of Biology, University of Thessaloniki, Greece, for providing the laboratory facilities.

SOIL SCIENCE

Organic Matter as a Measure of Bulk Density of Soil

THE compactness of a soil is known to be related to its content of water and air, and to the temperature and the supply of nutrients[1,2]. Although a rough estimate of compactness is sometimes obtained with penetrometers, bulk density provides a more correct overall picture of the physical conditions of a soil. Loosely packed soils, which have a lower bulk density, will usually have better aeration, better drainage, will be warm and will have a longer growing season.

The bulk density of soil is dependent on the specific gravity of the particles it contains and their arrangement. Since the specific gravity of the mineral portion of soils is more or less constant, soil structure is chiefly responsible for fluctuations of bulk density. The structural properties, in turn, are determined largely by the interacting influences of texture and degree of aggregation—especially that due to organic matter. Thus, there is a relationship between bulk density and content of organic matter in soils rich in organic matter. It has been reported[3] that determinations of organic matter in forest soils may be used to estimate the bulk density, the exact measurement of which is time-consuming.

With such an end in view, data collected in the Ohio Soil Survey have been subjected to statistical analysis to establish the relationship between organic matter, determined by the rapid method of Walkley and Black[4], and bulk density. The soils were classified into three groups—well-drained, imperfectly drained and humic-gley soils. Simple correlation coefficients between content of organic matter and bulk density are significant (Table 1).

Table 1. CORRELATION COEFFICIENTS AND REGRESSIONS BETWEEN ORGANIC MATTER AND BULK DENSITY IN SOME OHIO SOILS

Soil group	No. of samples N	Organic matter mean X	Bulk density mean y	Correlation coefficient r	Regression equation
Humic-gley	30	6·13	1·24	−0·858*	$Y = 1{\cdot}62 - 0{\cdot}06X$
Imperfectly drained	40	2·98	1·37	−0·805*	$Y = 1{\cdot}53 - 0{\cdot}05X$
Well drained	40	2·05	1·40	−0·633*	$Y = 1{\cdot}52 - 0{\cdot}06X$

* Significant at 1 per cent level.

From the regression equations, it is plain that the contribution of the organic matter content to the bulk density is not very different for soils of these three categories. In humic-gley and well-drained soils, its contribution is −0·06 g/cm³ for each 1 per cent of organic matter. In imperfectly drained soils it is −0·05 g/cm³ for each 1 per cent of organic matter.

These studies suggest that organic matter in Ohio soils has a definite relationship to the bulk density of surface soils, and an estimate of the latter can be made from organic matter determined by Walkley and Black's rapid titration method.

This work was done at the Ohio State University on a research assistantship from the Ohio Agricultural Experiment Station. I thank Prof. N. Holowaychuk for the soil samples and for helpful suggestions.

Trace Element Content of Organic Accumulations

A STUDY of the distribution of trace elements in rocks, soils and plants in Snowdonia[1], to be reported in detail elsewhere, has led to a realization of the relative importance of material borne in the atmosphere as a source for the trace elements in certain organic accumulations. Relevant analytical data are provided from two sources—first, from an investigation into the role of saxicolous lichens in the initial stages of pedogenesis and, second, from a routine survey of the trace element status of mountain topsoils.

As part of the investigations into the relationships between saxicolous lichens and their substrata, trace element analyses were made of a number of lichen species together with the weathered and fresh zones of a variety of subjacent rocks. Detailed examination of the results reveals a tendency for the concentrations of individual elements in a particular lichen species to converge to a 'preferred value'; composition is apparently dominated by some constant factor. For this reason, the correlation of the trace element content of a lichen with that of its rock substratum is normally poor, and the effect of the substratum is only dominant in the case of crustaceous species on rock types that weather rapidly, such as calcareous basic tuffs and ultrabasic rocks. The correlation of the 'preferred values' between different lichen species within one region (*Parmelia omphalodes* and *Lecanora gangaloides* in Snowdonia) is better than that obtained between samples of the same species in different regions

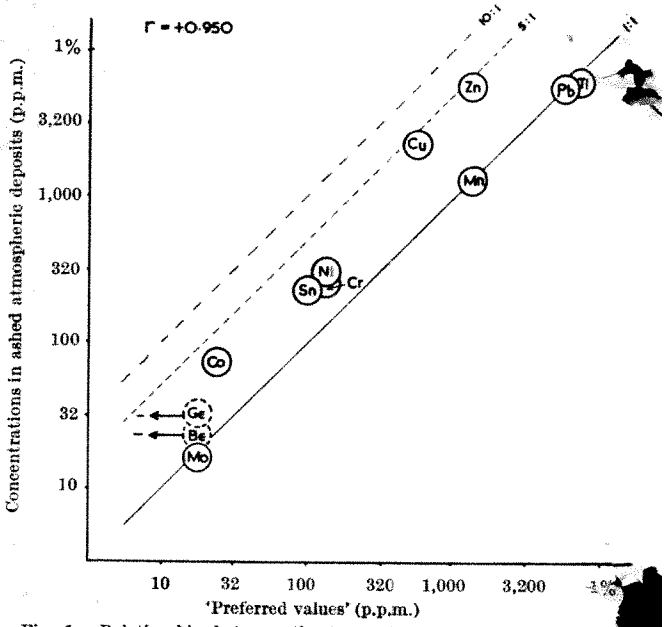

Fig. 1. Relationship between the trace element contents of ashed atmospheric deposits (average of four rural sites, 1947, supplied by Warren Spring Laboratory) and the "preferred values" in the ash of *Parmelia omphalodes* from Snowdonia

(*P. omphalodes* in Snowdonia and Finland[2]). The constant factor involved would therefore appear to be external and regional in nature rather than internal or physiological. In this study, a close correlation has also been demonstrated between values in lichen ashes and values for the ash of material deposited from the atmosphere[3] (see Fig. 1).

The 127 topsoils analysed during a survey of Nature Conservancy experimental sites in Snowdonia included rankers, peats, and peaty varieties of podsols and gleys. The distribution patterns observed in the concentrations of trace elements can be interpreted in terms of such factors as mineralogy, parentage, soil-type, organic matter content, and *p*H. The relationships between the amounts of individual elements in the ignited soils and the amounts of organic matter, adequately determined here as percentage loss on ignition[4], were evaluated in the form of the partial correlation coefficients with soil *p*H (r) in Table 1. By inspection, interference from soil parentage is inferred to be insignificant. Detectable concentrations of tin, molybdenum and silver also show a distinct association with soils of high organic matter content, but are too few to justify the evaluation of correlation coefficients.

From a comparison of the available data on the average composition of the lithosphere[5] with that of atmospheric material[3], it is possible to obtain an order of enrichment of trace elements to be expected in an organic soil due to atmospheric contamination:

Bi, Pb, Cu > Sn, Zn > Ni > Mo, Be, Ge, Co, Cr > V, Mn

This series has similarities with the sequence of correlation coefficients already given. On the basis of their concentrations relative to lead and copper in atmospheric material, the absence or rarity of detectable concentra-

Table 1. PARTIAL CORRELATION COEFFICIENTS OF ELEMENT CONCENTRATION AND *p*H

	r	
Tin	+0·69	*
Lead	+0·59	*
Copper	+0·50	*
Nickel	+0·17	†
Strontium	+0·15	†
Yttrium, barium, cobalt, gallium, chromium, manganese, zirconium, vanadium, rubidium and lithium	+0·05– −0·38	

* Significant at the 1 per cent level.
† Significant at the 5 per cent level if arbitrarily referred to zirconium (r = −0·19) as an "inert standard" to compensate for dilution by metabolically accumulated organic ash.

tions of bismuth, molybdenum, beryllium and germanium in the soil samples analysed is consistent with an atmospheric origin. Zinc should, however, be detectable in more soils than is the case, although further investigations[1] have shown that, in several of the organic-rich soils concerned, zinc is decidedly more mobile than lead or copper in terms of extractability by 0·5 N acetic acid. Further evidence of this similarity of trace element compositions is provided by the lead : copper concentrations in the ignited soils (Fig. 2). Here it can be seen that the dispersed ratios at low lead and copper concentrations converge at higher concentrations in more organic soils to a value of 2·4 which equals that recorded for the ash of matter deposited from the atmosphere[3].

It is therefore apparent that the contents of trace elements in both the saxicolous lichens and the organic topsoils follow a pattern similar to that of ashed atmospheric deposits. Correlation is, in fact, surprisingly good considering both the variable composition of atmospheric material between different size grades and within time and space, and also the possibility of differential mobilization and absorption or rejection of trace elements by the organic matter. It is not easy, however, to assess how far the trace element composition of organic accumulations is in fact controlled by atmospheric contamination. In the case of the lichens, which have particularly slow growth rates[6] and are ectohydrates[7], the evidence for the dominance of atmospheric sources in their trace element composition is strong. This is in accord with early views on their nutrition[8], but conflicts with the emphasis placed on the substratum as a source of nutrients by later investigators[2,9,10].

For organic soils, however, it is probable that the contribution of pedological and metabolic processes to the accumulation of specific trace elements is more important. Atmospheric contamination achieves greatest significance in deposits of particularly low mineral content (for example, 'acid' peats) and of elements such as copper which are known to be readily immobilized in organic soils. Concentration of lead, copper, zinc, tin, molybdenum and silver in the organic horizons of soils has been noted by numerous soil analysts[11], although it has usually been ascribed to accumulation by organic processes[12,13], and only rarely to atmospheric contamination[14]. The importance of the latter, as implied by the present studies, could be confirmed by comparisons with analyses of soils, lichens and atmospheric deposits from areas affected to a lesser degree by industrial contamination, or with analyses of buried organic soil horizons the formation of which pre-dated the industrial revolution.

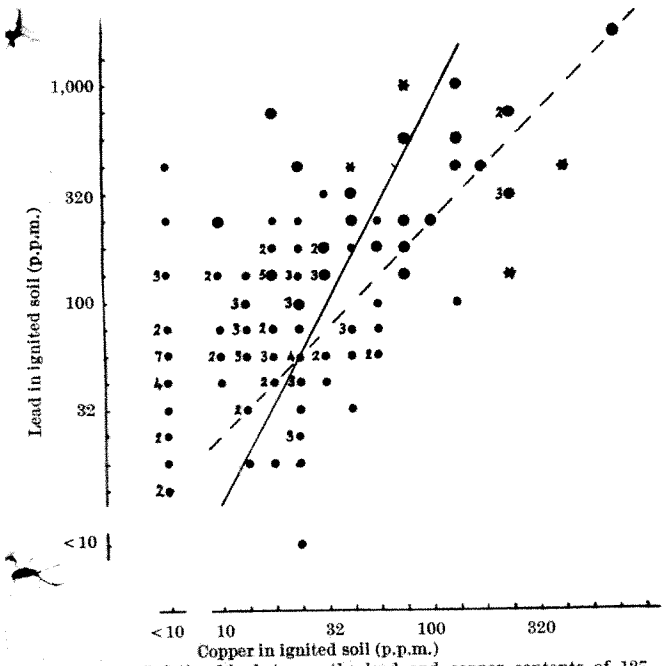

Fig. 2. Relationship between the lead and copper contents of 127 ignited topsoils from Nature Conservancy experimental plots in Snowdonia. *, Samples associated with ore deposits; •, loss-on-ignition <40 per cent; ●, loss-on-ignition >40 per cent; - - - -, ratio of lead : copper in ashed atmospheric deposits; ——, regression line of lead on copper (Pb = 11Cu − 97)

There are interesting corollaries to these conclusions. In the case of lichens, there is the possibility of using inorganic composition to monitor atmospheric contamination or, in particularly long-lived crustaceous species with an age measured in centuries[6], of tracing changes in the composition of atmospheric material. In soils, the contamination that can be detected in slowly accumulating organic topsoils ('mor' formation) must obviously also apply to soils where the organic matter is redistributed and decomposed within the profile ('mull' formation). Although obscured, it may still be of importance in trace element nutrition.

The composition of atmospheric material itself is at present presumably determined mainly by the selective volatilization of coal, supplemented in the case of lead by exhaust fumes from petrol engines and possibly, in the case of nickel, by extra-terrestrial material[15]. Coal is itself a lithified organic accumulation in which the concentration of such trace elements as bismuth, beryllium, germanium, silver, molybdenum, zinc and lead has been recorded. In some cases this concentration may be due to the low redox potential generated or to diagenetic processes, but it has also been ascribed[16] to accumulation in the original plant tissues by physical and metabolic processes. In organic matter accumulating at the present day processes of the latter type still operate[16,17], but in addition selected elements, concentrated organically some 250 million years ago, are now being returned by industrial atmospheric contamination. This complicates the interpretation of the trace element content of recent organic accumulations and poses many interesting problems.

Some of the results reported here form part of a survey carried out on behalf of the Bangor Research Station of the Nature Conservancy, and we acknowledge with gratitude the assistance and interest of the staff of that Station.

Pyrophosphate in Soil; some Physico-chemical Aspects

As part of a series of experiments in this laboratory to evaluate *pyro*phosphate as a source of phosphorus for plants[1,2], attention has been given to the comparative rates of movement of *ortho*phosphate and *pyro*phosphate in soil and to their adsorption isotherms.

The adsorption isotherms were examined by shaking 5-g samples of finely ground soil overnight with 100 ml. of phosphate solutions which ranged from 0 to $1{\cdot}2 \times 10^{-3}$ molar. The quantity of *ortho*phosphate adsorbed was determined from the change in phosphate concentration in solution. To determine the true adsorption of *pyro*-phosphate without bias from the change in phosphate concentration in solution resulting from exchange of *pyro*phosphate with soil *ortho*phosphate, labelled *pyro*-phosphate was used. The quantity of *pyro*phosphate adsorbed was determined by the relative radioactivities of the solution after shaking with soil and of an appropriate standard. The soils were autoclaved before the experiment to prevent biological hydrolysis of *pyro*-phosphate. Phosphate adsorption maxima for eight soils, including those later used in the phosphate movement experiments, were calculated by adopting the Langmuir concept used by Olsen and Watanabe[3] (Table 1). The phosphate adsorption isotherms for two of them are shown in Fig. 1. The *pyro*phosphate sorption maxima range from 0·6 to 9 times those of *ortho*phosphate, implying that sites exist in soil which adsorb one form of phosphate but not the other.

Table 1. SOIL PHOSPHATE SORPTION MAXIMA
(m.moles phosphate per kg soil)

Soil	*Ortho*phosphate	*Pyro*phosphate	*Pyro* maximum / *Ortho* maximum
2	7·1	12·3	1·7
3	3·7	8·9	2·4
5	7·9	16·4	2·1
7	3·7	8·5	2·3
11	3·7	5·8	1·6
340	45·6	27·2	0·6
482	13·5	10·6	0·8
526	2·4	21·6	9·0

The relative rates of movement of NaH_2PO_4 and $Na_2H_2P_2O_7$ were examined in two experiments using soils which had been found to have contrasting adsorption characteristics (Table 1). In the first experiment the relative rates of diffusion into crumbs were followed using a technique previously described[4]. The soil crumbs were immersed at laboratory temperature in $1{\cdot}27 \times 10^{-3}$ molar labelled phosphate solutions for one week. The distribution of labelled phosphate across the face of sections of three crumbs of each soil can be seen in Fig. 2. In the soils examined it is apparent that *pyro*phosphate diffused very much more slowly than *ortho*phosphate. Similar differences were also observed using $6{\cdot}4 \times 10^{-4}$ molar solutions.

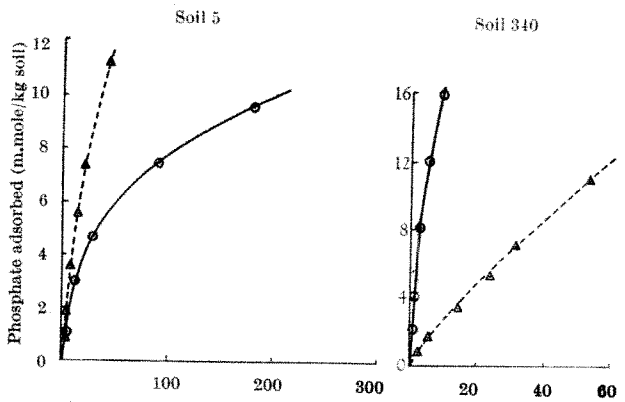

Fig. 1. Phosphate adsorption isotherms in soil 5 (*p*H 5·9, moderate *ortho*phosphate sorption capacity) and soil 340 (*p*H 5·3, high *ortho*-phosphate sorption capacity). ——, *Ortho*phosphate; - - - - -, *pyro*-phosphate

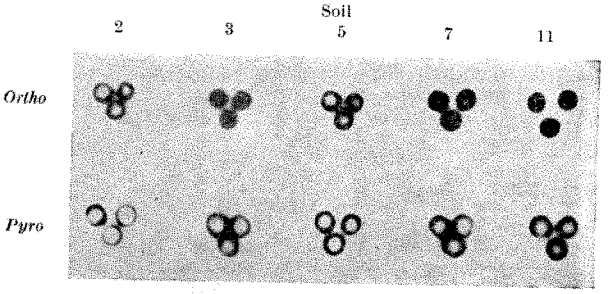

Fig. 2. Autoradiograph showing the distribution of phosphorus-32 across the face of soil crumbs after immersion for 1 week in $1{\cdot}27 \times 10^{-3}$ M phosphate solutions

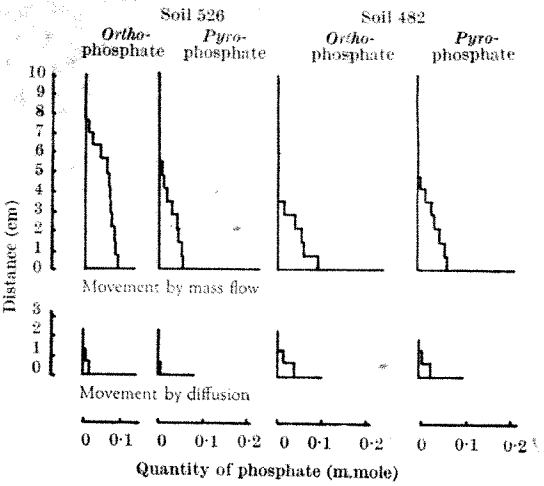

Fig. 3. Upward movement of phosphate in soil columns

In the second experiment a comparison was made between movement of 1×10^{-2} molar solutions of the two labelled phosphates up a column both by mass flow and diffusion. A 'Perspex' column similar to that used by Bodman and Coleman[5] was filled with < 2 mm soil. For mass flow, air-dry soil was used and the solution moved up the soil by capillarity. For diffusion, the soil was previously moistened and subsequent water movement was avoided by covering the soil column with a bell jar to prevent evaporation. After 5·5 h of mass flow and 18 h of diffusion the column was drained and sectioned, and the radioactivity in each 6·5 mm thick section was determined. The quantity of phosphate that was transported up the column and the distance which it moved were very much greater when movement was by mass flow (Fig. 3). On soil 526 both the total quantity of phosphate that moved beyond the basal section (Table 2) and the distance that it moved were greater with *ortho*phosphate than with *pyro*phosphate whether movement was by mass flow or diffusion. On soil 482, however, although diffusion of *ortho*phosphate was more rapid than *pyro*phosphate, mass flow rates were similar for the two forms of phosphate.

Table 2. PHOSPHATE DIFFUSED BEYOND THE BASE SECTION (m.mole)

		*Ortho*phosphate	*Pyro*phosphate
Soil 526	Mass flow	0·507	0·226
	Diffusion	0·014	0·004
Soil 482	Mass flow	0·248	0·252
	Diffusion	0·049	0·026

Thus these experiments, which are of an exploratory nature, show that *ortho*phosphate and *pyro*phosphate anions behave differently in soil and that the extent and direction of these differences vary from soil to soil. The physico-chemical significance of this in relation to the phosphate sorbing components of soil will provide a subject for further examination.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Tuesday, June 21

UNIVERSITY OF LONDON (at Charing Cross Hospital Medical School, London, W.C.2), at 6 p.m.—Prof. S. G. Hershey. "The Microcirculation".*

Tuesday, June 21—Thursday, June 23

BRITISH VETERINARY ASSOCIATION, and BRITISH SMALL ANIMAL VETERINARY ASSOCIATION (at the Zoological Society of London, Regent's Park, London, N.W.1), at 9 a.m. daily—Symposium on "Some Diseases of Animals Communicable to Man in Britain".

Wednesday, June 22

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. R. Stoneley: "The Structural Development of the Gulf of Alaska Sedimentary Province in Southern Alaska".

CHALLENGER SOCIETY (in the rooms of the Linnean Society, Burlington House, Piccadilly, London, W.1), at 5.45 p.m.—Mr. D. J. Shearman and Dr. G. Evans: "On the Recent Sediments of the Persian Gulf".

Friday, June 24

MEDICAL RESEARCH COUNCIL (at the National Institute for Medical Research, Mill Hill, London, N.W.7), at 4.30 p.m.—Prof. Frank J. Fenner (Australian National University). "Some Recent Studies in the Genetics of Animal Viruses".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

TEMPORARY ASSISTANT LECTURER (preferably with interests in marine biology) IN ZOOLOGY—The Registrar, The University of Hull, Hull (June 23).

LECTURER IN THEORETICAL PHYSICS—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (June 24).

RESEARCH FELLOW IN THEORETICAL PHYSICS—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (June 24).

ASSISTANT LECTURER (preferably with research experience in fields other than soils or dairying, for example, food or taxonomy) IN THE SECTION OF FOOD AND AGRICULTURAL BACTERIOLOGY (situated in the Department of Agriculture)—The Registrar, The University, Leeds, 2 (June 25).

FELLOW IN THE DEPARTMENT OF MATHEMATICS to undertake research in elasticity or a related field—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (June 25).

LECTURER and an ASSISTANT LECTURER (with qualifications and experience in the fields of the strength of materials and/or structures) IN ENGINEERING (Civil) IN THE FACULTY OF SCIENCE—The Registrar, The University, Manchester 13, quoting Ref. 144/66 (June 25).

RESEARCH DEMONSTRATOR (with an honours degree in zoology and interested in working towards a higher degree) IN ZOOLOGY—The Chairman, Natural Sciences Committee, Magee University, Londonderry, Northern Ireland (June 25).

TUTORIAL STUDENT IN THE DEPARTMENT OF BOTANY—The Secretary, The University, Aberdeen (June 25).

CHAIR OF VIROLOGY—The Registrar, The University, Manchester, 13 quoting Ref. 137/66 (June 27).

SENIOR RESEARCH FELLOW (with a structural background and a particular interest in industrialized building) IN THE DEPARTMENT OF CIVIL ENGINEERING to work with Dr. E. R. Bryan on the stiffening effects of light cladding in buildings—The Registrar, The University, Manchester 13, quoting Ref. 138/66 (June 29).

DEMONSTRATOR (with a special interest in plant pathology, crop production or genetics, and preferably some research experience) IN THE DEPARTMENT OF AGRICULTURAL BOTANY; and RESEARCH ASSISTANTS (with, or expecting to obtain, a good honours degree in agricultural botany, botany or genetics) to carry out research in plant pathology, crop production or genetics—The Registrar, University College of Wales, Aberystwyth (June 30).

EXPERIMENTAL OFFICER (with a university degree or equivalent qualification, and preferably a knowledge of chemistry) IN THE DEPARTMENT OF PHYSICS OF THE FACULTY OF SCIENCE, to run an evaporation and target construction laboratory in the Nuclear Physics section of the Department—The Registrar, The University, Manchester 13, quoting Ref. 142/66 (June 30).

FELLOW (plant biochemist or microbiologist) IN BIOLOGY to study the biochemical self-sufficiency of chloroplasts—The Registrar, University of York, Heslington, York (June 30).

LECTURER IN CERAMICS—The Registrar, University of Manchester Institute of Science and Technology, Sackville Street, Manchester, 1 (June 30).

LECTURER IN PHARMACOLOGY at the Institute of Basic Medical Sciences (Royal College of Surgeons of England and University of London)—The Secretary, Institute of Basic Medical Sciences, Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2 (June 30).

LECTURER (with a higher degree in chemistry and/or biochemistry) IN PHYSIOLOGICAL CHEMISTRY at the University of the Witwatersrand, Johannesburg, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, June 30).

POSTDOCTORAL RESEARCH ASSISTANT IN PLANT BIOCHEMISTRY to work with Dr. H. Smith on the phytochrome regulation of phenolic biosynthesis, with special reference to hydroxylation mechanisms—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (June 30).

RESEARCH FELLOW (with good teaching experience and qualifications in biology and preferably an interest in, and knowledge of, measurement techniques) AT THE INSTITUTE OF EDUCATION, to assist in the work on the evaluation of the effects of science teaching at the G.C.E. Ordinary level—The Deputy Secretary, The University, Southampton (June 30).

TEACHING FELLOW IN PURE MATHEMATICS at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar of the University (June 30).

CHAIR OF SENIOR LECTURER IN MATHEMATICS; and a LECTURER OR ASSISTANT LECTURER IN CHEMISTRY at the University of Malawi—The Inter-University Council, 38 Bedford Place, London, W.C.1 (July 1).

DEMONSTRATOR (with an honours degree in animal physiology, physiology, zoology or agricultural sciences) IN ANIMAL SCIENCE in the School of Agriculture—The Registrar, The University, Nottingham (July 1).

LECTURER IN VIROLOGY IN THE DEPARTMENT OF BIOLOGICAL AND HEALTH STUDIES—The Academic Registrar, Battersea College of Technology, Battersea Park Road, London, S.W.11 (July 1).

SENIOR LECTURER (suitably qualified person with research experience in either some aspect of computer science, such as system programming, or in numerical analysis) IN COMPUTING SCIENCE—The Secretary of the University Court, The University, Glasgow (July 1).

POSTDOCTORAL RESEARCH ASSISTANT (preferably with a strong interest in biochemistry) IN ORGANIC CHEMISTRY to pursue research upon the chemistry of the catabolism of porphyrins and related compounds, in collaboration with Dr. R. Bonnett—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (July 7).

GRADUATE PROFESSIONAL FORESTERS (preferably with colonial forest service and under the age of 40); and NON-GRADUATE FORESTERS (with at least 10 years experience in forestry) WITH THE WEST AUSTRALIAN FOREST SERVICE—The Official Secretary, Agent General for Western Australia, Western Australia House, 115 Strand, London, W.C.2 (July 8).

LECTURER IN THE TEACHING OF MATHEMATICS AND PHYSICS in the Institute of Education, University of Ibadan, Nigeria—The Inter-University Council, 38 Bedford Place, London, W.C.1 (July 8).

SCIENTIFIC OFFICER (chemist, with a good honours degree and interested in the practical aspects of soil fertility and crop nutrition)—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting Ref. 1051/74 (July 8).

CHAIR OF GEOGRAPHY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (July 9).

CHAIR OF SOCIOLOGY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (July 9).

GRADUATE for insect sampling in connexion with pest forecasting systems for the International Biological Programme—The Secretary, Rothamsted Experimental Station, Harpenden, Hertfordshire, quoting Ref. 1052/87 (July 9).

JUNIOR RESEARCH FELLOW IN GEOGRAPHY—The Registrar, The University, Sheffield (July 9).

LEVERHULME RESEARCH FELLOW (physical or inorganic chemist with interest in the kinetics and photochemistry of inorganic compounds) IN THE CHEMISTRY DEPARTMENT, University of the West Indies, Jamaica—The Inter-University Council, 38 Bedford Place, London, W.C.1 (July 10).

SENIOR LECTURERS or LECTURERS (with an interest in either (*a*) theoretical chemistry and/or molecular spectroscopy or (*b*) physical chemistry with an interest in gas kinetics) IN CHEMISTRY at the University of Ibadan, Nigeria—The Inter-University Council, 38 Bedford Place, London, W.C.1 (July 11).

RESEARCH ASSISTANT (university graduate or person of equivalent status) IN THE SCHOOL OF CHEMISTRY, to be responsible for the maintenance of a mass spectrometer, type MS9, and for recording and interpreting spectra—The Registrar, University Senate House, Bristol, 2 (July 15).

ASSISTANT LECTURER (with a degree in veterinary science, agricultural biochemistry with nutrition or agricultural science) IN THE DEPARTMENT OF ANIMAL HUSBANDRY AND VETERINARY HYGIENE—The Secretary, The Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (July 16).

RESEARCH SCIENTIST or SENIOR RESEARCH SCIENTIST (Combustion or Chemical Engineer) (with a Ph.D. degree in an appropriate discipline or postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability in chemical engineering, combustion science or fuel technology) IN THE DIVISION OF COAL RESEARCH, Commonwealth Scientific and Industrial Research Organization, North Ryde, Sydney, N.S.W., Australia—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 480/504 (July 16).

JUNIOR RESEARCH OFFICER (with, or about to obtain, an honours degree in botany) IN THE DEPARTMENT OF BOTANY, to work on root competition and its relation to productivity—The Registrar, University College of Wales, Aberystwyth (July 20).

LECTURER (with a good honours degree and preferably interests in one or more of the following fields: philosophy of science, ethics or Greek philosophy) IN PHILOSOPHY at the University of Lagos, Nigeria—The Inter-University Council, 38 Bedford Place, London, W.C.1 (July 22).

LECTURER (with teaching experience, good academic qualifications in biology, and preferably a higher degree in education) IN EDUCATION—The Registrar, The University, Keele, Staffs (July 30).

SENIOR LECTURER or LECTURER IN PSYCHOLOGY at the University of Cape Town, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (July 30).

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (Agricultural Meteorologist) for research on irrigation and associated micro-meteorology—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (August 15).

CHAIR OF MATHEMATICS and HEAD OF THE DEPARTMENT—The Academic Registrar, The City University, St. John Street, London, E.C.1.

ENTOMOLOGIST (young, British) for technical development work in the Sudan—The Manager, Agrochemical Group, CIBA Laboratories Limited, Horsham, Sussex.

RESEARCH ASSISTANT (suitably qualified chemist) for isotopic tracer studies of combustion mechanisms—Dr. C. F. Cullis, Chemical Engineering and Chemical Technology Department, Imperial College of Science and Technology, London, S.W.7.

RESEARCH ASSISTANT (preferably graduate with research experience); and a POSTGRADUATE RESEARCH STUDENT (with, or expecting to receive this year, an honours degree) IN THE DEPARTMENT OF PURE AND APPLIED CHEMISTRY, to join a team working on the characterization and properties of highly branched and network polymers—Prof. M. Gordon, Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, C.1.

RESEARCH ASSISTANT (with a good honours degree in mathematics or similar qualification, and preferably some experience of computing) IN THE DEPARTMENT OF MATHEMATICS, to study methods of stress analysis of engineering structures under the direction of Prof. J. N. Hunt—The Assistant Bursar (Personnel), University of Reading, Reading, Berkshire.

RESEARCH ASSISTANT (with a good honours degree or equivalent in botany, microbiology, biochemistry or related subjects) IN MICROBIAL GENETICS IN THE MICROBIOLOGY DEPARTMENT—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

RESEARCH ASSISTANTS (with good honours degrees in physics and prepared to work for higher degrees as full-time internal students of the University of

London) IN THE DEPARTMENT OF PHYSICS, to join teams working in the following fields: cosmic ray physics and high energy particle counting techniques; electrical discharges in gases and spectroscopy—Head of the Department of Physics, Northern Polytechnic, Holloway, London, N.7.

RESEARCH ASSOCIATE (serologist/immunologist of Ph.D. level)—Mason Research Institute, Harvard Street, Worcester, Massachusetts, U.S.A.

RESEARCH FELLOW or SENIOR RESEARCH FELLOW IN APPLIED MATHEMATICS, to join a group studying electrochemical topics, including nerve conduction, by the methods of mathematical physics—The Registrar, University of Queensland, Brisbane, Queensland, Australia.

RESEARCH OFFICER (with a degree or other qualification, and preferably a leaning towards physical chemistry of instrumentation) IN THE BIOCHEMISTRY DEPARTMENT, for a cancer-oriented project entailing the study of liver components (including nucleic acids) by various biochemical techniques—Dr E. Reid, College Annexe, Battersea College of Technology, 14 Falcon Road, London, S.W.11.

RESEARCH PATHOLOGIST (medically qualified) to take charge of mouse skin painting experiments, histological and bacteriological services, tissue culture work and animal husbandry—The Secretary, Tobacco Research Council, Glen House, Stag Place, London, S.W.1, marking envelope 'Personal'.

SENIOR LECTURER or LECTURER (physical or inorganic chemist) IN THE DEPARTMENT OF CHEMISTRY INCLUDING BIOCHEMISTRY—The Registrar, University of the Witwatersrand, Jan Smuts Avenue, Johannesburg, South Africa.

SENIOR LECTURER or LECTURER (preferably with interests in physiology, but other interests not excluded) IN THE DEPARTMENT OF ZOOLOGY, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1.

STATISTICIAN (with a first- or upper second-class honours degree in statistics or in mathematics with statistics, and preferably a knowledge of Mercury autocode or Algol) IN THE MATHEMATICS SECTION which is concerned with the solution of a wide range of problems arising from the field of electrical engineering—The Personnel Officer, Electrical Research Association, Cleeve Road, Leatherhead, Surrey.

TECHNICIAN IN CHEMICAL PATHOLOGY for the recently modernized and re-equipped laboratories—Hospital Secretary, Queen Mary's Hospital, Roehampton, London, S.W.15.

GAMBLING ON INNOVATION

THE view that one should not do things for the first time has, of course, a great deal to commend it. Nothing ventured, nothing lost, is as good a proverb as the more familiar version taught to schoolchildren still innocent of disappointment. The difficulty is that caution, however prudent, is the enemy of innovation. A person, a company, or a nation wishing to do something for the first time must be prepared to take a gamble. Good management may limit some of the risks, while zeal, enterprise and hard work can improve the chances of success. Yet all technical innovation entails the possibility of failure and financial loss. Sometimes, ironically, technical success may not ensure financial success. Fortune is not always kind to the innovators.

Considerations like these were not very deeply hidden last week when the British Hovercraft Development Corporation and its associated companies displayed the tiny collection of air cushion vehicles so far produced by the investment of some £10 million in the development of hovercraft. Superficially, of course, the mood was optimistic. For every design in production, there were half a dozen on the drawing boards. By the end of a week of excited talk and speculation, engineers were speaking of trans-Atlantic hoverships almost as if they were accomplished facts. Southampton Water seemed closer to the centre of technological change than it has been since the huge flying boats began to land there in the decade before the Second World War.

In reality, however, hovercraft are still a gamble. Technical problems, of construction as well as operation, remain to be solved before hovercraft large enough to be economically competitive can be put into service. Recent experience has been encouraging, but the venture is not yet certain of success. And there is always the danger that even successful hovercraft will become white elephants because of some more successful but competitive innovation over whose progress the developers of hovercraft have no control. What then should be the strategy of a nation such as Britain towards further investment in risky undertakings of this kind ?

The first thing to be said is that the problem of the hovercraft is a valuable example of the economic dilemma of innovation as well as a nasty conundrum for the United Kingdom. On what scale should development now be supported ? How quickly should the programme be made to move ahead ? Is it best to attack on a narrow front, with the hope that at least some of the investment will return quickly, or is it wiser to look for more distant benefits from a broader programme ?

Questions like these should be in the minds of all who support the development of innovations on whatever scale. A pharmaceutical company looking for a drug to serve some chosen purpose, or a nation wanting to put a man on the Moon, must take a view on most of them. In the nature of things it is no more possible to find a sure recipe for avoiding disappointment than it is to find an algorithm for picking horserace winners. As with horse-racing, however, it is best to know the rules.

The first need is for a hard-headed assessment of the potential benefits and the potential risks of embarking on each particular innovation. Unfortunately the innovators, who share some of the sentimentality of the racecourse, are not always as ruthless as they should be. There is no other way of understanding how, for example, the British and French Governments have decided to invest more than £300 million in the development of the *Concord* supersonic aircraft. The costs are certain to be high, and almost certain to be higher than any estimate prepared in advance. But the chances of recovering them, which depend on selling enough aircraft at a price which airlines think is economic, are bound to be uncomfortably small, if only because of the enormous strength and flexibility of the aircraft industry in the United States. The chances of recovering the development cost several times over, which should be the objective of well directed innovation, is almost negligible.

In less speculative fields it is possible, but unfortunately not habitual, to make much more precise estimates of the balance between risk and reward. Companies planning to develop a new kind of motor-car can usually estimate the demand for their product with some degree of accuracy. The same could and should be done with, for example, developments in machine tools or chemical processes. If technical innovation remains a gamble, it is still possible to estimate the odds and, thus to ensure that neither money nor the efforts of skilled people are rashly put at risk. Doing this should be more commonly regarded as an essential part of the management of modern research and development.

As well as estimating the odds, it is also sometimes possible to take steps to reduce them. In the language of the race-course, it is possible to lay off some bets. Much may be done by diversifying a programme of technical development so as to ensure that the product is not merely a working prototype of a particular design but an assurance of technological skill in a broad field. The guiding principle here is that the costs of a successful development project must be expected steadily to increase as it moves from the laboratory to the workshop and finally into production. This means that it is frequently economic, and certainly wise, to follow several lines of development at the beginning of a programme on the understanding that the less promising alternatives will be weeded out as time goes on.

From this point of view the U.K. Atomic Energy Authority took a great risk when it decided, more than a decade ago, to base all its reactor development on gas-cooled designs. It is lucky that water-cooled reactors did not turn out to be decisively more economic. Now, with hovercraft, there is a case for arguing that the British development should invest modestly in versions that move on rails as well as in versions which move on the sea, for, at this stage, it is not possible to know how the economics of the whole enterprise will work out. Penny-pinching could be a false economy.

The risks of false economy are especially acute when technical developments are competitive. If two organizations are embarked on the same development, the one who first succeeds with it is likely to win a commanding commercial advantage. To come second often brings only meagre rewards. Those engaged in the British hover-

craft development are all too acutely aware of the danger. The British aircraft industry has a long record of this kind of disappointment. The difficulty, of course, is very real. With limited money and limited manpower, it is tempting to cover as much ground as possible by spreading the available effort thinly. The consequence is often to ensure second place—or worse—in everything. In reality there is no escape from hard decisions to invest heavily in some projects and to ignore others.

How are decisions like these to be arrived at sensibly? The first need, of course, is that those responsible for making such decisions should know how complicated is the task. It is now a long time since a man with imagination and a good eye could design an aircraft or, for that matter, a tea-cup. The close interaction between the process of design and miscellaneous activities such as market research and production engineering is a necessary feature of modern technology. Industry is not always aware of its problems—and of the opportunities which their solution may present. Yet it may frequently be too much to ask that particular industries in isolation should make sensible decisions about their own affairs. In the last resort there is no substitute for a well-informed technical community within which there can be a vigorous appraisal of technical problems and opportunities. It is hard not to think that the decision about hovercraft in Britain would be much easier if it had been more widely argued.

AVIATION NO MORE

THE disbandment of the Ministry of Aviation has been talked of for so long that the actual announcement a week ago came as something of a surprise. With Mr. Fred Mulley, the Minister of Aviation, embattled with the other European members of ELDO, and with familiar anxiety about the costs of development projects such as *Concord*, it had begun to seem as if the Ministry's survival was assured for all time. For quite apart from the suspicion that the survival of the Ministry was a part of natural law, there was also the possibility that other ministers would be reluctant to take under the wings the troubles (and the capacity for inviting troubles) which have beset the Ministry of Aviation almost since its formation out of the old Ministry of Supply. But in any event the Ministry is to be dismembered in the summer. Most of it will go to the Ministry of Technology but responsibility for civil aviation, previously a dependant of the Ministry of Transport, will go to the Board of Trade.

The sequence of changes is important because the research establishments of the Ministry of Aviation are the most powerful research and development organizations in the United Kingdom. Though they are by no means exclusively harnessed to the needs of defence research, but on the contrary anxious to diversify their interests as much as possible, the establishments may now be able to make a greater contribution to civil research and development in the United Kingdom. That, at least, is what the Government is hoping. Fortunately the Ministry of Technology has by now lived through its early brashness, and so is unlikely to expect too much too quickly: that could be disastrous for morale at the establishments. The most urgent need is somehow to create the impression that this third major upheaval within three years of the administration of public science will, for the time being, be the last. If that can somehow be accomplished, the Government's hopes may easily be justified.

DECODER MISLED?

Stonehenge Decoded

By Gerald S. Hawkins in collaboration with John B. White. Pp. xiv+202+23 plates. (London: Souvenir Press, 1966.) 30*s*. net.

THIS book is an expansion of two articles in *Nature* (200, 306; 1963, and 202, 1258; 1964). It is tendentious, arrogant, slipshod and unconvincing, and does little to advance our understanding of Stonehenge.

The first five chapters, on the legendary and archaeological background, have been uncritically compiled, and contain a number of bizarre interpretations and errors. The rest of the book is an unsuccessful attempt to substantiate the author's claim that "Stonehenge was an observatory; the impartial mathematics of probability and the celestial sphere are on my side". Of his two main contentions, the first concerns alignments between pairs of stones and other features, calculated with a computer from small-scale plans ill-adapted for this purpose. Their directions were compared with the azimuths of the rising and setting Sun and Moon, at the solstices and equinoxes, calculated for 1500 B.C. Any alignment falling within $\pm 2°$ of one of these eighteen azimuths is accepted, arbitrarily, as "significant". The limit of error adopted is unrealistically large, since experiment shows that such alignments can be laid out with a pair of sighting-sticks to a repeatable accuracy of ± 5 min. Moreover, the assumption that the builders aimed at the full orb of the Sun and Moon, tangent to the horizon, instead of at the first or last flash, is not confirmed by an analysis of the author's (unpublished) tables of vertical errors.

In claiming to have found thirty-two "significant" alignments, Hawkins has in five cases exceeded his own limits of "significance". Furthermore, he has failed to show that his results are due to anything but chance. Even with the most favourable choice of data, no more than six of his alignments can be shown to be significant in the statistical sense. Before these can be accepted, they need to be measured on the site, and not from plans.

Hawkins's second contention is that the fifty-six Aubrey Holes were used as a "computer" (that is, as tally-marks) for predicting movements of the Moon and eclipses, for which he claims to have established a hitherto unrecognized 56-year cycle with 15 per cent irregularity; and that the rising of the full moon nearest the winter solstice over the Heel Stone always successfully predicted an eclipse. This, if substantiated, will provide the best explanation so far of this stone, though it should be noted that no more than half these eclipses were visible from Stonehenge. As for the suggested use of the Aubrey Holes, it may be remarked that a ring of pits, filled up as soon as they had been dug, is not a very practicable form of permanent tally. Moreover, it is questionable whether a barbarous and illiterate community (for this is Stonehenge I, not Stonehenge III), which has left us no other evidence of numeracy, could successfully have recorded the data needed to establish a cycle which exceeded the contemporary life-span, and could not even have been recognized as a cycle until several generations had elapsed.

The fundamental objection to this and to other equally unconvincing suggestions in this book arises from the false logic of Prof. Hawkins's working hypothesis, declared in the preface. "If I can see any alignment, general relationship or use for the various parts of Stonehenge," he says, "then these facts were also known to the builders." As he so truly adds in the next sentence, "Such a hypothesis has carried me along over many incredible steps".

R. J. C. ATKINSON

BARE BONES OF HEREDITY

Towards an Understanding of the Mechanism of Heredity

By H. L. K. Whitehouse. Pp. xii+372+4 plates. (London: Edward Arnold (Publishers), Ltd., 1965.) 55*s*. net.

THE problem of presenting genetics has radically changed in the past 10 years. Formerly, the subject having become the connecting framework of biology, the most obvious requirement was to explain its connectedness. This task was fairly straightforward. A common chemical basis for heredity, certain universal principles of differentiation, processes of evolution experimentally demonstrated, a mechanism known to control differentiation and evolution and also to be subject to them, these together offered us a wide choice of connected treatments.

To-day the task is more complicated. New mechanisms of heredity have been discovered which are understood at different levels and with different degrees of exactness. Their evolutionary connexion is not yet fully clear. Their chemical relationship is uncertain. Their physiological scope, owing to the range of size between bacteria and the higher organisms, is sharply contrasted. The experimental evidence in the new fields is fragmentary and sporadic. We may give the name of chromosomes to the structures responsible for heredity in all organisms. And we may agree that they are all based on DNA. But we also know that the organization of the DNA is of different kinds and the mechanisms which they operate may therefore vary in character.

In these circumstances an attempt to present the whole story in one volume is bound to seem hazardous and even heroic. Dr. Whitehouse has understood this and has attempted to get round the difficulties by a radically new approach. Let us, he says in effect, put crossing over in the centre of the field and let us try to separate the mechanism of heredity from its biological background. Let us in this way cut out the evolutionary and physiological trimmings and show the bare bones of the subject.

How does the method work? Undoubtedly the result provides a review and an interpretation of the whole subject, unified, documented and illustrated, in the way a research worker needs. The account proceeds in historical order of study, beginning mainly with the higher organisms. Here, outside the field of crossing over, Whitehouse refers to gene action, nuclear-cytoplasmic reactions, plastid inheritance, sex determination, and the induction and analysis of mutation. Within the field of crossing over he discusses some of the consequences of structural hybridity. He sacrifices genotypic control and its relation to the breeding system, which is a pity as they throw light on several aspects of the strictly mechanical problem. Also at this point he makes one commonly repeated mistake, derived probably from Morgan. He refers to Janssens as supposing that the structure of a chiasma and the event of crossing over had one character, one origin and one connexion. In fact Janssens' theory was not this at all. He assumed every conceivable kind of character, origin and connexion for them; and one of his assumptions for the connexion we now believe to have been correct.

It is in the fields of micro-organisms, however, that Whitehouse comes to grips with the problem of crossing over on the chemical level and makes his own original interpretations. Here he meets the difficulty of reconciling his views of micro-organisms with the properties of chromosomes in the higher organisms. He overcomes it by supposing that the chromosomes of the higher organisms are composed of single DNA molecules. The known variations in the size of chromosomes and of their DNA contents, however, do not allow this view.

They are usually multiples; they are also variable multiples; and the degree and timing of their multiplication, as recent observations have shown, vary under genotypic control. The multiple (or polynemic) DNA molecule creates several theoretical difficulties. It not only excludes Dr. Whitehouse's attempt to reconcile chromosome structure in different classes of organisms; it also, as was realized 30 years ago, introduces problems for the theory of gene mutation. But we must not think we can reach quick conclusions by ignoring a part of the evidence.

These are examples of the kind of questions, new and old, that will arise from reading Dr. Whitehouse's book. And his book will have to be read by those who want to answer them.

C. D. DARLINGTON

TWO VIEWS ON INSECTS

Basic Arthropodan Stock with Special Reference to Insects

By A. G. Sharov. (International Series of Monographs in Pure and Applied Biology, Division: Zoology, Vol. 30.) Pp. xii+271. (London and New York: Pergamon Press, Ltd., 1966.) 80*s*. net.

A LACK of distinction between fact and fiction characterizes this book. The author's views, for which there is frequently no evidence, are put down as if they were accepted facts. The uninformed reader, seeking information, can have no clue as to what is factual and reliable and what is not. For example, we are told that the Onychophora are a side branch of the Annelida, with no evidence given, and no consideration of the now considerable body of evidence derived from studies on functional morphology. Then we are told what happened to the ctenophore-like ancestor of the Articulata when it became a creeper, as if this was an established fact. Further, the Spintheridae are stated to be the most primitive of present-day Polychaeta, but in fact they are highly specialized Amphinomidae, entirely lacking in the attributes described by Sharov which form the keystone for his view on the origin of the Arthropoda. *Spinther* possesses polychaete parapodia of a specialized nature, not lobopodia. The anterior segments do not become preoral; the "cyclometry" of the adult has nothing to do with ctenophore ancestors and is entirely absent in the young worm which has normal worm-like proportions of its body and an almost terminal mouth. Turning to the Arachnida, we find many statements which are unacceptable to workers on this group. That the Pedipalpida originated from the Eurypterida is pure conjecture. Errors of facts, often several per page, occur throughout the book.

Conclusions of others, based on good evidence, are set aside or altered to mean something contrary. For example, it is said that Tiegs and Manton consider that the Myriapoda were derived from the Onychophora. Neither of these authors has ever at any time expressed such a view. Their suggestion that the Myriapoda and Onychophora may have had a common origin, and that they stand closer to each other than to any other group of invertebrates, is an entirely different statement, and it is based on facts. Similarly, an extra segment (labial) is pushed into the head of Crustacea by Sharov, in defiance of the abundant good work on crustacean embryology published since 1928. An extra segment is also planted into the onychophoran head; no distinction is made between a statement by Pflugfelder[1] concerning an embryo of *Paraperipatus* and the close series of stages belonging to four species of *Peripatopsis*[2,3]. Ten years of work on hundreds of embryos of *Peripatopsis* was summarized by a selected series of accurate reconstructions. It happens to be usual for the cavities of the anterior somites of these Onychophora to arise from several initial spaces which then rapidly fuse. This is no evidence for the existence of multiple anterior segments, and the super-

structure of classification and so on based on this erroneous concept of head segmentation is valueless.

The basic organization of the Arthropoda is scarcely considered. Instead we have a series of topics. But a dissertation on primary and secondary segmentation puts back the clock on those that have preceded it. Havoc is made of the known facts concerning the composition of the head in Arthropoda. The error of Snodgrass[4] concerning his suggested protocephalon of the Anostraca, erected on false premises[5], is built on. The confines of the acron are not precisely appreciated, nor the fact that anterior segments are frequently not cylindrical, the dorsal part of the head being derived from unsegmented embryonic tissue[3,6,7].

The account of trunk segmentation and of leg structure is equally fallacious. What Sharov calls paratergal lobes in Crustacea, most persons would regard as pleural. We are now beginning to have accurate information concerning the significance of the structure of the pleuron, leg-base and leg structure in arthropods[8–10]. A first essential is accurate information, both of structure and of usage. Sharov's whole discourse on legs is perverted in support of the monophyletic idea of arthropod evolution.

A short text-book account of the Monura and Thysanura precedes a consideration of the derivation of the Pterygota from Thysanura-like animals.

Only at page 218 do we come to brief reference to the internal structure of arthropods. But at once we are confronted not with essential anatomy, but with speculations put down as facts. Non-speculative data and sounder ideas based on facts are passed by.

The "new principles of classification" of the lower Arthropoda emerging from this welter of distortions and inaccuracies are without value. For example, the Arachnida are not composed of the five listed classes but of at least sixteen; the Merostomata comprise the Xiphosura *and* the Eurypterida; the simplification of the Crustacea is not helpful here, although Dahl was at liberty to discuss the possible relationships between the recognized classes. The structure of the proboscis and its mode of action in *Spinther* and in the Pyconogonida are entirely different. The proboscis of *Spinther* is not even typical of the Polychaeta, but is unique. The extrusion mechanism is dependent on septa, septal muscles and coelomic pressure. The evolution of an arthropodan haemocoel in a *Spinther*-like animal would render the proboscis mechanism inoperative. Functionally, therefore, there is no basis whatever for Sharov's suggested Proboscifera exhibiting an early arthropodan stage of evolution. Then, the categories Dignatha and Trignatha are used as taxa for which there is now no justification; these terms indicate grades of advancement, not relatedness of the constituent animals[5]. The weighty evidence against the validity of the Mandibulata is not considered, although the data are included in the references. Neither is evidence mentioned which is against the supposed crustacean origin of myriapods or the proto-symphylan origin of insects. Even the Scutigeromorpha among centipedes are claimed to be the most primitive members of this class although there is abundant evidence to the contrary[9].

The whole book purports to prove the accuracy of the ideas of Snodgrass[11] concerning the monophyletic evolution of the Arthropoda, and fails most thoroughly. Snodgrass himself, had he lived, would have been broadminded enough to have reorientated his ideas in the face of the newer evidence

BRITISH ANIMAL MEDICARE

Animal Health

A Centenary 1865–1965—a Century of Endeavour to Control Diseases of Animals. (Ministry of Agriculture, Fisheries and Food.) Pp. xvi + 396 + 30 plates. (London: H.M.S.O., 1965.) 80*s*. net.

OCTOBER 1965 was the centenary of the Government veterinary service in Britain and to mark the occasion the Ministry of Agriculture, Fisheries and Food published a historical survey of official veterinary activities in Britain which had started in 1865 with the formation of a Veterinary Department of the Privy Council to deal with a disastrous outbreak of cattle plague, and which had been carried on since then without a break by various bodies, culminating in the Ministry's Animal Health Division of the present day.

During that period, the State Veterinary Service has achieved many notable successes in the control and eradication of the more serious diseases of farm animals; cattle plague, contagious bovine pleuro-pneumonia, epizootic lymphangitis, rabies, glanders, psoroptic and sarcoptic infestation of horses and sheep have all been eliminated, bovine tuberculosis virtually so, and swine fever is apparently well on the way to final eradication; increasing success is being attained in keeping foot-and-mouth disease from these shores while the sporadic cases of anthrax which occur are kept well under control. This is a record of which the Division can well be proud and it is to be congratulated on setting down the story of its vicissitudes in such detail, as this could provide a useful guide, both to further veterinary activities in Britain and to developing countries which have still to undertake the tasks tackled by the British veterinary service over the past century.

Animal Health is divided into three main sections. The first is a general historical review describing the evolution of the Animal Health Division; then a long section dealing with the activities of the Division, including a description of the main animal diseases with which it has to deal; and finally a brief description of the international veterinary scene followed by a discussion of the principles and practice of veterinary preventive medicine.

The historical survey, divided into two main sections, namely, 1865–1914 and 1915–1965, concentrates on the most important events in disease control in Britain during the past 100 years. Taken presumably largely from official reports which it extensively quotes, this is probably the least readable, though possibly the most important section of the book and it is one to which future veterinary historians will undoubtedly find themselves indebted. By contrast, the section on animal health responsibilities, dealing as it does *in extenso* with individual scheduled diseases and various others with which the Division has to deal, will be of more general interest. The various diseases are well described along with the measures taken for their control and eradication, the difficulties—technical and administrative—that were encountered and the steps taken to overcome them. The effects of these measures in relation to the notifiable diseases are graphically shown in a series of charts illustrating fluctuations in disease incidence over the past 100 years.

The second part closes with a chapter outlining the research and investigation services of the Division. This deals at some length with the development and activities of the Central Veterinary Laboratory at Weybridge and its subsidiary at Lasswade near Edinburgh. There is also a short account of the Veterinary Investigation Service which acts in a consultative capacity assisting veterinary surgeons in practice to deal with unusual flock and herd problems and carries out investigations into animal disease problems of local concern..

Part 3 describes the activities of various international organizations concerned with animal health and disease

such as the World Veterinary Association, the Office International des Epizooties and the Food and Agriculture Organization of the United Nations. The Ministry's Animal Health Division has played an important part in building up and supporting such bodies, the importance of which has grown with the enormous increase in international traffic in livestock and their products and with the need to devote ever increasing attention to animal disease problems of developing countries in the war against want. To such countries in particular the final chapter dealing with the principles and practice of preventive-medicine will be of special significance. A. ROBERTSON

NEW INTERNATIONAL REFERENCE ATMOSPHERE

CIRA 1965

Cospar International Reference Atmosphere 1965. Compiled by the Members of Cospar Working Group IV. (Committee on Space Research established by The International Council of Scientific Unions.) Pp. xi+313. (Amsterdam: North-Holland Publishing Company, 1965.) 54*s*.

SINCE the advent of the first artificial satellite in 1957 a great deal has been learnt about the Earth's upper atmosphere. On the basis of the earliest results, the Committee on Space Research started work on a reference atmosphere in 1960 and the first tables were published towards the end of the following year under the title *CIRA 1961*. Over the next few years many new results were obtained for different levels of solar activity. A new set of tables has, therefore, been compiled by members of Cospar Working Group IV, and is known as *CIRA 1965*, although much of the tabulation was complete by May 1964.

The reference atmosphere is presented in three parts, each of which is preceded by a description of both the observational data and the methods used in the construction of the tables. Part 1 was prepared by K. S. W. Champion and gives the mean atmospheric structure for heights between 30 and 300 km. The maximum and minimum departures of the atmospheric properties from their mean values are also indicated. Part 2 is concerned with the atmospheric structure and its variations in the region from 30 to 80 km. This section was prepared by G. V. Groves using data obtained from a large number of rocket firings; temperature, pressure, density and west-to-east wind components are all given as functions of latitude and season.

The largest section, Part 3, was prepared by I. Harris and W. Priester and contains tables of density, temperature, pressure, scale height, mean molecular weight and number densities for heights between 120 and 800 km. This region of the atmosphere is under strong solar control and exhibits several different types of variation. The atmospheric properties are tabulated at two-hourly intervals of local time for ten levels of solar activity, the radiation flux on a wave-length of 10·7 cm being taken as the index of long-term solar activity. Although the procedure for interpolating the tables to give the atmospheric properties at any particular time appears complicated at first sight, it is not difficult provided one has ready access to geomagnetic indices and solar flux data. There are two deficiencies in Part 3: first, the reference atmosphere applies only to the equatorial and temperate zones of the Earth and, secondly, there is now evidence that the magnitude of the diurnal variation in density is under-estimated in the region below 200 km for conditions of low solar activity. An additional parameter, which could usefully have been tabulated in this part, is the density scale height.

Two review papers are included as appendixes. In the first, K. S. W. Champion discusses the structure of the lower thermosphere, which comprises the region between 100 and 200 km. It is a pity that, in an otherwise admirable paper, the author should have perpetuated Izakov's error in believing that King-Hele's values of density can be improved by juggling with values of drag coefficient and density scale height. In the second review, L. G. Jacchia gives an extremely lucid account of the structure and variations of the atmosphere above 200 km. Recent results have shown, however, that he was too pessimistic when discussing the possibilities of evaluating density above 600 km at solar minimum.

CIRA 1965 represents the most detailed tabulation of upper atmospheric properties that has ever been attempted, and Cospar Working Group IV is to be congratulated on the result. The discussion in each part and the two review articles ensure that the reader is fully aware of the limitations in the data which were used to compile the model. G. E. COOK

LAWYERS AND MONOPOLIES

Competition and the Law

By Alex Hunter. (University of Glasgow Social and Economic Studies.) Pp. 328. (London: George Allen and Unwin, Ltd., 1966.) 45*s*. net.

THE modern British economy, at least in its large private sector, is theoretically one of private enterprises operating in competition. But it has been well known for years that that competition has not been free or unfettered. The period since 1945 has seen significant investigations into the degree of competition, and the increased realization of the limits on competition imposed by the enterprises themselves has provoked Parliamentary attempts, by legal means, to loosen these fetters and to restore greater freedom of competition.

Competition and the Law is an economist's examination of what has become a field of interest to both economists and lawyers, as well as to industry and commerce themselves, and made, moreover, by a scholar who has had personal experience of the systems of investigation and control, having assisted and advised on some of the early cases prepared for the Restrictive Practices Court. It is naturally, therefore, on the economic side that this book is strongest and most interesting; on the legal side it is at times rather shallow and cursory.

The first part comprises three chapters dealing with the background, the relevant economic theory and the measurement of monopoly power. They bring out the increasing concentration of industry and economic power in Britain, and the steady movement towards mergers which have tended to produce oligopolistic groupings in which the few (Table 1 takes as its basis the three) largest enterprises in given industries have a predominant share in net output and in percentage employment within that industry. Thus in 1958 in the man-made fibres industry the three largest enterprises had 89 per cent of the net output and 81 per cent of the employment; but equally in three-quarters of industries in that year the three largest enterprises had less than 50 per cent of either net output or of employment. The tendency to oligopoly production in the large-scale process industries is clear, and is even more clear in the cases of some sub-industries such as transmission chains and cotton thread.

The second, and much the longer, part of the book is an examination and criticism of the body of legislation in force in the United Kingdom as at mid-1965. (It is the author's, and the reader's, misfortune that the Monopolies and Mergers Act, 1965, was passed too late to be taken into account in the book.) In discussing the legal doctrines which existed before 1948 (and still exist, so far as not superseded by legislation) there might have been mention of much earlier legislative attempts to grapple with substantially the same problems, such as the Scots Acts

of 1535, 1540, 1579 and 1592 against forestalling and regrating, and the English Acts of 1266, 1353, 1533 and particularly of 1549 and 1552 on the same subjects.

Prof. Hunter discusses the legislation setting up the Monopolies Commission and its work, particularly the general Report on Collective Discrimination of 1955, which led to the Restrictive Trade Practices Act, 1956. This Act is in turn examined very thoroughly, particularly the fundamental Section 21, which established the rule that a restriction in pursuance of any agreement under review was to be deemed contrary to the public interest, unless the Court were satisfied of at least one of seven stated sets of circumstances, and also that the restriction was 'not unreasonable'. The author devotes two chapters to the operation of judicial review, as exemplified by the cases hitherto contested, considering the criteria established by the Act, and various defects in the processes.

Prof. Hunter then turns to resale price maintenance, which is a newer subject of judicial control and on which we have as yet no judicial guidance and where the operation of the legal control has yet to become apparent, and concludes by discussing monopoly, oligopoly and merger. In general Prof. Hunter finds the present system satisfactory; indeed, he considers the Monopolies Commission "an investigatory instrument of great flexibility and potential range", but he has a number of recommendations for change in the present legislative structure, most of which appear to have substantial merit.

The book is very readable, despite an unfortunate number of phrases masquerading as sentences, and not overburdened with technicality, and its carefully analysed exposition of the present situation presents a clear and fair picture.

DAVID M. WALKER

MAGNETISM DIGEST

Magnetism and Magnetic Materials

1965 Digest—a Survey of the Technical Literature of the Preceding Year. Edited by R. L. White and K. A. Wickersheim. Pp. xiii+260. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 88*s*.

THE problem of keeping abreast of the scientific literature in any field of research is immense. As a partial solution to this problem, for several years the American Institute of Physics and Institute of Electrical and Electronic Engineers, on the occasion of their annual conferences on magnetism and magnetic materials in the United States, have sponsored the production of a *Magnetic Materials Digest*. These volumes contain references, drawn from a large number of sources, to work in the field of magnetism and magnetic materials published in the preceding year. They therefore provide a very convenient way of surveying the work done in a particular field of magnetism over the previous years.

The 1965 *Digest* differs slightly from its predecessor. There has been a change in title to emphasize that it is not a manufacturer's source book and the volume has a new, improved format following a change in publisher. Those readers familiar with previous volumes in the series will find the usual changes in chapter and section headings reflecting the changes of interest and emphasis in magnetism research. The Bell Telephone Laboratories *Index to the Literature of Magnetism* has again been the principal source of references, more than sixteen hundred of which are listed, the great majority having been published in 1964.

If the number of publications is taken as a measure of interest in a topic, then for 1964, non-metals, theory, soft magnetic materials and thin films head the list in that order. However, these numbers may be misleading because the contents of some papers are such that they are, or could have been, referred to in more than one chapter. An outstanding example is that of the chapter on superconductivity which in *Magnetism and Magnetic Materials* has nineteen references compared with 208 in the *Digest* for 1964. Many of the papers on superconducting phenomena now appear in their more natural places rather than in a special chapter of their own.

J. H. PHILLIPS

SCIENTIFIC BIOGRAPHIES

Geschichte der Mikroskopie

Leben und Werk Grosser Forscher. Herausgegeben von Hugo Freund und Alexander Berg. Unter Mitarbeit Namhafter Autoren. Band 1: Biologie. Pp. xv+375. Band 2: Medizin. Pp. xv+506. (Frankfurt am Main: Umschau Verlag, 1963, 1964.) n.p.

VOLUMES 1 and 2 of *Geschichte der Mikroskopie* form the first in a collection of short biographies of scientists written mostly by German authors. A third volume dealing with the physical sciences and technology is in preparation. Despite the title, most of the subjects are people who have used the microscope as a tool and only a minority have made any contribution to microscopy as such. Judging from modern experience, one might comment wryly that possibly many of them had little knowledge of either the instrument itself or of the proper way to use it. A sceptic might answer that this is unimportant because optics is such a poor way of forming images in any event; after all, even a perfect lens trying to form an image of a point source only manages to get about 84 per cent of the light anywhere near the right place! All the same, one might still wish to see fewer stopped down or lowered condensers, badly tilted mirrors and uncentred lamps at allegedly scientific demonstrations.

Volume 1 begins with a general review by the editors covering the history and the development and applications of microscopy. The treatment is inevitably sketchy and occasionally irritating, as when the name of C. R. Burch is omitted from the discussion of reflecting microscopes. The bibliography, however, is quite extensive and useful. In general the bibliographies are one of the most valuable features of the book; each chapter is followed by a selection of the papers of the subject himself as well as related references. Another pleasant feature is the inclusion of a good photograph or portrait of each subject.

It is only to be expected that major prominence is given to German scientists. In Volume 1, for example, no British names appear and only four American (Chambers, McClung, Minot and Wilson) out of a total of thirty articles. One might have thought that at least one out of Brown, Bowman, Hardy, Sharpey-Schäfer or Strangeways merited inclusion. Histochemistry is poorly represented and Raspail, one of the founders of the subject, is not mentioned. W. Flemming, the great German cytologist, and the Swede, Retzius, who produced such a fantastic volume of illustrated work with the microscope, are other surprising omissions.

Volume 2, dealing with medicine, contains forty-six articles, of which three are on American and three on British workers. The latter include Alexander Fleming and Grafton Elliott-Smith; truly the word 'microscopy' is liberally interpreted!

When all this is said, however, these books do make pleasant reading and several of the great names in microscopy such as Abbé, Harting, Köhler, Naegeli, Schwendener, Strugger, Ambronn, Purkinje and Valentin are to be found, as well as a host of others distinguished in the use of the microscope as an essential tool in their biological or medical research. Collections of this sort can always be criticized for their choice of material but on the whole this is a welcome addition to the literature of scientific biography.

R. BARER

Kempe's Engineers Year-Book for 1966

Edited by C. E. Prockter under the direction of B. W. Pendred. 71st edition. Vol. 1: Pp. xiv+1356. Vol. 2: Pp. 1399. (London: Morgan Brothers (Publishers), Ltd., 1966.) 95*s*. net the two volumes.

A NEW edition of *Kempe's Engineers Year-Book* is an annual event, though recent editions differ only slightly one from another in their content of data and descriptive matter relating to most branches of engineering, with references to original sources.

This seventy-first edition has one new chapter on rubber as an engineering material. The chapters on legal notes for engineers, nuclear energy and grinding and abrasive processes, respectively, have been rewritten; otherwise there are additions and minor modifications to a number of chapters. Noteworthy among the additions are rocket engines, including theory and fuels; details of positive displacement rotary flow meters and density metering; theory of detonation and explosive forming and electric instruments for linear measurement (surveying). Mention of the design criterion afforded by the plastic theory of ultimate load-carrying capacity of structures, in the chapter on design of steel structures, is a significant though minor improvement. Further revision of the chapters on theory and design of structures in respect of modern criteria and data, including flexibility and stiffness coefficients of structural members, would improve future editions.

The chapter on mining engineering will presumably require revision soon to take account of advances in automation in coal-mining and the re-organization of the National Coal Board which is taking place this year.

Useful as they are, these volumes could, it is believed, be improved substantially in respect of design charts and data. For example, tables of hyperbolic functions would improve the mathematical data provided, and water hammer and surge charts would be useful additions to the chapter on water engineering. Such additions could be made at the expense of descriptive material relating to obsolescent plant and equipment and theoretical matter which is readily available in elementary textbooks.

T. M. CHARLTON

Physics of Nuclear Fission

Edited by N. A. Perfilov and V. P. Eismont. Translated from the Russian. Pp. vi+210. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1964.) 63*s*.

THIS book consists of twenty chapters on various aspects of fission, varying from general topics like "Asymmetry in the Mass Distribution of Fission Fragments" to highly specialized ones like "Radiochemical Study of the Isotopes of the Rare-earth Elements formed in the Photofission of Uranium". Some chapters are short review articles, while others are accounts of single experiments. However, the original Russian edition, of which this book is a translation, appeared in 1962, and the latest references are (inevitably) to work published in 1961.

If this work had appeared in translation in a review journal in 1962 or 1963 it could have been recommended, but its present appearance in hard covers seems entirely pointless.

B. ROSE

Mechanisms of Hormone Action

Edited by P. Karlson. (A NATO Advanced Study Institute, Meersburg/Bodensee, 20–26 Mai, 1964.) Pp. xii+275. (Stuttgart: Georg Thieme Verlag; New York and London: Academic Press, 1965.) 49.80 D.M.

MECHANISMS of Hormone Action records the proceedings of the North Atlantic Treaty Organization advanced study institute held in Meersburg, Bodensee, in May 1964. At this conference there were twenty-five participants from Germany and thirty-one from other European countries and the United States. The intention of the conference was to invite experienced researchers to present results and discuss their ideas in detail and so to stimulate their younger colleagues in the development of new and independent research. Altogether twenty-one papers were presented, in English, French and German, under three main headings: "Hormone Action by Control of Enzyme Activity"; "Enzyme Action by Changes in Permeability"; and "Hormone Action by Gene Regulation and Enzyme Induction". A synopsis of the discussion is also included.

The idea of considering the mechanism of action of hormones under a number of headings is a useful one. It is perhaps not only a reflexion of the interests of those devising the programme of the conference but also an indication of the volume of published work and of general tendencies of thought that forty pages of the text are concerned with hormone action by control of enzyme activity, while ninety-eight pages are devoted to the subject of hormone action by changes in permeability; hormone action by gene regulation and enzyme induction takes up 137 pages of text. Of course some overlap between the subject-matter in these three sections is inevitable, but the relative weight of the sections is almost certainly significant.

To me, the absence of an index to this book is a definite disadvantage. Although the argument might be put forward that the preparation of an index could delay seriously the production of the volume, the extra time involved is surely less serious than the diminished usefulness of the book for purposes of reference which inevitably results from the absence of an index. If a scientific book is worth printing and publishing at all it is, in my view, worth indexing even at the expense of a little delay in publication. Apart from this blemish the book is well produced and the diagrams and photographs (numbering 115 altogether) are excellent.

F. G. YOUNG

Libraries in the Modern World

By George Chandler. (The Commonwealth and International Library of Science, Technology, Engineering and Liberal Studies: Library and Technical Information Division.) Pp. vii+164. (London and New York: Pergamon Press, Ltd., 1965.) 17*s*. 6*d*. net.

IT is a valid criticism of some books that the author has never made up his mind as to the type of reader he is addressing. When an author frankly admits that he is aiming at several levels of readership and disclaims satisfying any single level, the critic can be disarmed. Nevertheless, Dr. Chandler is fully justified in his hope that the various levels of readership will be sufficiently repaid for purchasing *Libraries in the Modern World*. The skill with which he contrives to display a balanced but accurate picture of all types of libraries, their activities and interrelations matches his candour, and the chief criticism that can be made of his effort is that he includes no reference to the various, more detailed accounts of particular classes of libraries which would enable the reader to pursue a particular interest further.

Dr. Chandler describes first the international function of libraries. This chapter alone contributes something towards the formation of the informed public opinion on the whole subject of the library service which is needed in Britain. Chapters follow on local public libraries, on academic libraries, private libraries, industrial libraries and on national special libraries, while finally there are two chapters on international libraries and documentation services and on international and national library associations. The chapters are not all of equal merit and that on industrial libraries is rather patchy and has some surprising omissions. None the less, if due regard is paid to such limitations, Dr. Chandler has provided what could be a useful introduction to a wide range of readers interested in one aspect or another of the use and management of libraries.

R. BRIGHTMAN

A POSSIBLE GENETIC BASIS FOR SPECIFIC PATTERN IN ANTIBODY

By SIR MACFARLANE BURNET
School of Microbiology, University of Melbourne

IN the original formulation of the clonal selection theory of immunity[1], it was suggested that the necessary range of immune patterns might arise if "at the appropriate stage of development a limited genetic determinant carrying the coding responsible for globulin pattern releases control in such a fashion that purely random arrangments are allowed" (ref. 1, p. 60). Since 1958–59 there have been great advances in the understanding of protein structure and particularly of the structure of immunoglobulins (see, for example, ref. 2). In addition, there has grown up in the past 10 years an intense interest in the evolution of chemical pattern in proteins which may well have a very important bearing on the antibody problem. It seems appropriate, therefore, at this time to attempt to rephrase the above quotation in the light of recent developments.

Structure of Immunoglobulin G Antibodies

It is generally accepted that an IgG antibody molecule is an elongated flexible structure of dimensions, according to Edelman and Gally[3], of 240 × 54 × 19 Å. It is symmetrical in character with specific combining sites at each end. The physical character of the combining sites is unknown, but it is accepted that they represent a configuration of parts of the peptide chains making up the macromolecule.

Appropriate treatment with proteolytic enzymes, reducing agents capable of splitting disulphide bonds, and detergents has provided a series of large fractions the interrelations of which are conventionally shown in Porter's well-known diagram[4] (Fig. 1). This shows four chains held together by three (or five) disulphide linkages. The two light chains have a molecular weight of about 25,000 with 212 amino-acid residues[5]; the heavy chains with a molecular weight of 55,000 ± would have ± 450 residues. Attached to the heavy chains is an oligosaccharide unit containing galactose, mannose, fucose, acetylhexosamine and sialic acid[6].

In man, the light chains have a common character in all types of normal immunoglobulins and are found in most types of myeloma proteins. The Bence-Jones proteins found in the urine of myelomatosis patients appear to be identical with light chains[7]. There are two serological types of light chain characterized by antigens κ and λ.

Recent work from several laboratories is consistent with the finding first announced by Hilschmann and Craig[5] that the light chains of myeloma proteins have two halves each comprising 106 residues which are strikingly different in character[8,9]. Most work has been done with proteins the light chains of which are of κ type, but it seems clear that, apart from differences in the sequence

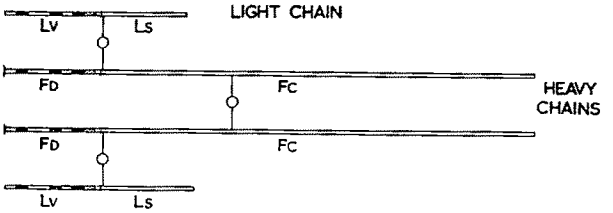

Fig. 1. A modification of the Porter diagram to illustrate the hypothesis of four "variable" sub-chains all of the same pattern

of the C-terminal region related to the L–K antigenic difference[10], all light chains are made up in essentially the same fashion. The C-terminal half of κ-type light chains is identical in the three that have been investigated except for single residue replacements at three points. One of these, No. 189, is of special interest because replacement of leucine by valine is associated with a change in allotype from INVa to INVb (refs. 8 and 11). The N-terminal half, residues 1–106, differs strikingly from one myeloma κ protein to another. Milstein finds an indication in one that even the cysteine residues can be displaced. It is clear (*a*) that the C-terminal half is a typical polypeptide chain controlled by a stable cistron and subject only to rare mutational replacement of single residues, and (*b*) that the N-terminal half must have an entirely different type of genetic control. Yet, because this half is uniform in all myeloma protein molecules produced by the single clone of neoplastic cells, it is evident that there is firm genetic control during at least the productive phase of the disease. It is scarcely conceivable that the controlling sites in the genome are in the same cistron, and for ease of discussion we may speak of Ls (stable, C-terminal) and Lv (variable, N-terminal) sub-chains.

The heavy chain is not so amenable to investigation and no amino-acid residue sequence has been published. It is evident from the work of Meltzer *et al.*[12], Franklin *et al.*[13], and Franklin[14] that the crystallizable fraction Fc is of uniform structure apart from the presence or absence of two peptides which are correlated with the Gma+ or Gmb+ allotype antigens. Tryptic peptide maps of myeloma protein heavy chains show additional spots individual for each protein and therefore presumably carried on the Fd segment. In the comparable position in similar tests on normal IgG heavy chain there is much weak 'background', and this indicates that there is great heterogeneity in these peptides[15]. It seems certain, therefore, that the heavy chain, like the light chain, is composed of a variable Fd and a stable Fc segment. So far as I know, there is nothing to exclude the possibility that Fd and Lv are identical.

Nature of the Combining Site

Appropriate manipulation of fragments and recombined fragments of IgG antibody has shown:

(1) That half molecules containing one light and one heavy chain can bind specifically to antigen but have no precipitating power[16,17]. They can be recombined from two antibodies to produce hybrid antibody molecules never found in Nature[18].

(2) Separated light chains have only very little or no binding power for antigen (hapten). Separated heavy chains usually have definite binding power, but this is greatly increased when homologous light chain is recombined with it[19,20].

(3) Light chains recombine specifically with homologous heavy chains to re-create full biological activity[21]. According to Metzger and Mannik[22], this is more striking if the corresponding antigen is included in the system.

(4) It is possible to investigate the combining site directly by using hapten either to shield the site from iodination, etc., "pair labelling"[23,24], or when appropriately modified to transfer tritium label to amino-acids in the site ("affinity labelling")[25]. Results are consistent in showing

that both light and heavy chains are involved[24,25]. The first group using pair labelling found most of the shielded residues in the light chain, while with affinity labelling both are involved.

(5) In a report which is in the course of being published, Doolittle and Singer[26] present evidence that similar peptides are labelled in both light and heavy chains. The peptides from the two chains concur in the average size of the labelled peptides, their hydrophobic quality and the range of heterogeneity.

There is a relatively simple hypothesis which satisfactorily covers all these findings and which could be tested experimentally. This is that the binding site is composed of a loop in which two identical chains Fd and Lv lie congruently, residue to residue, either parallel or in spiral relationship. This chain is controlled by a specific cistron *V* (variable) and is represented four times in the IgG molecule.

Fig. 2 suggests the disposition of such a duplex chain at one end of the IgG molecule. The primary requirement of a combining site is that it should present a specific adsorptive pattern that is constant in character and uniquely differentiable from the essentially random configurations of portions of other polypeptide chains which make up the surface of the macromolecule. The simplest unique quality that could be applicable to a wide variety of random patterns is that two (or more) strands of identical character should lie in parallel or helical contact with each residue matched with its equivalent residue on the other chain. Many more complex arrangements could be imagined, but the one suggested has the advantage that it can in principle be tested simply by establishing the sequences at the N-terminal end of the light chain and of the Fd section of the heavy chain with due regard to the fact that the N-terminal amino-acid is blocked on this chain[27].

In addition to the findings already noted, this hypothesis accounts for the symmetry and equivalence of the two combining sites, and for the similarity, sometimes very striking[28], of the specificity and avidity of IgM and IgG antibody when the change over from M to G occurs. It also requires a much smaller degree of phenotypic restriction than if the immune pattern is controlled by a number of separate genetic segments and leaves open an approach to the sub-cellular transfer of genetic (immunological) information if future experimental results should establish the occurrence of such processes.

Somatic Mutation as a Source of Diversity

The obvious implication of the hypothesis by which each combining site is composed of two identical chains varying widely from one IgG to another is that they are controlled by a single cistron of quite unusually labile character.

A rough calculation suggests that at birth a child may possess of the order of 3×10^{10} stem cells, thymocytes and lymphocytes which have undergone 32+ cell generations from the fertilized ovum. To ensure that at birth at least one amino-acid replacement from the initial pattern had occurred in all cells would require a mutation rate of $1 : 10^{4}$ per nucleotide per cell generation. This is the same order of frequency as the phage mutation *T2r*$^{+}$ to *T2r* (ref. 29). Even more relevant is the existence of 'hot spots' of high mutability in the phage *T4* (ref. 30), and the fact that with bromuracil the mutability of a given locus may be raised to 10^{4} times the spontaneous rate. The possibility of an unduly high mutation rate in a mammalian cistron cannot therefore be excluded *a priori*.

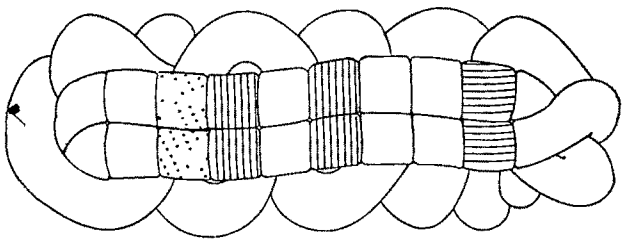

Fig. 2. A diagram to indicate the possible arrangement of a duplex polypeptide as combining site at the end of an IgG antibody. The cross-section of the molecule has been taken as 54 Å × 19 Å and the average effective size of an amino-acid residue as 5 Å.

From an examination of the first accounts of amino-acid sequence in the Lv chain of three myeloma proteins, the results quite closely resemble what is found in comparative investigations of the structure of haemoglobin—including the relation of myoglobin and the individual globin chains (reviewed by Zuckerkandl and Pauling[31]) and of cytochrome *c* (reviewed by Margoliash and Smith[32]). Perhaps the most important impression one gains from this work on species differences in proteins is the random character of the changes that have occurred in the course of evolution. The number of invariant groups in the globin chains, that is, residues constant in position through the whole of the available material, has now fallen to 11 in 150–160, and Jukes[33] has published a table indicating that the number of alternatives known for each site gave a distribution very close to a Poisson one with a mean of 2·1 alternatives per site. Similarly, the lengths of sequences which are invariant in the cytochrome *c* material from yeast to man also show a close approach to a Poisson distribution. In evolutionary changes the important matter is not the fact of mutation but the ability of a given mutation (*a*) to allow adequate function of the cells involved, and (*b*) to replace the previously existent sequence as that characteristic of the species. Only an infinitesimally small number of the mutations of protein sequence that must occur will ever find opportunity, through selective survival, genetic drift and other processes, to become a new standard for the species. Even so, it appears from the pattern of results that random processes predominate.

If it is legitimate to look for somatic mutation at an accelerated rate in cistron V for the source of immune patterns, one would expect, despite the fantastic difference in the time-scales involved, to find essentially similar random changes of amino-acid sequence occurring. Such random changes produced in one way or another are vital to any theory of clonal selection.

The present hypothesis of the origin of immune pattern has at least the virtue of demanding experimental tests. It should be found that the Fd and Lv chains from a given myeloma protein are identical or have considerable segments in common. Available information does not exclude the possibility that the variable portions of light and heavy chains are derived from distinct cistrons and, if there is no identity in pattern found experimentally, a more complex hypothesis will have to be sought. One would prefer, however, not to abandon the simple hypothesis solely on evidence from myeloma proteins, until it is more clearly established that they are structurally equivalent to monoclonal antibodies.

Should the results show a consistent pattern in the variable segments it will become of first-rate importance to look for evidence as to how the variable pattern arose. There have been reports of myeloma proteins showing two spikes on electrophoresis, presumably indicating either a secondary mutation in the primary myeloma clone or a second primary mutation to neoplastic activity. The difference between the two patterns, both presumably derived from the pattern(s) characteristic of the fertilized ovum, should be illuminating. In any such investigation, the existence and extent of phenotypic restriction would be highly relevant. Since the Lyon phenomenon by which, in the female, one of the two *X*-chromosomes becomes non-functional in every cell is the only fully established example of phenotypic restriction at the somatic level, it is perhaps worth considering the possibility that the 'variable' cistron is carried on the *X*-chromosome. For

this reason, a search for diclonal 'gammopathies' in males might be more rewarding than in females.

There seem to be at least three possible origins of diversity: (1) accelerated replacement of single nucleotide pairs as suggested here; (2) intra-cistronic inversions, duplications or deletions as suggested by Smithies; (3) a process equivalent to transformation in bacteria in which the replacing segment of DNA may come either from within the cell or from an active adjacent cell. When further variable chains have been examined for sequence it should become possible seriously to consider these alternatives.

INTENSITY OF THE GEOMAGNETIC FIELD IN INDIA OVER THE PAST 4,000 YEARS

By R. N. ATHAVALE

Tata Institute of Fundamental Research, Colaba, Bombay 5

BAKED bricks and pots acquire magnetization as they cool from the high temperatures prevailing inside kilns and hearths to normal temperatures. This effect can be detected later, when it is termed 'thermoremanent magnetization'. The magnetization is in the direction and proportional to the ambient magnetic field of the Earth at the time of firing. Folgheraiter[1] and Koenigsberger[2] suggested that such materials obtained from ancient (archaeological) sites could be used for studying the Earth's past magnetic field. Such an application had to await the development of a satisfactory technique for studying detailed variation in field-strength itself. This was achieved by Thellier *et al.*[3], who compared ancient remanent magnetization in brick samples with that acquired when these samples were heated and cooled in the present magnetic field. This pioneering work led to the interesting observation that 2,000 years ago, the Earth's magnetic field in France was about 60 per cent stronger than it is at present.

In view of the importance of this result to geomagnetic studies and other allied fields, it was considered desirable to conduct similar studies in other areas. India has a geomagnetic latitude spread of 0°–25° N. and also has a large number of archaeological sites, many of which have recently been dated by the Radiocarbon Laboratory at this Institute. In view of these considerations, the present study was undertaken.

The method used was, in principle, the same as that of Thellier *et al.*[3], who mainly used bricks for the purpose. The materials most commonly obtained from archaeological excavations are, however, pots and potsherds. In order to make use of these, a suitable technique had to be devised. Small pieces of pottery or brick were firmly embedded in plaster of Paris inside individual cylindrical porcelain containers (height, 4 cm; diameter, 4 cm). With their orientation thus fixed, the magnetic moment of the sample was measured by means of an astatic magnetometer (sensitivity, 10^{-5} gauss). Each sample was first rotated below the magnetometer along the axis of the cylinder (Z component) and the directions of maximum (X-direction) and minimum (Y-direction) deflexion determined. Proper reference marks were then made and the deflexions along the X, Y and Z co-ordinates measured by the standard procedure which involved making a correction for sample inhomogeneity. The sample concerned was then heated to 300°–400° C with the X-direction aligned with the meridian, cooled and its magnetization remeasured. The sample was then reheated to the same temperature in reverse orientation, cooled and the magnetization measured again. These measurements enable us to obtain partial thermoremanent magnetization in ancient and laboratory fields by addition and subtraction of the vector co-ordinates X, Y and Z in the manner suggested by Thellier[3]. The sample was further heated to 675° C (which is the Curie point for haematite), cooled and its magnetization remeasured. This enabled us to deduce another value for the ratio of the ancient field strength to the present one.

The samples were heated in a non-inductive portable furnace. The heating elements were constructed from 22 gauge platinum wire, wound around quartz tubes with the lead wire of each element passing through the centre of the tube in a direction opposite to that of winding[4]. Ten such elements were mounted symmetrically inside a cement pipe (diameter, 22·5 cm; height, 13 cm). A thick copper vessel (diameter, 16·5 cm; height, 7·5 cm) was placed co-axially inside the furnace. Four samples were heated simultaneously inside this vessel in nitrogen atmosphere. A duplicate assembly made it possible to use the furnace to heat one set of samples while the other set cooled.

The precision of the experimental procedure was determined in the following way. A single pot was heated to 1,000° C in an oxidizing atmosphere for 2 h in order to destroy initial magnetization and to ensure that the constituent minerals remained stable during subsequent heatings, and then allowed to cool. In this way it acquired

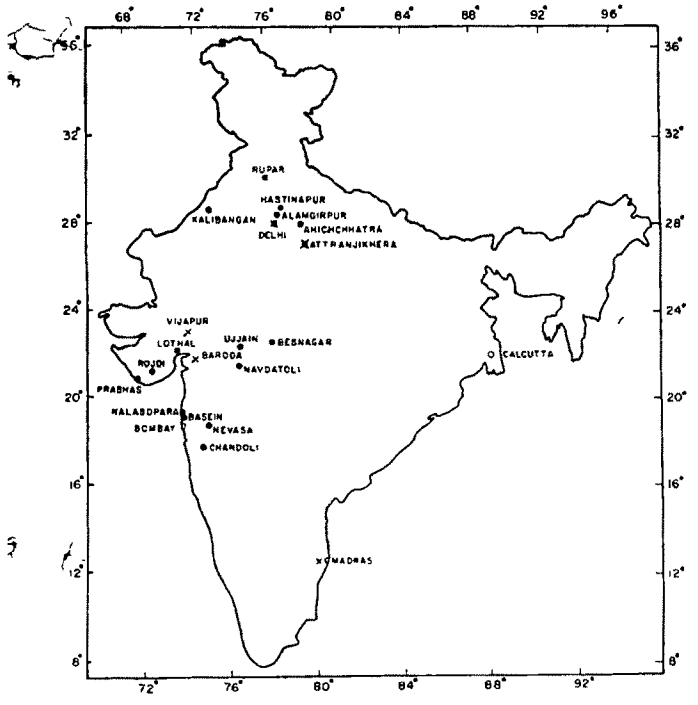

Fig. 1. Map of India showing sample collection sites. ×, Modern samples, ●, archaeological samples

a magnetization corresponding to the laboratory field. Four pieces of this pot were then run through the experimental cycle already described. The ratio of the two magnetizations in the laboratory field thus determined should theoretically be 1·00; the average of eight values deduced from the experiment was 1·03. The scatter in the values corresponded to a standard deviation of 9 per cent, which may be taken as an indication of the magnitude of the overall error of the measurements.

Results on Modern Samples

The basic assumption made in all such archaeomagnetic intensity studies is that the thermoremanent magnetization acquired by baked bricks and pots is proportional to the strength of the Earth's ambient field at the time of firing and that it does not change afterwards. In order to verify the first part of this assumption, we collected samples of modern pottery from five different localities and ran them through the experimental procedure already described. Fig. 1 shows the localities whence the modern samples were collected. Table 1 gives the field strength at the various sites as determined experimentally from measurements on modern pottery and also the value derived from the co-ordinates of the sites from data reported by Vestine *et al.*[5] for 1945 and extrapolating them to 1963. Bearing in mind that the actual field at the site of the hearth could be different from the extrapolated value by a few per cent, agreement between the extrapolated values and the experimental ones (within a standard deviation) is quite satisfactory. This indicates that the method is effective for modern pottery. Our procedure involved the determination of intensity ratios at only two temperatures; however, the elaborate method adopted by Thellier *et al.*[3] involved measurement of ratios at a series of temperatures, thereby making possible more accurate determinations. The precision of our procedure is, however, quite adequate for detecting any variation of large magnitude such as has been observed by other workers[3,6].

Table 1. Results on Modern Samples

Site	Geographical lat. N.	Co-ordinates long. E.	No. of samples	Experimental value of field (G)	Calculated value of field (G)
Delhi	28° 35′	77° 12′	8	0·458 ± 0·045	0·478
Attranjikhera	27° 42′	78° 44′	4	0 461 ± 0 086	0·474
Vijapur	23° 30′	72° 40′	4	0·435 ± 0·020	0·447
Baroda	22° 10′	73° 37′	4	0·437 ± 0 030	0·445
Madras	13°	80°	8	0·428 ± 0 031	0·413

Criterion for Stability of Magnetization of Samples

Only perfectly baked red ware giving a good metallic sound was chosen for the work. Samples showing grey core or giving a dull note when struck were not used, as it was considered that these would most likely contain unstable magnetic minerals. The baking temperature for material thus selected is generally above 700° C and it can be assumed, therefore, that samples chosen on this basis had acquired their thermoremanent magnetization over the entire range of temperature from 675° C (the highest Curie temperature—that of haematite) to the environmental temperature to which they cooled.

For each sample, we obtained two values for the ratio of ancient to laboratory field expressed in terms of the magnetization acquired by the sample; one for an intermediate temperature (partial thermoremanent magnetization) and one for the Curie temperature. In order to ensure that the magnetic minerals in the ancient samples had not undergone any chemical change during the reheating process in the laboratory, a comparison was made between the two ratios. Any archaeological sample the ratio of which differed by more than 30 per cent was considered to contain an excessive amount of unstable minerals and was rejected. Such samples formed only about 15 per cent of the measured samples.

Results on Archaeological Samples

Fig. 1 shows the location of archaeological sites whence the samples were obtained. Table 2 gives the results of magnetic measurements and other pertinent data for these samples. The "ages" of the samples are based on radiocarbon dates and archaeological evidence.

The ratios of the ancient to present fields at the sites, averaged from a set of samples, are given in the final column; the errors quoted are one standard deviation, which indicates the magnitude of scatter in the results. The present field at the sites was estimated by first making use of tables compiled by Vestine *et al.*[5] for 1945 and then correcting the value given to the 1963 one by a factor obtained from 1963 and 1945 values at the Bombay Magnetic Observatory. In Fig. 2 the values deduced for the intensity (normalized to Bombay) are plotted. A considerable random scatter in the data is obvious and no

Table 2. Results on Archaeological Samples

Site	Geographical co-ordinates Lat. N.	Long. E.	No of samples	Age (before present)	Ancient/present fields at site

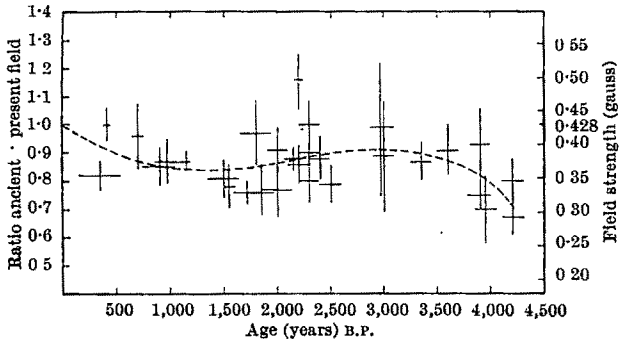

Fig. 2

marked secular variation is indicated. The data show, however, that in the past the field intensity was smaller by about 15 per cent.

We have also drawn a continuous curve through the points based on a least square analysis. If this is seriously considered it may be taken to indicate that the ancient mean field strength over India was about 15 per cent lower than the present 1,300 years ago, about 10 per cent lower 3,000 years ago, and about 30 per cent lower 4,000 years ago.

In determining the intensity ratios we have not taken into account any viscous magnetization which the samples might have acquired since they were first baked. It is known, however, from previous investigations that the magnitude of the error arising from this effect is quite small. Thellier *et al.*[3] have reported that out of the nine different sites selected by them, samples of baked earth from eight had secondary magnetization which was between 0·2 and 2 per cent of the initial magnetic moment. In samples from only one site the contribution due to this factor was 4·6 per cent. It is, therefore, safe to assume that accounting for the effect of viscous magnetization would not significantly alter the results presented here as they were obtained with a technique which had a precision of ± 9 per cent.

Discussion

Results of archaeomagnetic intensity obtained so far can be divided into three categories:

(1) The French[3] and Russian[6] results on baked bricks and clay; these show a gradual increase in the field intensity in the past with a peak value of 1·6 times the present value for 2,000-year-old samples and before this a decline to a value almost the same as at present for 4,600-year-old samples.

The measurements of Thellier *et al.*[3] were made on oriented samples so that the inclination of the field at the time the bricks were fired could also be measured, and a correction made for the measured intensity in order to allow for any variation in inclination with respect to the present one. The application of such a correction changes the absolute value of field-strength by as much as 10 per cent in some of their results.

(2) The Japanese results[6] on basalts and baked pottery; these show the present intensity for 1,000-year-old samples, a sharp increase by a factor of 1·5 for approximately 2,000-year-old basalt samples, and an equally sharp decline to present value for 3,000-year-old samples.

The results on basalts, which contain complex mineralogical constituents, are usually considered less reliable for estimating ambient field strength. Furthermore, these results were for unoriented samples, and were not corrected for any changes in intensity brought about by any secular variation in inclination of the field. Watanabe[7] has carried out extensive work on this aspect in Japan on samples as old as 6,000 years and finds the range of secular variation of inclination to be between 40° and 60° around a mean value of 50°. DuBois[8] reports a similar spread of values between 40° and 60° for the first millennium of the Christian era, for samples from the south-western United States. Using the formula $F = \frac{2M}{R^3(1 + 3\cos^2 I)^{\frac{1}{2}}}$ (where F is the field intensity at the site, I is the inclination, and M and R are the magnetic moment and radius of the Earth), and taking the extreme values of 40° and 60° and average value of 50° for the inclination in Japan, it can be seen that the uncertainty in the estimation of intensity values due to this cause could be as much as ± 12 per cent.

(3) Indian results on baked pottery and brick samples over the past 4,000 years show that the average field was not much different from the present—in fact lower only by about 15 per cent. These results are also for unoriented samples, and for reasons already discussed they may show variation in field intensity to the extent of ± 8 per cent due to possible variation in inclination (the present inclination in this region is about 25°).

There are obvious discrepancies between the three groups of data if the variation is considered to be global in scale. All three results can, however, be reconciled if they depict regional phenomena. Magnetic observatory records over the past 100 years tend to support this contention. They show that the intensity at the Indian and other South East Asian stations has been increasing while that at the European stations has been decreasing. It seems, therefore, that definite conclusions regarding the absolute variation of the dipole moment, averaged over the world, can be made only after data from many other regions are available.

On the other hand, recent measurements of the variation in the activity of carbon-14 produced by cosmic rays over the past few thousand years indicate that some changes in the dipole moment have probably occurred. Damon *et al.*[9] measured the activity of carbon-14 in a number of tree-rings and historically dated wood samples. They found the variation, $\Delta\ ^{14}C$, small (± 1–2 per cent) as far back as 2,000 years B.P., and a systematic increase in the carbon-14 content in the more distant past with a gradient of about 0·4 per cent per century. They give a $\Delta\ ^{14}C$ value of about + 7 per cent for a 4,600-year-old (historical date) Egyptian sample. Recently, Schell[10] has made similar observations based on studies on tree-rings going back 3,100 years. He has also summarized other available data in carbon-14 variation and has shown that they follow the same general trend as already discussed here. If we assume that the variation in carbon-14 activity is mainly caused by changes in the dipole moment, then the increase in radiocarbon production before 2,000 years B.P. would require the average strength of the Earth's magnetic field to be lower than its present value. This is in qualitative agreement with our magnetic data, if they are considered on a global scale.

I thank Prof. D. Lal for his guidance in this work, Dr. Rama for valuable criticism of the manuscript, and Prof. K. R. Ramanathan, D. P. Agarwal, C. Radhakrishnamurthy and P. W. Sahasrabudhe for helpful discussions. I also thank Shri A. Ghosh and other officers of the Archaeological Survey of India and H. D. Sankalia, J. M. Nanavati, R. C. Gaur and others for generously providing samples, and E. Noronha and A. S. Tamhane for assistance in the measurements and computations.

MECHANICS OF LIQUIDS AND GASES
SECOND REVISED EDITION

International Series of Monographs in Aeronautics and Astronautics, Division II, Aerodynamics, Volume 6

L. G. LOITSYANSKII

A course in fluid mechanics extending from first principles to a very advanced level.

Contents: The kinematics of continuous media; General equations and theorems of the motion of a continuous media; Principal equations and theorems of the dynamics of ideal fluid and gas; One-dimensional flow of ideal gas; Level turbulence-free motion of an ideal incompressible fluid; Level turbulence-free motion of ideal gas; Three dimensional turbulence-free motion of fluid and gas; Dynamics of incompressible viscous fluid; Turbulent motion; Dynamics of viscous gas; Index.

816 pages, £8/$25.00

INTEGRAL EQUATIONS AND THEIR APPLICATIONS
VOLUME I PARTS 1, 2, and 3

International Series of Monographs in Pure and Applied Mathematics, Volume 88

W. POGORZELSKI

Contents: Part 1—The general properties of Fredholm's and Volterra's equations. Part 2—Systems of linear integral equations; Non-linear integral equations; Applications of integral equations in the theory of differential equations. Part 3—Properties of the Cauchy type integrals; Boundary problems in the theory of analytical functions; Linear and non-linear singular integral equations.

724 pages, £6/$18.50

THE CORTICOVISCERAL THEORY OF THE PATHOGENESIS OF PEPTIC ULCER

K. M. BYKOV and I. T. KURTSIN, *I. P. Pavlov Institute of Physiology, Leningrad*

Contents: The role of the cerebral cortex in the regulation of the functions of the visceral organs; The significance of interoceptive impulses in the formation of cortico-visceral dynamics; Interaction between exteroceptic and interoceptive conditioned reflexes: The role of functional disturbances of the cerebral cortex in the genesis of some pathological processes; Participation of the nervous component in the disturbance of the vascular reaction in patients with peptic ulcer; Participation of the nervous component in the disturbance of the secretory processes of the stomach in patients with peptic ulcer; Analysis of theories of the pathogenesis of peptic ulcer; Basic principles of the corticovisceral theory of peptic ulcer; Treatment of peptic ulcer in the light of the new view on its aetiology and pathogenesis.

342 pages, 70s./$11.00

COMPARATIVE BIOCHEMISTRY AND PHYSIOLOGY

Executive Editor—G. A. KERKUT, *University of Southampton*

This journal publishes papers containing the results of original research on the biochemistry and physiology of animals, vertebrate and invertebrate. Particular attention is paid to those papers in which the subject is approached from a comparative point of view.
Recent Contents include: WELTON L. LEE—Pigmentation of the marine isopod Idothea montereyensis; A. O. CHRISTIE and D. J. CRISP—Toxicity of aliphatic amines to barnacle larvae; PETER F. HALL—Tyrosinase activity in relation to plumage color in weaver birds.
Published monthly. Specimen copy and subscription rates available on request.

IN FOUR VOLUMES. . .

Mutational Processes

SET PRICE 600s.

The Centenary of Gregor Mendel's "Experiments in Plant Hybridization" was the occasion of two symposiums held in Brno and in Prague in 1965, in which leading geneticists from all parts of the world participated. These volumes contain a wealth of information on the recent progress in the most important fields of genetics with particular emphasis on the various aspects of mutation and genetic variation. Approximately 200 papers and their discussions are gathered in the four volumes. Should be of great value to all scientists interested in biochemical, pharmacological, radiological, and microbiological aspects of genetics.

Volume 1:

Mechanism of Mutation and Inducing Factors

edited by **Zdeněk Landa**

August 1966, 524 pp., 240s.

Volume 2:

The Physiology of Gene and Mutation Expression

edited by **Margita Kohoutová**

and co-workers of the Department of Microbial Genetics

August 1966, 340 pp., 160s.

Volume 3:

Mutation in Population

edited by **Robert Hončariv**

August 1966, 196 pp., 96s.

Volume 4:

Genetic Variations in Somatic Cells

edited by **Marta Vojtíšková and Vladimír Zelený**

August 1966, 456 pp., 224s.

ALL VOLUMES REPRODUCED PHOTOGRAPHICALLY FROM TYPEWRITTEN MANUSCRIPTS

Available from Academic Press in all countries except the Socialist Republics
Co-published with the Czechoslovak Academy of Sciences

Lectures on Functional Equations and Their Applications

By **János Aczél**

University of Debrecen, Debrecen, Hungary

VOLUME 19 of **Mathematics in Science and Engineering:** A Series of Monographs and Textbooks.

The first systematic treatise on the theory of functional equations, this book gives an account of the present state of the theory in addition to descriptions of general methods for solving functional equations.

May 1966, 510 pp., 156s.

Volume 1:

Advances in Teratology

edited by **D. H. M. Woollam**

Emanuel College, Cambridge

CONTENTS: L. S. PENROSE, The Causes of Down's Syndrome. MARY F. LYON, X-Chromosome Inactivation in Mammals. GORDON C. BROWN, Recent Advances in the Viral Aetiology of Congenital Anomalies. ROBERT L. BRENT, Immunologic Aspects of Developmental Biology. F. BECK and J. B. LLOYD, The Teratogenic Effects of Azo Dyes. SAMUEL P. HICKS and CONSTANCE J. D'AMATO, Effects of Ionizing Radiations on Mammalian Development. R. W. SMITHELLS, Drugs and Human Malformations. References. Indexes.

June 1966, 300 pp., 84s.

A Logos Press Book

Nuclear Spin-Parity Assignments

edited by **Norwood B. Gove**

Oak Ridge National Laboratory

associate editor **Russell L. Robinson**

Oak Ridge National Laboratory

This volume presents the proceedings of a conference on techniques which give unambiguous nuclear spin parity assignments, direct spin measurements, internal conversion, and angular distribution of nuclear radiation.

July 1966, 463 pp., 60s.

Symmetries in Elementary Particle Physics

THE PROCEEDINGS OF THE INTERNATIONAL SCHOOL OF PHYSICS "ETTORE MAJORANA"

edited by **A. Zichichi**

A lucid collection of lectures, seminars, and formal discussions, with emphasis placed on the most recent advances in physics. This volume includes a most comprehensive treatment of unitary symmetries.

1965, 429 pp., Clothbound 96s., Paperbound 63s. 6d.

Optimal Shutdown Control of Nuclear Reactors

By **Milton Ash**

E. H. Plesset Associates Inc., Santa Monica, California

Studies the problem of optimal shutdown and subsequent startup of nuclear reactors with respect to their concomitant isotopic poisons, mainly xenon-135.

September 1966, 169 pp., 68s.

Academic Press 111 Fifth Avenue, New York 10003
Berkeley Square House, London, W.1

OBITUARIES

Prof. F. Debenham

PROF. FRANK DEBENHAM had been a colleague, friend and helper to so many that his death on November 23, 1965, at the age of eighty-one brings sadness to all. His was a life of vigour and indeed of vision, for he constantly looked ahead to new organizations and new methods which should be improvements on those already in being. Into old age he retained his enthusiasms, his friendships and his continued interest and writing on a variety of small but always practical topics in the realms of cartography and survey. Not least he remained fascinated by those frozen fishes which appeared so mysteriously on the surface of the Ross Ice Shelf and which excited such interesting hypotheses about the nourishment of ice shelves by the freezing of sea-water.

Born in Australia in 1883, Debenham was of the right age and training to become geologist to Scott's second Antarctic Expedition between 1910 and 1913. There he did much valuable work and forged the links of friendship with Sir Raymond Priestley and Sir Charles Wright, which later bore such excellent fruit in the foundation of the Scott Polar Research Institute in Cambridge. Intervening war service and wounding in Salonika preceded his return to Cambridge and his appointment in 1919 as Royal Geographical Society lecturer in cartography. There he soon succeeded Philip Lake as reader in geography, and not long afterwards had the distinction of being appointed the first holder of the new chair of geography in the University of Cambridge. His activities were such that by 1936 the new Department had been built and was well on the way towards that distinction which it possessed by the time of his retirement from the chair in 1949.

Yet many will think of 'Deb' primarily as the 'architect' of the Scott Polar Research Institute, of which he was part-founder and director from 1925 until 1946. The death of Scott and his companions returning from the South Pole in 1912 had stirred Britons perhaps more than any other peacetime event in centuries. They rallied nobly to Scott's last appeal to "see that those who are dependent on us are properly provided for". The subsequent Mansion House Fund reached a total of £76 500, a large sum at that time.

When the Mansion House Fund had fulfilled its dual task of providing for dependants and of publishing the scientific reports, there still remained a sum of £15.000 set aside as a 'Polar Research Fund'. It was in the early 'twenties that Debenham, before ever he was professor, put forward proposals which sprang from discussions a decade before in Antarctica with Raymond Priestley and Charles Wright. Their practical idealism was now to bear fruit. Debenham was able to show convincingly that often hard-won experience of polar expeditions in the past had been lost when their members dispersed, and that the techniques of life and travel in cold regions had been inadequately recorded. To ensure that future expeditions might fully profit from the past, on the sure basis of recorded experience, Deb proposed the foundation of an institute for polar research. That was the origin of the Scott Polar Research Institute in Cambridge—first an idea; then a tiny beginning in an attic room in the Sedgwick Museum of Geology in 1920; later, the construction, with the residue of the Mansion House Fund, of a particularly beautiful small building opened in 1934; and gradually the growth of the Institute to its present position of international repute. Deb happily lived to know of the recent munificent bequest from the Ford Foundation which will now allow the Institute, which was so close to his heart, to expand anew some 40 years after he had laid the first foundation.

G. C. L. BERTRAM

Prof. José María Albareda

PROF. JOSÉ MARÍA ALBAREDA died in Madrid on March 27, within a few days of his sixty-fourth birthday. Albareda was born in Caspe. He studied at the University of Madrid, where he graduated in pharmacy, obtaining his doctorate in 1927. He then studied chemistry in the Faculty of Science in Zaragoza and obtained his doctorate in chemistry in 1931. He immediately embarked on his career of soil research, at first under Prof. Rocasolano and Rius Miró in the University of Zaragoza. Between 1935 and 1936 he developed a course in soil science while holding the Conde de Cartagena chair of the Royal Academy of Science of Spain.

He was the first director of the Institute Ramiro de Maeztu of Madrid, and in 1940 was appointed to the chair of geology and zoology in the Faculty of Pharmacy in the University of Madrid, where he remained until his retirement in 1959. He helped towards the development of the new University of Navarra at Pamplona, and was appointed rector in 1960, a position he held at the time of his death. In 1959 he was ordained a priest.

Albareda was a leader in the field of pure and applied research, and with considerable foresight he, in collaboration with various university professors, planned the development of research in Spain, particularly through his service to the Spanish Research Council. After the foundation of the Consejo Superior de Investigaciones Científicas in 1939 he was appointed general secretary, and remained so until his death. Albareda directed much of his attention towards the development of soil science and to the problem of development of agriculture in Spain. He was in charge of the Instituto de Edafología from its formation in 1942 until his death. During this period the work performed by Albareda and his colleagues covered a wide field of soil science and had important practical applications. During the 26 years in which Albareda was general secretary in the Council he built up an extensive research programme with a great number of centres in Madrid and other cities entirely dedicated to research, and he established the foundation of a new era in the history of Spain.

The work of Prof. Albareda received international acclaim and he was elected corresponding, foreign or honorary member of a number of European societies. He was awarded a great number of distinctions, including his election as a member of the Spanish Royal Academy of Science in 1941, of Pharmacy in 1941, and of Medicine in 1952, of the Pontifical Academy of Sciences of the Vatican in 1948, and also of the Royal Academies of Science of Barcelona and Zaragoza.

Prof. George Humphrey

THE death of George Humphrey at the age of seventy-six on April 24 has removed one of the last surviving links in Great Britain with the pioneer psychological laboratory of Wilhelm Wundt at Leipzig. He acquired at Leipzig a

profound knowledge of the methods and the content of the German psychology of his day, which was to serve him as the basis for much of his later work. From Germany he moved to Harvard, where he completed his postgraduate studies under another eminent pioneer in experimental psychology, Raymond Dodge. Humphrey spent most of the next thirty years in North America, settling in 1924 in Canada as professor at Queen's University at Kingston, Ontario. He helped with many of the applications of psychology during the Second World War, and from 1938 to 1944 was successively secretary and president of the Canadian Psychological Association. At Queen's, too, he wrote one of his most important works, *The Nature of Learning* (1933). The experimental demonstration of the phenomenon of habituation in snails, and the discussion of the fundamental importance in all organisms of learning not to respond to stimuli, was a notable contribution to the psychology of learning.

In 1947 Humphrey returned to Britain as first professor of psychology in the University of Oxford. He was then fifty-eight years of age, and it was a bold decision to undertake to establish a school of psychology in a university that had been conspicuously resistant to it. The present size and standing of the Oxford school is a tribute to the skill with which Humphrey laid the foundations. While at Oxford he completed his second major book, *Thinking: Its Experimental Psychology* (1951).

Humphrey retired in 1956 and moved to Cambridge, where he continued to write almost to the end of his life, his last book on *The Chemistry of Thinking*, written in collaboration with C. R. Coxon, appearing in 1963. Right up to the end he campaigned for the need to experiment in psychology. "When any branch of knowledge can experiment, it must experiment, or it will die a dreary death" he maintained in one of his last essays. And this applied, he believed, not only to the conventional field of experimental psychology, but to the more dangerous areas of social psychology. L. S. HEARNSHAW

Mr. H. W. Simmonds

MR. H. W. SIMMONDS died in Auckland, New Zealand, on March 16, 1966, at the age of eighty-nine.

He was born in Kent, but left England in 1902 to go to New Zealand. Throughout his life he was a devoted lover and observer of Nature, his interests covering a wide field of natural history, though the study of insects was his main concern, particularly the biological control of insect pests.

In 1920 he joined the Colonial Service as Government Entomologist in Fiji, and it was during his period of Government service, from 1920 to 1937, that the greatest successes in biological control of insect pests and weeds in Fiji occurred. A team of entomologists—Tothill, Taylor and Paine—successfully controlled three serious pests which threatened the coconut-growing industry of Fiji. Simmonds worked in association with the team throughout, and, in the course of this work, travelled extensively in the South Pacific and the East Indies. One result of his travels was the publication of his bulletin on insect pests and diseases of the coconut palm in Melanesia and Southern Polynesia.

Undoubtedly the two successes in biological control for which Simmonds will be chiefly remembered by the people of Fiji are those which brought about control of the weed Koster's Curse and the insect housefly. In 1930 Simmonds brought back from Trinidad a thrips which was successful in controlling the weed. In 1938 he brought in a predatory beetle from Java which is said to have reduced formidable housefly populations to the reasonable level which exists to-day.

After retirement, Simmonds continued to work in the field of entomology, and in 1938 and 1945 made overseas trips on behalf of the Government of Western Samoa, seeking parasites of the coconut rhinoceros beetle, and in 1945 he introduced the parasite *Scolia ruficornis* to Samoa, where it is now well established. In 1963, when the coconut rhinoceros beetle was first discovered in Fiji, Simmonds joined the Coconut Pests and Diseases Board, with which organization he was still working at the time of his death, most of his time having been occupied with work on *Scolia ruficornis*, which is now established in Fiji.

Simmonds was a talented illustrator of insects, a student of mimicry in insects, an enthusiastic worker for Nature conservation and a devoted and gifted gardener and orchid-grower. He was awarded the O.B.E. for his services while employed by the Government and was made an Honorary Life Member of the Fiji Society in recognition of his work for Nature conservation and the establishment of nature reserves. B. A. O'CONNOR

NEWS AND VIEWS

Theoretical Physics in the University of London: Prof. R. K. Eisenschitz

PROF. R. K. EISENSCHITZ retires this year from the chair of theoretical physics in the University of London at Queen Mary College. He is well known for his contributions to statistical mechanics and the theory of liquids, made over a number of years at the Royal Institution under Sir William Bragg, at University College, London, under Prof. Andrade, and at Queen Mary College. His early career in Germany at the Kaiser Wilhelm Institute was notable for his work with F. London on the quantum-mechanical calculation of van der Waals forces but, like many of the theoretical physicists who moved to Britain, he had begun as an experimenter and worked for a time in industry. In his theoretical studies Prof. Eisenschitz moved naturally from general problems in statistical mechanics and the theory of elastico-viscous properties of matter to the fundamental problems of liquid theory. In recent years he has paid special attention to Kirkwood's approach and to approaches implying ideas of collective motion. More recently he has studied properties of electrons in liquid metals. Many of Prof. Eisenschitz's research students are now in important positions and owe much to his thorough and rigorous training. Before his appointment to Queen Mary College there was no theoretical research school in physics and no theoretical option for final-year undergraduate physicists; the new professor will find about a dozen students in each. Prof. Eisenschitz's many friends and colleagues at the College and in the University will miss his kindly interest and judgment.

Conservation Unchanged

THE British Nature Conservancy, now incorporated into the newly formed National Environment Research Council, seems not to be suffering from the association. The Research Council for the past year has been responsible for the Conservancy, the Geological Survey, the Institute of Oceanography and for research in fisheries and hydrology. Dr. Duncan Poore, the new director of the Conservancy, calls them "uneven bedfellows", but expects to gain from the association through co-operation on research with the other similarly oriented organiza-

tions. Dr. Poore thinks that more paper work may be involved, but noted that the responsibilities of the Conservancy remain the same—to acquire and manage the nature reserves, conduct research and publish information. The Nature Conservancy now has to share its cake with a number of other organizations, but the cake is larger, so Dr. Poore feels "there will be more give and take".

In the year ahead Dr. Poore hopes to place greater emphasis on the interaction of the Conservancy's research with its management of the reserves. The most important projects include research in Scotland on the management of grouse and deer, in Wales on the most productive uses of sheep, and a number of projects on productivity and conservation in conjunction with the seven-year International Biological Programme of the International Council of Scientific Unions. In the past the staff may have been too small to apply satisfactorily the results of research, but Dr. Poore hopes that the Nature Conservancy will improve this aspect of its work, chiefly by acting as a catalyst and stimulating and co-ordinating various bodies to produce guide-lines for future action. One example of such activity is the recent *Report on Broadlands* (Nature Conservancy, 1965).

Industry at Warwick

THE new University of Warwick is doing its best not to be an ivory tower above the car works of Coventry. In an attempt to bring industry into close contact with the University, five associate professors from industrial research have joined the teaching staff on a part-time basis, and further appointments are planned. By bringing men from industry into its teaching, Warwick is following a practice long established in such countries as The Netherlands; in the United Kingdom the practice has spread to the Manchester Institute of Science and Technology, the University of Birmingham and the Imperial College of Science and Technology, but Warwick plans to extend this concept to disciplines other than science, including economics, humanities and the social sciences.

Three appointments have been made in the school of molecular science and two in engineering science. The industrialists will give advice, direct research, and take part in postgraduate teaching through lectures and supervision of research. No courses are being given as yet, but a number are planned for the autumn; they will probably take the form of a series of twelve or fourteen lectures.

Graduate students have been using industrial laboratories, such as those at Bristol Siddeley, since the University opened in 1964 (though undergraduates were not admitted until October 1965), but by establishing a more personal contact the University hopes to increase the use of such facilities. Prof. J. A. Shercliff, head of the School of Engineering Science, plans to involve appropriate industrial research organizations as various divisions in his School are set up. For example, Dr. R. H. Macmillan, the director of the Motor Industry Research Association and one of the new associate professors, will be concerned largely with the automotive engineering aspect of the School of Engineering.

In another field, Mr. Peter Hall, director of the Royal Shakespeare Theatre in Stratford, has been appointed associate professor of drama, and the University hopes to start a drama department working in close collaboration with the nearby Royal Shakespeare Company.

Radiobiology at Harwell

AFTER nearly two decades of existence, the Radiobiological Research Unit of the Medical Research Council at Harwell has grown to be the largest but one of the Council's specialist research units. Yet a recent visit showed that there are still opportunities for the Unit to spread its wings. The facilities, of course, are excellent. The graphite moderated reactor *Beppo* has, for example, made possible a long-term study of the production of mutations in mice by radiation. The Unit is now reaping a rich harvest of results from this work. Accumulated evidence on the overall effects of genetic mutation suggests that the mouse is less mutable than had been thought. One intriguing finding has been that the frequency of specific mutations produced by neutron radiation can differ between males and females.

Goats are being used by the Experimental Pathology Group to simulate something like the reactions which human beings might show to acute whole-body neutron irradiation. Apart from lethal dose experiments, the degree of injury to the gut and bone marrow is being investigated. Death within the first few days after irradiation can usually be attributed to injury of the gut, and later deaths, up to 30 days after irradiation, are considered to be the consequence of injury to bone marrow and other tissues. Death from gut damage seems to result from the release of bacteria in the gut into the general circulation.

Adaptations of Moorhead's method for culturing human lymphocytes have proved a great boon to those studying the effects of X-rays and reactor radiation on human chromosomes. The group under Dr. J. Loutit, director of the Unit, is embarking on a study of the chromosome damage produced in these cells by various types of radiation. Dose response and dose-rate effects seem to be linear for neutron radiation, but curvilinear for γ-radiation.

In the effort of the Radiochemical Group to decrease the uptake of radioactive strontium by dietary supplementation, a number of compounds have been tested. Among the most efficacious are calcium phytate and sodium alginate—the latter reducing the strontium-90 uptake by as much as 75 per cent when given as 5 and 10 per cent additives.

Non-symbiotic Nitrogen Fixation

THERE are so many ways for nitrogen to enter and leave the soil that the difficulties of drawing up a nitrogen balance are formidable. The numerous types of microbial action that may be involved, the variations in the experimental data from different parts of the world, and the serious lack of knowledge of the quantitative aspects of many of the processes, make it a complex problem. This applies particularly to non-symbiotic fixation on which a valuable review entitled "Non-symbiotic Nitrogen Fixation in Soil and Soil–Plant Systems", by A. W. Moore, is presented in *Soils and Fertilizers* (29, 113; 1966). Reliable figures on the rate of accumulation of nitrogen per unit area are still required. However, there is overwhelming evidence that nitrogen is fixed by blue-green algae in rice paddy fields and that the fixation is increased by the presence of the rice plant, a fact of agronomic importance. It is also probable that there is a net gain of nitrogen in other soil–plant systems, such as under forest conditions, but it has not yet been possible to obtain evidence by growing plants satisfactorily in a gas-tight closed system using atmospheres labelled with nitrogen-15. A great many species of micro-organisms have nitrogen-fixing power, and it seems that biological nitrogen fixation is an exothermic reaction, so that a supply of energy is needed only for the growth of the organism. The organism also requires mineral nutrients, adequate moisture, heat and aeration, and probably a suitable *p*H range. It is also probable that 'growth factors' are involved and that there are interactions between nitrogen fixing and non-fixing organisms. There remain the possibilities of nitrogen fixation by higher plant tissues and by litter, and of the part played by plant roots.

Malayan Soil Survey Manual

THE development of agriculture has been accorded a high priority by the Government of the States of Malaya,

and a survey of soil resources is being actively pursued. To standardize techniques and nomenclature and to assist the surveyor, a compact guide to the description and mapping of soils has been produced: *Soil Survey Manual for Malayan Conditions*, by M. L. Leamy and W. P. Panton (Pp. x+226. Ministry of Agriculture and Co-operatives, Malaysia. Division of Agriculture, Bull. No. 119. Kuala Lumpur, 1966. 11*s*. 8*d*.). There are brief descriptions of the geography, parent material, vegetation and physical features of the country, followed by instructions on examining and describing the soil profile. There follow descriptions of mapping units and classification with emphasis on the special difficulties in Malaya presented by inaccessible forest regions, swamps and steep hills. Aerial photographs have been of limited use, but a geological map (1 in. to 12 miles), a rainfall map, and good quality topographic maps are available. The mapping scale of 2 in.–2½ in. to 1 mile has been chosen for reconnaissance survey purposes. About 100 soil series have been accepted as a basis of a register, but classification will remain fluid until more data have been collected. Many of the main series are in the great soil groups: reddish-brown latosols and yellow latosols, ground water laterite, yellow podsolic, organic and alluvial.

Protection for Tuna

ATLANTIC tunas will share with whales some immunity from hunting as a result of a convention on conservation drafted, by the representatives of seventeen nations, at what is called the Conference of Plenipotentiaries on the Conservation of Atlantic Tunas held at Rio de Janeiro in May this year. The convention has been prompted by evidence in recent years that more boats are chasing fewer fish. It applies to the whole of the Atlantic Ocean and adjacent seas, and the hope is that it will maintain the population of tuna and tuna-like fish, defined as the Scombriformes with the exception of the families Trichiuridae and Gempylidae and the genus *Scomber*, at those levels which permit the greatest sustainable catch. The commission that will be responsible for administering the convention when this has been ratified by at least seven countries will be empowered to collect information and to recommend research programmes. It may also, on the basis of the evidence it collects, recommend limits on the rate of catch in the convention area.

Parliament in Britain

ANSWERING questions in the House of Commons on June 16, the Prime Minister, Mr. H. Wilson, announced the Government's decision that responsibility for the aircraft industry should, in due course, go to the Ministry of Technology, together with most of the research and development functions: responsibility for civil aviation would go to the Board of Trade. Responsibility for the shipbuilding industry would also be transferred from the Board of Trade to the Ministry of Technology, thus placing both the aircraft and the shipbuilding industry ministerially with the rest of the engineering industry. Mr. Wilson said the decision was also in line with the Government's declared policy to transfer more and more of its research from defence to civil industry. Responsibility for the supervision of the air corporations and independent airlines would remain with the present Minister of Aviation until decisions had been taken regarding future purchasing programmes of the airline corporations, but all other aspects of civil aviation would be transferred immediately to the Board of Trade.

While it was intended to transfer most of the research and development work conducted by the Ministry of Aviation to the Ministry of Technology, a comprehensive examination was being made to determine to what extent procurement responsibilities of the Ministry of Aviation might more appropriately be transferred to the Ministry of Defence, and this examination could be completed before the Ministry of Technology assumed their new responsibilities. Questioned further as to the future of the Royal Radar Establishment and the other Royal Establishments such as Farnborough, Mr. Wilson said that their importance was growing in the civil field and particularly in electronic developments for export. There was no question of fragmenting the Royal Radar Establishment and he expected that responsibility for it would pass, together with responsibility for the electronics industry, to the Ministry of Technology.

IN a written answer in the House of Commons on June 16, the Minister of State for Education and Science, Mr. G. Roberts, stated that the Patent Office building was transferred from the Board of Trade to the British Museum on April 1, to form, with the Museum's own collection of scientific literature, the nucleus of the National Reference Library of Science and Invention. Temporary accommodation in London has been found for that part of the total collection which could not be housed in the existing Patent Office building, and the Ministry of Public Building and Works was negotiating a site for a permanent building. The library will offer its users an information retrieval service, but it is too early to say what part the library will play in the mechanization of storage and retrieval of information.

IN answer to a question in the House of Lords on June 16, Lord Champion said that the Selective Employment Payments Bill contains a provision that will bring into entitlement for the selective employment premium those establishments certified by the Minister of Technology to be engaged in scientific research relevant to manufacturing activities. This includes independent laboratories working for manufacturing industry. Establishments of this kind do not conform to any set pattern and every case will have to be judged on its merits. The clause is intended to ensure that such organizations receive equitable treatment.

University News: London

DR. A. B. FOSTER, reader in organic chemistry at the University of Birmingham, has been appointed to the chair of chemistry in the Institute of Cancer Research, Royal Cancer Hospital. Dr. N. Lichfield has been appointed to the chair of economics of town planning, tenable at University College. The title of professor has been conferred on the following: Dr. L. S. Bosanquet (mathematics, in respect of his post at University College); Dr. F. F. Heymann (physics, in respect of his post at University College); Dr. J. L. Mongar (pharmacology, in respect of his post at University College).

Massachusetts Institute of Technology

DR. J. P. RUINA, professor of electrical engineering at the Massachusetts Institute of Technology, who has been on leave since September 1964 while serving as president of the Institute for Defense Analyses in Washington, D.C., will return to M.I.T. on July 1, as vice-president for special laboratories. He will be the Institute's senior officer on matters relating to the two national service laboratories the Institute administers for the Federal Government—Lincoln Laboratory and Instrumentation Laboratory. Dr. Thomas K. Sherwood has been appointed as the first to occupy the Lammot du Pont professorship of chemical engineering. Prof. Sherwood is one of the world's leading authorities on fluid flow and mass transfer, and wrote the first significant text in this field, *Absorption and Extraction*, in 1937.

Pennsylvania

DR. CHARLES C. PRICE has been appointed University professor of chemistry in the University of Pennsylvania. University professorships were established at Pennsylvania in 1961 to honour those faculty members who are

the higher frequencies (Table 1) we see that there is excellent agreement over an 80 : 1 range of frequency, thus providing very strong evidence that the radiation has a black-body spectrum. The values from Table 1 are shown plotted in Fig. 1 compared with the spectrum of a black-body at 3° K. Also indicated are the minimum brightness temperatures measured at lower frequencies where the galactic radiation is dominant.

One obvious possibility to account for the excess brightness at 7·35 cm and 3·2 cm was the integrated radiation from a population of hitherto undetected radio sources

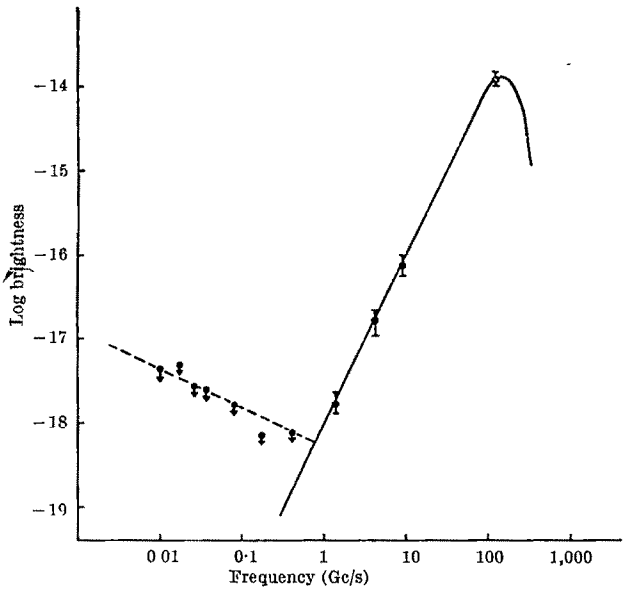

Fig 1. The excess radio brightness, in units of ergs sec^{-1} cm^{-2} (c/s)$^{-1}$ ster^{-1}, is shown plotted against frequency. The solid line is the brightness expected from a black-body at a temperature of 3° K. At frequencies less than about 0·8 Gc/s radiation from the Galaxy becomes dominant

Table 1

Wave-length (cm)	Excess brightness temperature (° K)	Ref.
0·26	2·84 − 3·34	3
3·2	3·0 ± 0·5	2
7·35	3·1 ± 1	2
20·7	2·8 ± 0·6	Present paper

with spectra peaking at centimetric wave-lengths. This is most unlikely to be the explanation of the 20·7 cm excess since Kellermann and Read[19] have carried out a survey of radio sources at 21 cm wave-length in an area of 1 steradian and found no such population. The integrated emission from all the radio sources at this wave-length is thought to be less than 0·1° K.

We thank Prof. M. Ryle, Dr. R. G. Gordon and Mr. F. Sadler for their advice and assistance. One of us (T. F. H.) also thanks the Science Research Council for a maintenance grant.

NUCLEAR RIBONUCLEOPROTEIN PARTICLES CONTAINING MESSENGER RIBONUCLEIC ACID

By O. P. SAMARINA, A. A. KRICHEVSKAYA and Dr. G. P. GEORGIEV
Institute of Molecular Biology, Academy of Sciences of the U.S.S.R., Moscow

IT has been shown that the chromosomes of animal cells contain significant quantities of D-RNA—RNA with DNA-like base composition[1,2]. Chromosomal D-RNA is actively hybridized with homologous DNA, and stimulates the incorporation of amino-acids in a cell-free system[4] and the biosynthesis of specific proteins in non-damaged cells[5]. It would seem, therefore, that chromosomal D-RNA contains the newly formed cellular *m*RNA. In hybridization experiments, cytoplasmic RNA competes with chromosomal D-RNA[6]. Thus at least part of the latter is transferred after the synthesis into the cytoplasm.

We endeavoured to obtain information about the nuclear structures containing D-RNA as it was felt that this might help to establish the state of nascent *m*RNA. Moreover, such information would throw some light on mechanisms of the removal of *m*RNA from DNA-matrix and its transport to centres of protein synthesis.

Nuclei were isolated from Ehrlich carcinoma cells with the aid of osmotic shock and from rat livers by the sucrose-glycerophosphate method. A 'nuclear pellet' was obtained from five rat livers, or 50 ml. of ascites tumour, and was successively extracted by 2–3 ml. portions of 0·14 M sodium chloride–0·01 M *tris*–0·001 M magnesium chloride (STM) at *p*H 7·0 and 7·8–8·0. The first extract obtained at *p*H 7·0 contained a mixture of *r*RNA (nuclear sap ribosomes), *s*RNA and traces of *m*RNA. On the other hand, the newly formed high molecular weight RNA of the second and third extracts, obtained at *p*H 7·8–8·0, was similar to DNA (*m*RNA).

These extracts were layered over sucrose gradients and ultracentrifuged. Two peaks of ultra-violet absorbing material were obtained which had sedimentation coefficients of 30*S* and 4*S*. The main part of radioactive *m*RNA was found in the 30*S* peak (Figs. 1 and 2). Using this method about two-thirds of the newly formed chromosomal *m*RNA could be obtained as the 30*S*-peak.

The data obtained indicate that the 30*S*-peak is an *m*RNA-protein complex. The presence of protein was evidenced by: (1) a relatively low D_{260}/D_{280} ratio of peak material—it is equal to 1·45–1·5; (2) the decrease in the sedimentation constant of *m*RNA after deproteinization of extract by SDS-phenol treatment: 12–18*S* instead of 30*S* (Fig. 1); (3) when amino-acid incorporation

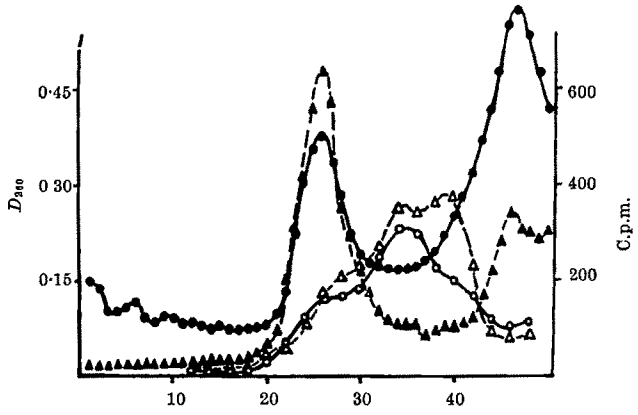

Fig. 1. Sedimentation profiles of nuclear extracts containing *m*RNA and of RNA isolated from these extracts. $Na_2H^{32}PO_4$ was injected intraperitoneally into mice with Ehrlich ascites carcinoma (50 μc per animal) 2 h before they were killed. Carcinoma nuclei were isolated by osmotic shock and extracted once by STM, *p*H 7·0, and twice by STM, *p*H 7·8. The second and third extracts were combined. Half of it was deproteinized by phenol–0·5 per cent sodium dodecylsulphate and RNA was isolated. Nuclear extract and isolated RNA (2 ml. portions) were layered over 25 ml of 15–30 per cent sucrose gradients (in STM, *p*H 7·0) and ultracentrifuged during 12 h at 25,000 r.p.m. Seven or fourteen drop-fractions were collected and analysed by their ultra-violet absorption and radioactivity. ●——●, Ultra-violet absorption of extract; ▲ - - - ▲, radioactivity of extract; ○——○, ultra-violet absorption of isolated RNA, △- - - - △, radioactivity of isolated RNA

into protein was investigated, the radioactive protein was observed in the same 30*S*-peak (Fig. 2). Thus the significant part of chromosomal *m*RNA is revealed as part of special ribonucleoprotein particles.

To elucidate the nature of particles observed, the following experiments were performed. The unfractionated[1,2] chromosomal *m*RNA or the main 18*S*-peak of chromosomal *m*RNA (obtained by means of gradient ultracentrifugation) were mixed with nuclear extracts in STM, *p*H 7·0. The mixtures were layered over a sucrose gradient and ultracentrifuged. In both cases some part of *m*RNA was degraded, but a considerable quantity of labelled *m*RNA, sometimes about 70–80 per cent, was revealed in the 30*S*-peak. If the RNA of the nuclear extract was labelled with adenine-^{14}C and free *m*RNA with phosphorus-32, both labels coincided (Fig. 3). Thus it is possible *in vitro*

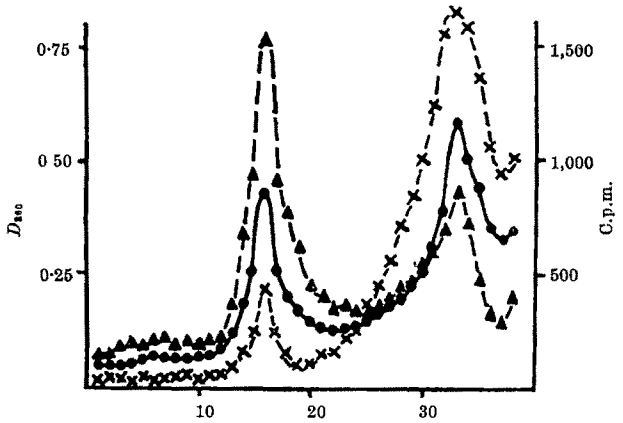

Fig. 2. Demonstration of labelled protein in 30*S*-peak. Rats were treated with $Na_2H^{32}PO_4$ (1 mc. per animal) and carbon-14 labelled protein hydrolysate (200 μc. per animal), after 2 h the animals were killed and liver nuclei isolated by the sucrose-glycerophosphate method (see ref. 2). Combined second and third extracts of nuclei by STM, *p*H 7·8, were ultracentrifuged in sucrose gradients (conditions as in Fig. 1). After determination of the ultra-violet absorption, each fraction collected was divided into two portions. One was treated with 5 per cent trichloroacetic acid for 30 min at 90° C in the presence of a carrier protein and then used for the determination of carbon-14 labelled protein in a scintillation counter. Both portions were washed on 'Millipore' filters and counted. ●——●, Ultra-violet absorption, × - - - - ×, carbon-14 counts (labelled protein); ▲ - - - - ▲, phosphorus-32 counts (labelled RNA)

to obtain 30*S* *m*RNA protein typical for nuclear extracts. It is interesting that nuclear extracts can bind the relatively large quantity of *m*RNA added (equal to about one-third to one-half the RNA already present in the 30*S*-peak.

A number of questions follow these findings:

(1) Is this reaction specific to *m*RNA? To answer this, the interaction of 18*S*-*m*RNA and 18*S*-ribosomal RNA with nuclear extracts was compared. In both cases some part of the radioactive material was displaced into the heavier zone, but only in the case of 18*S* *m*RNA was the radioactive 30*S*-peak observed (Fig. 3). It can be concluded that the type of interaction described is in fact specific for *m*RNA.

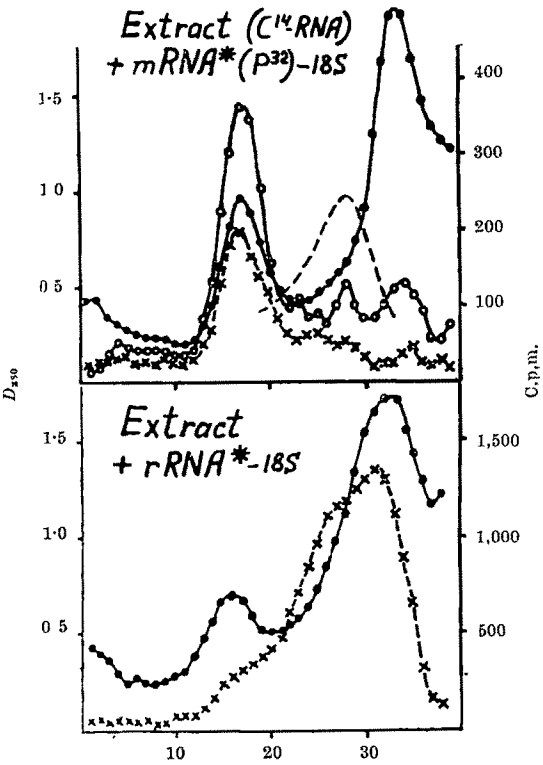

Fig. 3 Interaction of free RNAs with nuclear extracts. Rat liver chromosomal *m*RNA and cytoplasmic *r*RNA labelled with phosphorus-32 (over 12 and 36 h) were isolated and fractionated by sucrose gradient centrifugation. 18*S*-components of both fractions were collected, dissolved in STM and added (50 μg) to nuclear extracts obtained from rat livers, of animals administered with adenine-^{14}C (0·3 mc. per animal) 2 h before killing. The mixtures were ultracentrifuged in sucrose gradient (conditions—see Fig 1). Carbon-14 and phosphorus-32 counts were differentiated with the aid of filters ●——●, Ultra-violet absorption; ○———○, radioactivity of extract (^{14}C-RNA). × - - - ×, radioactivity of added RNA (*m*RNA-^{32}P or *r*RNA-^{32}P); - - - - , sedimentation profile of free 18*S*-*m*RNA (obtained in separate experiment) The profile of 18*S*-*r*RNA is similar

(2) What is the mechanism of this interaction? Are *m*RNA molecules bound to already existing 30*S*-particles or is the formation of *m*RNA protein due to the combination of *m*RNA and proteins of lower molecular weight? In one experiment the excess of *m*RNA-^{32}P was mixed with nuclear extracts labelled with ^{14}C-amino-acids. The appearance of phosphorus-32 in the 30*S*-peak indicated the formation of *m*RNA-protein complex. The quantity of bound RNA was equal to ~60 per cent of the RNA which already existed in the 30*S*-peak. At the same time there was no enlargement of labelled protein in the 30*S*-peak (Fig. 4). In the second experiment, nuclear extracts were ultracentrifuged; fractions coinciding with the 30*S*-peak, 4*S*-peak and 6–25*S* zone were collected and dialysed. To each of the fractions was added the labelled free *m*RNA 18*S*-peak fraction. The

mixtures were recentrifuged and analysed (Fig. 5). Only with the 30*S*-peak was the labelled *m*RNA revealed as 30*S*-material. In other cases the sedimentation constant of *m*RNA was not significantly changed. Thus both types of experiment indicate that *m*RNA is bound to already existing 30*S*-particles and does not react with smaller protein molecules.

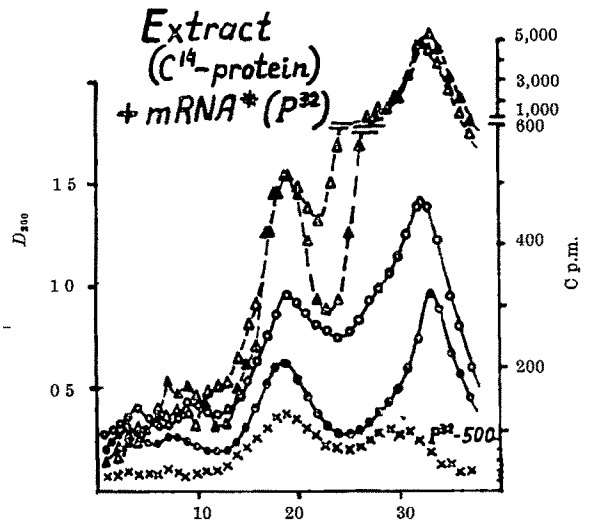

Fig 4. Interaction of *m*RNA with carbon-14 labelled proteins of nuclear extracts. Nuclear extracts of rat livers labelled with carbon-14 protein hydrolysate (200 μc per animal for 12 h) were mixed with excess of chromosomal *m*RNA (500 μg), labelled with phosphorus-32, and ultracentrifuged in sucrose gradient. The control extracts, containing the same quantity of material but without extra *m*RNA. were also investigated in separate tubes. Radioactivity of phosphorus-32 and carbon-14 was determined in separate portions, treated by cold (^{32}P-RNA) and hot (^{14}C-protein) trichloroacetic acid correspondingly. Carbon-14 was counted in a scintillation counter. ●——●, Ultra-violet absorption of control extract; ▲ - - - - ▲, radioactivity of control extract (carbon-14); ○——○, ultra-violet absorption of extract, mixed with *m*RNA; △ - - - - △, radioactivity of extract mixed with *m*RNA (carbon-14); × × ×, radioactivity of *m*RNA (phosphorus-32) added

(3) What is the significance of 30*S* *m*RNA-protein? Is it an already existing structure or an artificial one? Just as in the other cases concerning cellular nucleoproteins, these questions are not easy to answer. However, some indirect evidence may be mentioned in support of the theory of the pre-existence of the nuclear *m*RNA proteins observed. As has already been shown, actinomycin inhibited not only RNA synthesis but also *m*RNA transport. If the cells were incubated with phosphorus-32 and then treated with actinomycin, the main part of newly formed *m*RNA was retained in the chromosomes, and was not transferred into the cytoplasm[2]. In these conditions 30*S*-*m*RNA-protein is completely absent in nuclear extracts (Fig. 6). On the other hand, significant quantities of *m*RNA were observed in the nuclear residues obtained by exhaustive extraction of nuclei by STM-solutions. It is possible that 30*S*-*m*RNA protein is a type of nucleoprotein in which *m*RNA is transported from the nucleus into the cytoplasms—the inhibition of the latter process can be correlated with the disappearance of 30*S*-particles. It is interesting to note that the significant part of cytoplasmic *m*RNA is also not bound to ribosomes and is sedimented under similar centrifuge forces[7–9].

Our experiments indicate that *m*RNA newly formed in the cell nucleus is an integral part of special nucleoprotein particles with a sedimentation constant of about 30*S*. The mode of complex formation is specific binding of *m*RNA to already existing 30*S*-particles. Some indirect data make it possible to suggest that these *m*RNA-proteins are a transport form of *m*RNA. A further question concerns the nature of 30*S*-particles. They are not complexes of DNA, RNA polymerase and nascent RNA, since treatment of the extract with DNase does not

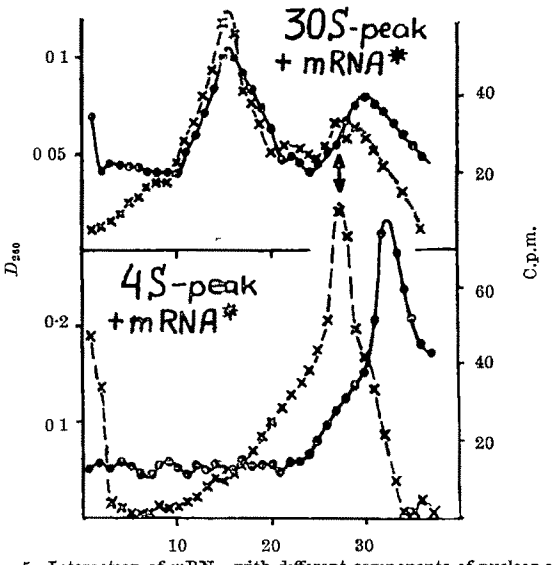

Fig 5. Interaction of *m*RNA with different components of nuclear extracts Non-labelled nuclear extracts were ultracentrifuged and analysed. 30*S* peak and low-molecular material (4*S*) were collected, dialysed against STM, *p*H 7·0, mixed with 18*S* *m*RNA (25 μg), labelled with phosphorus-32 and repeatedly ultracentrifuged in sucrose gradient. ●——●, Ultra-violet absorption; × - - - - ×, radioactivity. Arrow indicates the position of peak of free *m*RNA

change the properties of the 30*S*-peak fraction. One possibility is that 30*S*-particles are small ribosomal sub-units or the precursors of small ribosomal sub-units with a somewhat lower sedimentation constant. It was postulated that ribosomes may play a part in the liberation of *m*RNA from the enzyme-matrix-product complex of chromosome and transport of *m*RNA into the cytoplasm[10]. Lerman *et al.* suggested that whole ribosomes do not participate in this process, but instead their smaller sub-units[11].

30*S*-sub-units may bind chromosomal *m*RNA, transfer it to the cytoplasm and there, after addition of 50*S*-ribosomal sub-units, initiate protein synthesis. But as yet there are no conclusive data to prove this hypothesis.

Another possibility is that the 30*S*-particles observed are the nucleoprotein particles of a new, as yet unknown, type and that they are concerned with the transport of *m*RNA from the chromosomes to ribosomes.

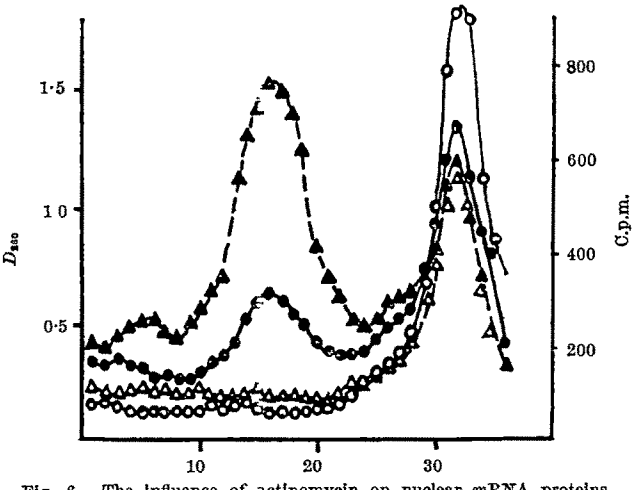

Fig. 6. The influence of actinomycin on nuclear *m*RNA proteins. Rats were treated with phosphorus-32 (1 mc. per animal) and after 1·5 h half the animals were killed (control) and the other half treated with actinomycin ('Aurantin', 1·5 mg per animal). The latter group was killed 3 h after the actinomycin had been administered. Nuclear extracts were obtained from rat livers of both groups and ultracentrifuged in sucrose gradient ●——●, Ultra-violet absorption of control extract; ▲ - - - - ▲, radioactivity of control extract; ○——○, ultra-violet absorption of extracts from actinomycin-treated animals; △ - - - - △, radioactivity of extracts from actinomycin-treated animals

Further experiments, needed to clear up this question, are now in progress.

BIOSYNTHESIS OF THE PHYTOSTEROL SIDE CHAIN

By DR. L. J. GOAD, A. S. A. HAMMAM, A. DENNIS and PROF. T. W. GOODWIN

Department of Biochemistry and Agricultural Biochemistry, University College of Wales, Aberystwyth

PHYTOSTEROL biosynthesis has become increasingly investigated during recent years[1–11], and one aspect which is at present receiving much attention is the introduction of the supernumerary group at C-24 of the sterol side chain. Several years ago the additional methyl group in ergosterol was shown to arise from methionine[11], and it has recently been established that the extra ethyl group of β-sitosterol[8] and α-spinasterol[9] and the ethylidene group of fucosterol[10] also arises from methionine by a double transmethylation. A transfer of an intact ethyl group from a donor such as ethionine does not occur[7,8]. A mechanism for the introduction of the methyl groups into phytosterols proposed by Castle, Blondin and Nes[8] is shown in Fig. 1.

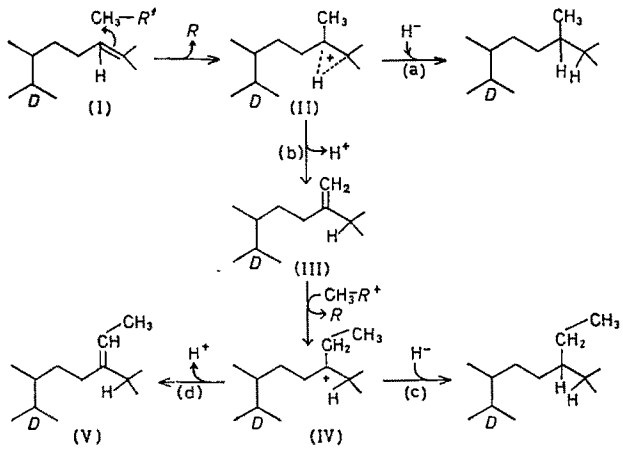

Fig. 1

Results obtained with [^{14}C,^{3}H-methyl]methionine[11] were considered to indicate the intact transfer of the methyl group as previously observed during methyl transfer to oxygen[12] and nitrogen[13]; this would be in accord with route (*a*) in Fig. 1. A recent re-examination of the problem has shown this conclusion to be in error[14]. Ergosterol biosynthesized by *Neurospora crassa* in the presence of [D_3-methyl]methionine was found by mass spectrometry to contain only two deuterium atoms. The production of a C-24 methylene steroid as intermediate (III, route *b*, Fig. 1) followed by reduction to a C-24 methyl steroid would account for this result, but a number of other possible mechanisms have also been proposed[15].

No experimental information is available to indicate the mechanism by which the ethyl group found in sterols such as β-sitosterol is introduced. Circumstantial evidence for the involvement of a C-24 ethylidene steroid is provided by the occurrence of 4α-methyl-$\Delta^{7,24(28)}$stigmastadien-3β-ol (citrostadienol, 24-ethylidene-lophenol) together with β-sitosterol, the major sterol, in citrus fruit[16] and potato leaves[17] and also by the presence of both fucosterol and β-sitosterol in pollen[15]. To provide experimental evidence that C-24 ethylidene steroids are intermediates in C-24 ethyl steroid biosynthesis we used [^{14}C,^{3}H-methyl]methionine. An isotope effect with tritium has been reported in chemical and biochemical reactions[18–20] so caution must be exercised in the design and interpretation of experiments which involve tritium. The results just discussed with [^{14}C,^{3}H-methyl]methionine indicated that 86–91 per cent of the tritium was retained in ergosterol biosynthesis[11]. However, if one hydrogen atom is lost, as indicated by investigations with [D_3-methyl]-methionine[14], then only 67 per cent of the tritium should be retained. The discrepancy between the two results has been ascribed to an isotope effect[15] in which carbon–tritium bonds are less readily broken than carbon–hydrogen bonds, with a consequent enrichment of the ergosterol in tritium. In an attempt to eliminate this source of error we adopted a comparative approach. [^{14}C,^{3}H-methyl]-methionine (prepared by mixing [^{14}C-methyl] and [^{3}H-methyl]methionine supplied by the Radiochemical Centre, Amersham) was incorporated biosynthetically into different steroids containing respectively a C-24 methylene, methyl, ethylidene or ethyl group. The radioactivity of the isolated steroids was determined in a Packard 'Tri-carb' liquid scintillation spectrometer and the tritium: carbon-14 ratio calculated[21].

The C-24 methylene steroid chosen was eburicoic acid[22], which was isolated from a culture of *Polyporus sulphureus* following incubation for 8 days with [^{14}C,^{3}H methyl]methionine. The tritium : carbon-14 ratio of the eburicoic acid was compared with that of ergosterol biosynthesized by *Blakeslea trispora* grown for 4 days in the presence of a sample of the same batch of [^{14}C,^{3}H-methyl]methionine. The tritium : carbon-14 ratios obtained were in good agreement (Table 1), which means that in this case the comparative approach is sound; it is known that one methyl hydrogen is lost in the biosynthesis of ergosterol[14], and because of its structure one methyl hydrogen must be lost from eburicoic acid. The major sterols of excised maize leaves incubated with a sample of the same methionine also had a tritium : carbon-14 ratio close to that observed for eburicoic acid and ergosterol (Table 1). Gas liquid chromatography (3 per cent *SE*-30) revealed that the maize sterols were a mixture of β-sitosterol (45 per cent), stigmasterol (30 per cent) and campesterol (25 per cent), which could not be separated on thin-layer chromatography. Accordingly, the mixture was subjected to ozonolysis and the ethyl isopropyl acetaldehyde derived from the side chain of

Table 1. TRITIUM : CARBON-14 RATIOS OF STEROIDS BIOSYNTHESIZED IN THE PRESENCE OF THE SAME SAMPLE OF [^{14}C,^{3}H METHYL]METHIONINE

Steroid	Source	Observed tritium. carbon-14 ratio
Eburicoic acid	*Polyporus sulphureus*	3·93 : 1
Ergosterol	*Blakeslea trispora*	3·75 : 1
β-Sitosterol, stigmasterol and campesterol mixture	Maize	3·73 : 1
Ethylisopropylacetaldehyde	Ozonolysis of the maize sterol mixture	3·78 : 1

stigmasterol isolated by steam distillation. This had the same tritium : carbon-14 ratio as the original sterol mixture and eburicoic acid and ergosterol (Table 1). It was important to examine a C-24 ethyl sterol if possible and to compare it with a C-24 ethylidene sterol, such as fucosterol. A survey of plant sterols by gas liquid chromatography revealed that about 95 per cent of the total sterols in leaves of larch (*Larix decidua*) collected shortly after their opening in the spring was β-sitosterol; minor amounts of campesterol and a sterol with a relative retention time the same as fucosterol on 'Hi-EFF 8*B*'[23] were detected, but no stigmasterol was observed. A recent report has also indicated the general predominance of β-sitosterol in conifers[24]. The same type of experiment was, therefore, carried out on larch leaves. Portions (1·0 g) of chopped 10–20 day-old leaves were incubated in conical flasks with 1·0 ml. of a solution containing [^{14}C,^{3}H-methyl]methionine. The flasks were incubated at 25° C with illumination provided by two 'Cryselco' daylight emission lamps (2 ft., 20 W) placed about 25 cm above the flasks. This method gave good incorporation of radioactivity into the non-saponifiable lipid. Samples of the same batch of methionine, which was different from that used in the previous experiments, were incubated with *Fucus spiralis*. Portions of chopped *Fucus spiralis* (2·0 g) were moistened with 2·0 ml. of the [^{14}C,^{3}H-methyl]-methionine solution, to which 2·0 ml. of "double strength" sea water (obtained by boiling a sample of sea water to half its original volume) were added. Incubations were at 25° C as for larch. Fucosterol was isolated as the main sterol and counted. To complete the comparison, samples of the same batch of [^{14}C,^{3}H-methyl]-methionine were incorporated into ergosterol by yeast (*Saccharomyces cerevisiae* N.C.Y.C.667) and into maize sterols under the same experimental conditions as described for larch. At the end of the incubations the non-saponifiable material was extracted from each incubate; the appropriate authentic sterol (5·0 mg) added as carrier (β-sitosterol in the case of maize) and the sterols precipitated as their digitonides. After regeneration the sterols were isolated by chromatography on alumina and assayed for radioactivity. Samples of the sterols were further purified by thin-layer chromatography and by recrystallization (four times) from chloroform-methanol after the addition of carrier sterol. The results obtained (Table 2) show good agreement for the tritium : carbon-14 ratios in the various sterols, irrespective of the method of purification.

The similarity of the tritium : carbon-14 ratios of fucosterol and ergosterol indicates that the four hydrogens of the ethylidene group of fucosterol are derived from the two methyl groups of methionine. Since the tritium : carbon-14 ratio of β-sitosterol was also in close agreement with the ratio observed for ergosterol and fucosterol this in turn suggests that only four of the five hydrogen atoms present in the ethyl group of β-sitosterol are derived from methionine. Thus, during alkylation in β-sitosterol biosynthesis, two hydrogen atoms appear to be lost from the introduced methionine methyl groups. These results are compatible with the intermediate production of C-24 methylene (III) and C-24 ethylidene (V) steroids by a mechanism envisaged in routes (*b*) and (*d*) of Fig. 1. The route shown in Fig. 2, while mechanistically acceptable, appears to be eliminated by the observed tritium : carbon-14 ratio of β-sitosterol; further, the loss of a methyl hydrogen atom during ergosterol biosynthesis[14] is not in accord with Fig. 2.

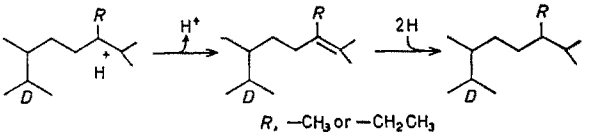

Fig. 2

Fig. 2 and route (*c*) of Fig. 1 would both require that five hydrogen atoms from methionine are retained in β-sitosterol. The present results tend to show that only four hydrogens are retained, but it is recognized that if a very considerable hydrogen isotope effect exists it might be difficult to differentiate between tritium : carbon-14 atomic ratios of 4 : 2 and 5 : 2, when the ratios of fucosterol and β-sitosterol are compared. Preliminary experiments designed to evaluate the extent of the hydrogen isotope effect in respect to the present problem indicate that it may not be so great as to invalidate our conclusions. Also it is hoped that the incorporation of [D_3-methyl]methionine into a C-24 ethyl steroid will further provide confirmation of our results.

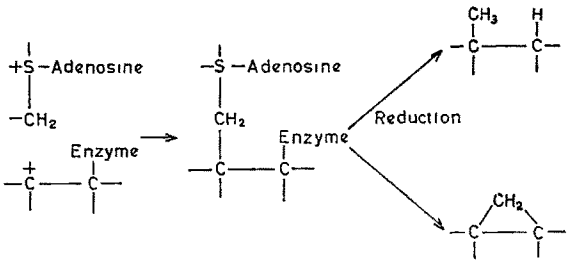

Fig. 3

Lederer[15] suggested that the introduction of the methyl group into ergosterol might involve an intermediate ylide derived by oxidation of S-adenosyl methionine (Fig. 3). This mechanism can be extended to explain the formation of ethyl and ethylidene derivatives; in this case the tritium : carbon-14 ratio would be the same as expected if Fig. 1 (routes *b* and *d*) were operative. Thus

Table 2. TRITIUM : CARBON-14 RATIOS OF STEROLS BIOSYNTHESIZED IN THE PRESENCE OF THE SAME SAMPLE OF [^{14}C,^{3}H METHYL]METHIONINE

Sterol	Source	Incubation time (h)	Observed tritium : carbon-14 ratios of sterols purified by: Digitonide precipitation	Thin-layer chromatography	Recrystallization
Ergosterol	Yeast	24	4·24 : 1	4·28 : 1	4·26 : 1
Fucosterol	*Fucus spiralis*	24	4·36 : 1	4·40 : 1	4·40 : 1
β-Sitosterol	Larch	24	4·36 : 1	4·30 : 1	4·30 : 1
		6	4·34 : 1	4·33 : 1	—
β-Sitosterol, stigmasterol and campesterol mixture	Maize	6	4·25 · 1	4·28 : 1	—

the experimental evidence available at present does not allow a definite choice to be made between these two mechanisms. However, the structure of *cyclo*laudenol could be cited as support for Fig. 1. As shown in Fig. 4 the carbonium ion, II, produced by addition of a methyl group to the double bond of I (for example, *cyclo*artenol) may be stabilized by loss of a proton not only as indicated to produce a C-24 methylene steroid III (for example, 24-methylene *cyclo*artenol) but also as shown to give a C-25 methylene steroid VI (for example, *cyclo*laudenol). This has an analogy in carotenoid biosynthesis in which a common carbonium ion can be stabilized by loss of a proton from either adjacent carbon atom to form a β-ionone or α-ionone residue[25]. Determination of the tritium : carbon-14 ratio of *cyclo*laudenol biosynthesized in the presence of [^{14}C,^{3}H-methyl]methionine or mass spectrometry of *cyclo*laudenol biosynthesized from [D_3-methyl]methionine would provide experimental evidence for the involvement or otherwise of an ylide derived from methionine.

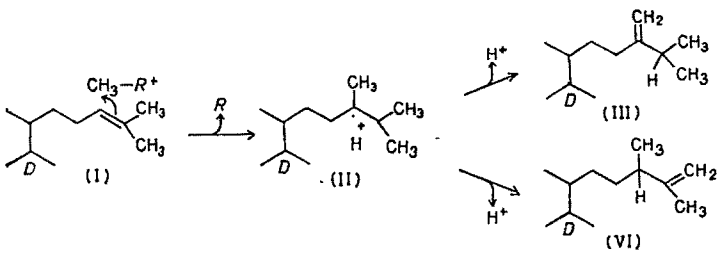

Fig. 4

The mechanism outlined in Fig. 1 requires that the introduction of the methyl group at C-24 will be accompanied by a migration of the hydrogen originally present at C-24 to C-25 in the C-24 methylene steroid produced. Moreover, during the second transmethylation step this hydrogen atom will remain at C-25 in both C-24 ethylidene and C-24 ethyl steroids. The synthesis of [4*R*-4-$^{3}H_1$-2-^{14}C]mevalonic acid has made it possible to test this experimentally. Cornforth, Popják and co-workers[26] showed that [4*R*-4-$^{3}H_1$-2-^{14}C]-mevalonate is incorporated by liver preparations into squalene without loss of tritium. Following squalene cyclization into lanosterol, one tritium atom from C-9 is eliminated to give a tritium : carbon-14 atomic ratio of 5 : 6. Subsequent modification of the lanosterol results in the loss of two more tritium atoms and one carbon-14 atom to give cholesterol with a tritium : carbon-14 atomic ratio of 3 : 5. As one of the tritium atoms retained in cholesterol is at C-24 of the side chain then, in phytosterols biosynthesized from [4*R*-4-$^{3}H_1$-2-^{14}C]mevalonate, the tritium: carbon-14 ratio would be the same as in cholesterol (3 : 5) or 2 : 5 depending on whether the hydrogen at C-24 is or is not retained during alkylation. Experiments with pea sterols (β-sitosterol, stigmasterol and campesterol)[27] and ergosterol in *Aspergillus fumigatus*[28] gave the same tritium : carbon-14 atomic ratio (3 : 5) as found in cholesterol[26], which showed that the tritium originally at C-24 before alkylation was retained. But these experiments provided no evidence for the possible migration of the hydrogen atom to C-25. Evidence for this movement has been provided by the biosynthesis of fucosterol from [4*R*-4-$^{3}H_1$-2-^{14}C]mevalonate by *Fucus spiralis*[29]. Chopped portions of *Fucus spiralis* were incubated with the doubly labelled mevalonate under conditions similar to those given above for the methionine experiment. Incubations were for 11 h at 25° C for experiment 1 and 24 h at 20° C for experiment 2. Fucosterol was isolated from the non-saponifiable lipid following the addition of 5 mg of authentic fucosterol by digitonide precipitation and alumina chromatography. Samples were further purified by silica gel thin-layer chromatography and crystallization from chloroform-methanol. Squalene was obtained by alumina chromatography and thin-layer chromatography. Determination of the tritium : carbon-14 ratios (Table 3) showed that no tritium was lost during squalene biosynthesis in *Fucus spiralis* as found previously in liver[26], peas[27] and *Aspergillus fumigatus* Fresnius[28]. The tritium : carbon-14 ratio observed in fucosterol indicated that three tritium atoms had been retained and was the same as that found in cholesterol[26], pea sterols[27], and ergosterol[28]. As no tritium can be present in fucosterol at C-24, a migration to C-25, or less likely to C-23, must have occurred.

Table 3. INCORPORATION OF [4*R*-4-$^{3}H_1$-2-^{14}C]MEVALONATE INTO SQUALENE AND FUCOSTEROL BY *Fucus spiralis*

	Observed tritium : carbon-14 ratio	Corrected tritium : carbon-14 ratio*
[4*R*-4-$^{3}H_1$-2-^{14}C]Mevalonate	5·33 : 1	1 : 1
Liver squalene†	5·34 : 1	6 6
Experiment 1.		
Squalene	5·37 : 1	6·05 . 6
Fucosterol (purified by thin layer chromatography)	3·28 : 1	3·08 : 5
Fucosterol (crystallized)	3·06 : 1	2·87 : 5
Experiment 2.		
Squalene	5·24 : 1	5·90 . 6
Fucosterol (purified by thin layer chromatography)	3 36 1	3·15 : 5
Fucosterol (crystallized)	3 36 1	3·15 : 5

* The corrected tritium: carbon-14 ratio was calculated assuming that the tritium: carbon-14 ratio of the original mevalonate was 1 : 1 (ref. 28).
† The sample of liver squalene was kindly provided by Dr. Popják for comparison purposes.

We thank Drs. G. Popják and J. W. Cornforth for generous gifts of [4*R*-4-$^{3}H_1$-2-^{14}C] mevalonic acid, and Prof. E. Lederer for discussions. The investigations described in this article were supported in part by a grant from the Air Force Office of Scientific Research through the European Office of Aerospace Research (OAR) U.S. Air Force, and in part by grants from the Science Research Council.

ELECTRON MICROSCOPICAL DEMONSTRATION OF FERRITIN IN THE DENTAL EPITHELIAL CELLS OF URODELES

By Miss MOYA RANDALL

Department of Oral Medicine and Oral Pathology, The London Hospital Medical College, London, E.1

THE teeth of urodeles have characteristic orange tips which are due to the incorporation of an iron compound into the outer layer of the tooth during development. Before coloration of the tooth, numerous orange-yellow granules can be seen in the cytoplasm of the inner dental epithelial cells which surround the developing tooth tip. Application of Prussian blue stain produces an intense positive reaction in these granules and a faint blue colour throughout the cytoplasm, indicating the presence of iron in the ferric state. This is indicative of both ferritin and haemosiderin[1] and not, as has commonly been believed, of haemosiderin only. A similar iron pigmentation occurs in the rodent incisor, in the dental epithelial cells of which the presence of ferritin has been demonstrated in the iron granules[2]. The purpose of the present investigation was to establish the presence of ferritin in the dental epithelial cells of urodeles.

Developing teeth of adult and larval forms of *Amblystoma mexicanum* and *Triturus vulgaris* were dissected from the jaws, fixed with glutaraldehyde followed by osmium tetroxide and embedded in 'Araldite'. They were afterwards sectioned for examination in the electron microscope.

Low-power electron micrographs of the inner dental epithelial cells surrounding the developing tooth tip revealed the presence of large granules of considerable electron density in positions within the cells corresponding to the yellow-orange granules seen in the light microscope.

At higher magnifications (Fig. 1) these granules, which ranged from 0·2 to 2·0μ in diameter, were seen to consist of aggregates of dense spherical particles, approximately 60 Å in diameter. Numerous identical 60 Å particles (*P*, Fig. 1) were dispersed throughout the surrounding cytoplasm. These presumably are responsible for the faint blue reaction in the cytoplasm with the Prussian blue stain. The 60 Å particles are of the same order of size as the ferritin molecules described by previous workers[3,4]. They did not appear to be associated with any of the organized cytoplasmic structures and certainly were not found within the mitochondria or the α-cytomembranes. They were, however, found within the nucleus in this tissue but never aggregated. Some of the cytoplasmic aggregates were enclosed within a membrane (*D*, Fig. 1) but in others no membrane was observed (*B*, Fig. 1). Some, but not all, consisted of a second, slightly less dense, component within which the 60 Å particles were embedded (*A*, Fig. 1). This may represent the protein moiety apoferritin. The distribution of the 60 Å particles within the aggregates was not generally uniform. However, a few have been found with very regular arrangement characteristic of crystalline order (Fig. 1). These features agree with those previously described for ferritin deposits in the liver[3–5].

The molecular structure of both isolated and intracellular ferritin has been described by Muir[5]. Only the central iron nucleus of the ferritin molecule can be seen in electron micrographs. The apoferritin protein coat surrounding the iron nucleus is indistinguishable from the cytoplasm and therefore measurement of the individual dense particles only gives a value for the central iron nucleus. It is this component which measures 60 Å. From the crystalline aggregates the total molecular diameter can be estimated by measuring the separation distances between the centres of the molecules in the crystal (*C*, Fig. 1). This was found to be 92 Å, which is in general agreement with a molecular diameter of 94 Å recorded by

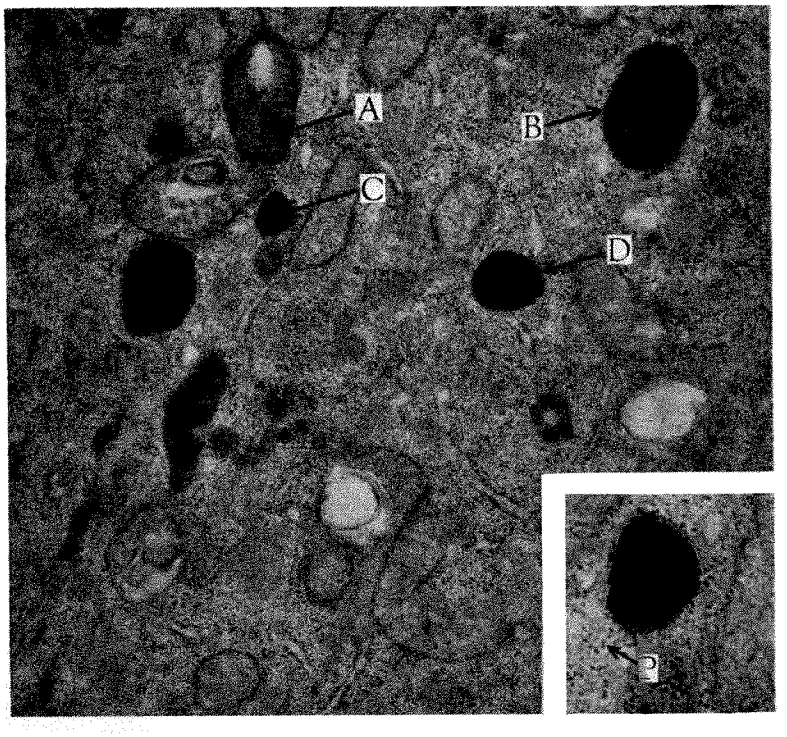

Fig. 1. Electron micrograph of part of an inner dental epithelial cell of *Amblystoma mexicanum* demonstrating ferritin aggregates in the cytoplasm. (×26,675.) Inset is a higher magnification of granule *C*. (×67,900)

Farrant[6] and Muir[5] from isolated horse spleen ferritin which had been shadow-cast.

Ferritin molecules also have a characteristic substructure which can be demonstrated in micrographs with a resolution of approximately 25 Å. The substructure of the molecule is due to the arrangement of the iron which is thought to be in the form of six micelles situated at the vertices of a regular octahedron and surrounded by a shell of protein. This molecular arrangement gives rise to five possible images in the electron microscope[5]. Examples of all these images have been resolved within the 60 Å particles in the present material both in the dispersed cytoplasmic particles and also in a few of the aggregated particles, the form most commonly observed being the paired parallel lines. In a number of the particles within the aggregates resolution of the characteristic substructure was not possible; there was also a variation in density and size of the particles. It has been claimed[3,7] that absence of any substructure, together with variation in density and size of the particles in the aggregates, is indicative of a different substance, namely haemosiderin, but this may not necessarily be the case. The increased density could be explained assuming that there is superimposition of one molecule of ferritin on the other; there are also likely to be many intermediate forms of substructure caused by random orientation of the molecules[5]. If these intermediate forms do represent incomplete micelles of iron hydroxide it would seem that they could be either ferritin which has been only partially synthesized from the apoferritin or, as suggested, ferritin molecules in various states of degradation into haemosiderin. Ultracentrifuge investigations[10] have demonstrated that crystalline ferritin is a heterogeneous mixture consisting of a complex of apoferritin-iron hydroxide and about 25 per cent free apoferritin. Fineberg and Greenberg[11] conclude that the iron-free apoferritin is the initial product in the synthesis of ferritin, but whether it is synthesized in the cytoplasm generally or within specific cytoplasmic organelles does not appear to be known. In addition, it has been shown by several workers[3,4,7] that ferritin is a component of haemosiderin and that it always precedes the formation of the latter[8]. The hypothesis has been suggested[9] that haemosiderin is formed by oxidation and proteolytic degradation of ferritin resulting in a rearrangement of the iron content and an altered protein structure. This would give rise to a different size and appearance of the iron micelles in the electron microscope indicative of haemosiderin and would explain the insolubility of haemosiderin in contrast to the soluble ferritin. The exact differences, in terms of electron microscopy, between ferritin and haemosiderin do not seem to have been conclusively demonstrated.

To obtain further information on the nature of the iron compound in this tissue, selected area electron diffraction was attempted on the aggregates of ferritin in the sections, and compared with the values obtained by Richter[7] for haemosiderin granules from human liver and for partly hydrated alpha ferric oxide ($Fe_2O_3.H_2O$). The results from this investigation (columns 1 and 2) and the values obtained by Richter (columns 3 and 4) are shown in Table 1.

Electron diffraction patterns were obtained from both the 'obviously ordered' (*C*, Table 1) and the 'apparently disordered' (*D*, Table 1) aggregates. The diffraction patterns are from the iron-containing core of the ferritin molecules only, which is presumably in the form of small crystallites. As can be seen from Table 1 the d_{hkl} values for both these types of granule are almost identical; this would suggest that they contain the same iron compounds. The agreement with Richter's values for $Fe_2O_3.xH_2O$ indicates the presence of hydrated Fe_2O_3 and the similarity of this material with liver haemosiderin. It is not possible to determine the degree of hydration of the ferric oxide using electron diffraction since the material has been previously dehydrated and may also undergo changes in the electron beam. It is also possible that the preparation procedures have altered the nature of the ferric oxide, which may not be in crystallite form *in vivo*.

Table 1. RESULTS OF ELECTRON DIFFRACTION ON INTRACELLULAR IRON GRANULES

d_{hkl} Å *C*	d_{hkl} Å *D*	d_{hkl} Å Haemosiderin	d_{hkl} Å $Fe_2O_3.xH_2O$
3·10	3·10	3·10	—
—	2·58	2·54	2·59
2·25	2·25	2·21	2·24
1·83	1·82	1·82	—
1·61	1·61	1·57	1·58
*1·30–1·17	1·30–1·17	2·35 1·30 1·20	1·36 1·36

The results given in the first two columns are from the present investigation; columns 3 and 4 are from those published by Richter (ref. 7).

* A range is given here since this outer ring is very diffuse, and may represent two or more d_{hkl} values.

This investigation has identified the iron present in the dental epithelial cells of urodeles as ferritin, by its molecular size, substructure, and electron diffraction pattern. It was seen to be present in considerable amounts in the cytoplasm and several of the molecular aggregates of ferritin appeared to be in crystal form. Ferritin molecules were also found dispersed within the nucleus. Ferritin has not previously been reported in amphibia except in a brief mention of its presence in the liver of the toad[5], and this was thought to be due to the diet of mammalian liver on which the animals were reared. It should be mentioned that most of the material in the present investigation was from animals feeding in their natural environment and is therefore an entirely normal occurrence. Most of the reports of the occurrence of ferritin in the liver have been on pathological material, or on experimental material in which excess storage of iron has been abnormally produced.

The reasons for the presence of this iron storage compound in what is regarded as a highly specialized and still metabolically active cell, and the subsequent secretion of iron into the developing tooth, are not known. The finding of the iron-hydroxide containing ferritin in the dental epithelial cells would seem to link up well with the suggestion by Schmidt[13] that the iron in the teeth is in the form of haematite (Fe_2O_3). In this connexion it is of considerable interest that ferritin has been demonstrated[12] in the epithelial cells which form the calcified denticles of the radula of a marine chiton and moreover that the iron here is in the form of the mineral magnetite ($Fe_2O_3.FeO$). The relationship between ferritin in the cells and the formation of the magnetite or haematite remains to be established.

In a very recent article[14], fractionated ferritin, of varying densities, has been examined with the electron microscope and it was found that the low-density fractions have molecules with a smaller iron nucleus than the higher density fractions. It is also suggested that the range of patterns of the iron-nucleus can be accounted for by a range of variable dense regions in which the number and geometrical arrangement of the iron-oxide crystallites are variable and are not necessarily in the form of six micelles as previously suggested, but randomly sited within the protein shell.

I thank Mr. R. W. Fearnhead for his assistance with the electron diffraction, and Prof. A. E. W. Miles, in whose department the work was undertaken during the tenure of a Medical Research Council grant.

PHOTOSYNTHETIC NITRITE REDUCTASE AND THE SIGNIFICANCE OF HYDROXYLAMINE IN NITRITE REDUCTION IN PLANTS

By DR. G. F. BETTS* and DR. E. J. HEWITT
Long Ashton Research Station, University of Bristol

PREVIOUS work[1,2] showed that a nitrite reductase system in vegetable marrow (*Cucurbita pepo*) was able to reduce nitrite quantitatively to ammonia at rates exceeding the reduction of hydroxylamine when using identical preparations and conditions. The direct electron donor was the reduced benzyl viologen free radical ($BV^{\cdot}$). From kinetic considerations of rates, K_m values for both substrates and inhibitory effects of nitrite on hydroxylamine reduction, it was concluded that free hydroxylamine is not an intermediate product of nitrite reduction by plants. This view is consistent with results reported for *Escherichia coli*[3,4], where NADPH was an electron donor, and is contrary to the classical idea of nitrite reduction[5] which has been widely accepted on the basis of recent work carried out with fungi[5,7].

The conclusion reached with marrow[2] was, however, limited in validity because of the use of a non-physiological electron donor, especially as in a reaction involving six electrons the possibility of some non-physiological steps could not be excluded. Natural electron carriers found to function in nitrite and hydroxylamine reduction in both light and dark systems of bacteria and plants[8,9-11] are non-haem iron proteins now described by the generic name ferredoxin[12]. In published reports[9,10] giving comparative data for ferredoxin-dependent systems, the rate of hydroxylamine reduction always exceeded that of nitrite. We have now established that nitrite is reduced to ammonia by the chloroplast-ferredoxin system at rates substantially greater than those for hydroxylamine.

Chloroplast grana were obtained from whole chloroplasts of *Spinacia oleracea* which had been extracted and washed once in a solution consisting of 0·4 M sucrose; 0·01 M sodium chloride; 0·05 M *tris*, *p*H 7·5[12]. The washed plastids were ruptured by suspending them in a large volume of 0·05 M *tris*, *p*H 7·5. Grana were collected by centrifugation at 19,000*g* and normally washed three times by re-suspension in 0·05 M *tris* unless stated otherwise. Spinach ferredoxin was prepared from washed, frozen[12] lamina by a method involving acetone fractionation, dialysis, protamine precipitation and DEAE-cellulose chromatography[13,14], and was pure by spectrophotometric criteria[14-16]. The protamine step[13,15] was found to be essential to obtain a correct spectrum at 260–278 mμ relative to values at 330, 420 and 465 mμ when using frozen leaves. Crude nitrite and hydroxylamine reductase protein was extracted from spinach as described for marrow (*C. pepo*)[2]. The protein was precipitated by ammonium sulphate between 50 and 75 per cent saturation resuspended in 7 mM *tris*, *p*H 7·3, and dialysed against several large volumes of this buffer for periods up to 16 h to remove ammonium ions. The reaction mixture included chloroplast grana equal to approximately 650 μg chlorophyll, 600 μg ferredoxin, 150 μmoles *tris*/hydrochloride buffer, *p*H 7·5, and crude enzyme in 3 ml. The reaction was carried out in Thunberg tubes in an illuminated water bath at constant temperature for 20 min at 20° C with 45,000 lux from 150-W tungsten spot lamps. The gas phase was either air, or argon when anaerobic conditions were required. Anaerobiosis was assured by heating the grana at 55° C for 5 min to destroy oxygen evolution activity and substituting the physiologically second light reaction of the chloroplasts by electrons from an ascorbate-indophenol couple[17]. Nitrite and hydroxylamine were both determined by a method which used alkaline iodine to prevent interference by ascorbate[9] or benzyl viologen[2] where used by the method already described[2]. No losses occurred in dark controls and all changes were differences from zero time values.

Table 1 shows results obtained from simultaneous assays (as described earlier) of nitrite and hydroxylamine reductase activities carried out with identical replicate samples of separate spinach preparations obtained on different occasions. Results obtained with a preparation from *C. pepo* (kindly provided by D. P. Hucklesby) which had been subjected to further purification on hydroxyapatite and DEAE-cellulose[18] are also included. Nitrite was reduced more rapidly (in one case six times faster) than hydroxylamine at equal substrate concentrations, and ammonia production from nitrite always exceeded that from hydroxylamine. These results thus confirm and extend the conclusion reached in earlier work[2,9].

Table 1. REDUCTION OF NITRITE OR HYDROXYLAMINE BY ILLUMINATED SPINACH GRANA FERREDOXIN AND DIFFERENT ENZYME PREPARATIONS ASSAYED FOR THE TWO ACTIVITIES SIMULTANEOUSLY*

Enzyme† preparation	Protein (mg)	Grana system‡	Activity* Nitrite loss	Ammonia gain	Hydroxylamine loss	Ammonia gain
Spinach *A*	4·2	Anaerobic	1890	1920	998	1415
Spinach *B*	1·3	,,	1165	—	190	—
Spinach *C*	1·3	,,	645	—	163	—
Spinach *D*	(I)3·4	Aerobic	1660	1700	852	365
Spinach *D*	(II)1·7	,,	1700	2010	865	900
Marrow	0·27	Anaerobic	1680	1780	657	104

* Assay for 20 min at 20° C, 650 μg chlorophyll, 600 μg ferredoxin; 2 μmoles substrate, 45,000 lux *p*H 7·5, in 0·05 M *tris*/hydrochloride 3·0 ml. Activity as loss of substrate or gain of ammonia (mμmoles).

† Spinach enzyme was precipitated by ammonium sulphate and dialysed as described in the text. Preparations *A*, *B*, etc., made on separate occasions: I, II, etc., tested on separate occasions. Marrow enzyme was further purified by chromatography on DEAE cellulose and gradient elution with citrate buffers (ref. 18).

‡ Spinach grana either washed 3 times as described and used in air (aerobic) or after heating 5 min at 55° C and used in argon with $1·25 \times 10^{-3}$ M ascorbate and 7×10^{-5} M dichlorophenol-indophenol (anaerobic).

Using rate-limiting ratios of reductase enzyme to chlorophyll and the anaerobic systems with heated grana, the rates of substrate reduction were plotted against total ferredoxin concentration (salt free) as shown in Fig. 1, and yielded different curves for the two substrates. This suggested that considerations of saturation concerned the reductase enzyme side and not the light-grana reduction side of the ferredoxin reaction. Reciprocal plots indicated tentative values of 10^{-15} M as the apparent K_m for total ferredoxin for a molecular weight[14,15] of 14,000 when mediating nitrite reduction and 3×10^{-6} M when mediating hydroxylamine reduction.

The difference in these values therefore resembled that observed for $BV^{\cdot}$ in the *C. pepo* systems[2], but the affinity for ferredoxin appears to be appreciably greater. Thus, not only are the observed values smaller for ferredoxin, but the quantities present in the reduced (donating) form would be some fraction of the total amounts shown in Fig. 1. Values calculated for V_{max} suggest that the concentrations used in Table 1 and other experiments were sufficient to produce 62 per cent maximal rates for nitrite and 74 per cent for hydroxylamine reductase activities. Thus any degree of unsaturation would have depressed hydroxylamine reductase less than nitrite. At maximal velocity, nitrite reduction could be more than seven times greater than hydroxylamine in some of the preparations used in this work.

* Present address: Department of Botany and Plant Pathology, University of Oregon, Corvallis, Oregon.

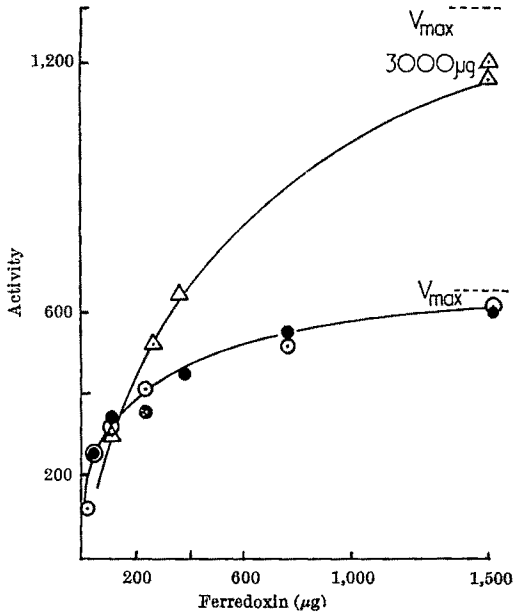

Fig 1. Effect of ferredoxin concentration on activity of nitrite or hydroxylamine reductase present in the same preparation assayed in presence of spinach grana equivalent to 650 µg chlorophyll illuminated with 45,000 lux, for 20 min at 20° C. Other conditions as described in text. Activity was measured as substrate loss (nitrite, triangles; hydroxylamine, circles); additional results for ammonia production from hydroxylamine (solid circles) are also presented. Values for V_{max} shown by horizontal lines were calculated from reciprocal plots

When the enzyme system was partially fractionated as shown in Table 2, there was a greater increase in specific activity for nitrite than for hydroxylamine reduction. Comparison of the activities obtained with ferredoxin and grana, or BV* (using the method already described[2]), showed the former to be the more effective for either substrate. The ratio between the two activities for nitrite was nearly constant and a less consistent but fair correspondence was found for hydroxylamine. In another experiment with enzyme which had been increased approximately fifty-fold in specific activity, the total reduction of nitrite (2 µmoles) produced 2 µmoles of ammonia. This showed that purification had not resulted in any lesion in the overall electron transfer reaction yielding ammonia when ferredoxin was the electron donor. In the corresponding 20-min period there was a loss of only 0·8 µmoles of hydroxylamine with quantitative ammonia formation. The inhibitory effect of nitrite on hydroxylamine reduction reported for *C. pepo* with BV as electron donor[2] was observed similarly when ferredoxin was substituted in a system utilizing glucose-6-phosphate and NADP as the electron donor system. These results justify the conclusion that benzyl viologen used strictly in the manner described in earlier work[2] is a valid reagent for the assay of nitrite and hydroxylamine reductase activities during fractionation and for certain kinetic studies.

Table 2 REDUCTION OF NITRITE OR HYDROXYLAMINE BY PARTIALLY FRACTIONATED SPINACH ENZYMES USING ILLUMINATED GRANA AND FERREDOXIN OR BV AS ELECTRON DONOR SYSTEMS*

System	Ferredoxin		BV*	
Activity†	Nitrite	Hydroxylamine	Nitrite	Hydroxylamine
Fraction used				
I Extract in 0 05 M *tris*/HCl, *p*H 7 5	53	37	15	14
II Ammonium sulphate-preparation 50–75 per cent	112	64	31	21
III 'Sephadex *G* 25'	88	45	25	13
IV Adsorption of DEAE-cellulose column, elution between 0·13 and 0·2 M sodium chloride, *p*H 7, re-adsorption and elution at 0·4 M sodium chloride	3050	670	810	144
IV Separate experiment‡				
Substrate loss:	1950	520	507	107
Ammonia gain:	2000	500	550	205

* Assay conditions were as for Table 1 in ferredoxin system, or as described for earlier work with *C. pepo* (ref. 2) in BV system using 34 per cent reduced dye.
† Activity as mµmoles substrate loss in 20 min/mg protein.
‡ All added nitrite (2,000 mµmoles) reduced in 20 min by 0·35 mg protein.

Table 3. EFFECT OF TREATMENT OF SPINACH GRANA ON REDUCTION OF NITRITE OR HYDROXYLAMINE IN RELATION TO ADDED ENZYME PROTEIN*

Treatment of grana and conditions	Substrate loss	
	Nitrite	Hydroxylamine
Grana washed once. No added enzyme	1028	672
Grana washed twice. ,, ,, ,,	417	183
Grana washed three times. No added enzyme	221	54
,, ,, ,, ,, plus 0 77 mg of added enzyme	817	508
,, ,, ,, ,, No added enzyme but ascorbate-indophenol couple included	133	27
Grana washed once. No added enzyme but grana heated 5 min at 55° C and ascorbate-indophenol couple included	178	156
Grana washed once, heated 5 min at 55° C plus 0·77 mg of added enzyme and ascorbate-indophenol couple included	1,135	1,245

* Assay conditions as for Table 1 under aerobic conditions but using 1,000 µg chlorophyll.

The possibility that nitrite and hydroxylamine reductase activities reside in the same protein has been raised[2-4]. During numerous attempts to fractionate the enzymes we have often observed a loss of hydroxylamine reductase relative to nitrite (see Table 2) without separation into different fractions. Very recently, however, we have obtained an apparent segregation into distinct proteins each of considerably increased specific activity using 'Sephadex *G* 200' when nitrite reductase was retarded less than hydroxylamine reductase.

Spinach chloroplasts washed once in the sucrose extracting medium, and once-washed grana, possess considerable nitrite and hydroxylamine reductase activity without added enzyme. Table 3 shows that successive washing of grana obtained after hypotonic rupture of chloroplasts caused a progressive loss of reductase activity and that the decrease was proportionately greater for hydroxylamine than for nitrite. Once-washed grana heated for 5 min at 55° C lost 75 per cent of endogenous nitrite and 50 per cent of hydroxylamine reductase activity, although they retained their capacity to reduce ferredoxin without added flavoprotein after prolonged washing[19] or after heating when they were also provided with the indophenol-ascorbate couple[20]. As can be seen from Table 3, the addition of enzyme restored the capacity of washed or heated grana to reduce both substrates in the ferredoxin system. There was no stimulation when the indophenol-ascorbate couple was provided for thrice-washed grana in the presence of added enzyme, under normal oxygen-evolution conditions. These results provide conclusive evidence for the presence of reductase activity in the chloroplasts but do not exclude the possibility of additional cytoplasmic sites.

Previous work[1,2] showed that when benzyl viologen is reduced more than about 75 per cent corresponding to a calculated redox potential of about −0·39 V a direct chemical reaction with nitrite occurs at *p*H 7·5 without a full yield of ammonia. Such a reaction also occurs at lower *p*H values with less reduced benzyl viologen[18]. The data of Table 3 show that no direct reaction is likely to be involved in the ferredoxin system under the conditions used, which provide substantial amounts of chlorophyll and saturating light intensity, and evidence for direct reaction has never been observed. The extent of net ferredoxin reduction during the reaction is at present unknown, but a redox potential of −0·39 V/−0·40 V would be expected for 30 per cent reduction[14]. The work of Chance and San Pietro[21] may, however, offer a guide as to the degree of reduction expected. In a steady-state system containing only 2·5 µg chlorophyll/ml. in equilibrium with dissolved atmospheric oxygen the reduction reached 28 per cent with a light intensity stated elsewhere to be saturating (see refs. 13 and 14 cited in ref. 21). In the presence of NADP as an acceptor the reduction decreased to about 0·4 of the above, namely 11 per cent. In our

work, anaerobic conditions have been used with more chlorophyll and in some cases (Fig. 1) rate-limiting amounts of reductase. The degree of ferredoxin reduction could therefore have exceeded 30 per cent even in the presence of the substrate, but typical Michaelis–Menton kinetics were nevertheless observed.

In previous work[9] with *C. pepo* grana, where notably lower light intensities were used, hydroxylamine reductase exceeded nitrite reductase activity. Suppression of oxygen evolution with chlorophenyl-dimethylurea (CMU) substantially increased both activities, but the disparity was much less because the increase was more than twice as great for nitrite as for hydroxylamine. In the present work with *S. oleracea* grana, which do not "age" quickly like those of *C. pepo*, inhibition of oxygen evolution by CMU in the presence of the indophenol-ascorbate couple has produced no advantage over an oxygen-evolving system although maximal rates so far obtained have been observed using heated grana with the couple under anaerobic conditions. These observations are consistent with the possible operation of a redox factor in the ferredoxin system similar to that thought to influence the BV system[2], and this point is under investigation.

Our results are interpreted as meaning that while nitrite and hydroxylamine are reduced photochemically by the same or closely related enzymes located in chloroplasts, hydroxylamine is not an intermediate in the commonly accepted sense in nitrite reduction in higher plants. This view is contrary to the situation envisaged for fungi[6,7], but is consistent with that proposed for *E. coli*[3,4].

ASCORBIC ACID AND THE LUNG

By Prof. D. R. SHANKLIN and T. E. O'DELL

Department of Pathology, College of Medicine, University of Florida, Gainesville

THERE have been no general investigations of the ascorbic acid levels in the tissues of guinea-pigs nor of their depletion on scorbutigenic diets since the comprehensive report of Penney and Zilva in 1946[1]. Reports on the effects of several substances such as ACTH and insulin on ascorbic acid levels[2] have appeared. Others have been concerned with the vagaries of precise determination[3,4] and the presence or absence of tissue binding[5].

In so far as we can ascertain, there have been no general investigations on the presence of ascorbic acid in the lung. Skirko and Grubina investigated the histochemical localization of vitamin C in lungs of rats exposed to silica particles[6]. The participation of pulmonary ascorbic acid in general depletion states in guinea-pigs has not been reported. This lack of information together with certain considerations of the vascular integrity of the lung prompted us to investigate two points: (*a*) whether ascorbic acid could be determined quantitatively in the lungs of guinea-pigs, and (*b*) whether these levels were responsive to depletion states induced by scorbutigenic diets. Both these questions were answered affirmatively. Evidence was also obtained which suggests that scorbutic depletion involves the mobilization of two possibly separate pools of ascorbic acid in guinea-pig tissues.

All the guinea-pigs used in these experiments were from mixed commercial stock obtained nearby. Two sets were used. The first consisted of twenty-seven adult females (391–613 g) obtained in November 1964. After several days on fresh stock diet (Rockland Guinea-pig Diet, Teklad Corp., Monmouth, Illinois) without supplementation, fifteen were set aside as follows: four were killed as zero-h controls and eleven were placed on a totally scorbutigenic diet (Nutritional Biochemicals, Cleveland, Ohio). A further three were killed at 72 h, four at 120 h, and four at 240 h. At the end of the first run, the remaining twelve animals, which had been fed continuously on stock diet, were treated similarly. Three were killed as zero-h controls, and then three each at 72, 120, and 240 h after starting on the scorbutigenic diet. The second set, obtained in February 1965, consisted of forty animals, four males (332–544 g) and thirty-six females (263–544 g). They were placed on stock diet for 2 weeks with water *ad libitum*. During this period, small amounts of fresh cabbage were added to the cages at irregular intervals. Four randomly selected animals were killed as zero-h controls. The remainder were placed on a scorbutigenic diet. Four more animals each were randomly selected from the cages at 24, 48, 72, 96, 120, 144, 240, and 336 h. The four remaining at the conclusion of the experiment were returned to stock diet.

All the animals were killed by a sharp blow on the head. They were dissected immediately. In the first set, lungs, liver and kidneys were removed for chemical analysis; these and the adrenals were removed in the second set. As appropriate, whole organs or portions of organs were blotted, weighed, and quickly frozen for later determination.

At the conclusion of each phase, after all the tissues had been frozen, they were quickly thawed in small batches. Quantitative determination of total ascorbic acid (TAA) was immediately undertaken according to the method of Roe and Kuether[7], as modified for solid tissues by Penney and Zilva[1].

The depletion curves from the first phase are shown in Fig. 1. The initial levels for the second half of the investigation accord with our general experience, namely, that higher levels are maintained by our stock diet and supplemental feedings of cabbage than are found on arrival from commercial sources. The levels for the lung are generally higher than those for either liver or kidney. Their decline on scorbutigenic diet is clearly indicated. Since we omitted the adrenal, we could not determine how the lung levels compared with those for other organs. This point, and the apparent biphasic nature of the

curves, especially those for the liver, led us to undertake the second and more detailed analysis.

The results of this experiment are shown in Table 1. The mean values with the calculated standard errors of the mean are given. These same figures are then plotted graphically on semi-logarithmic co-ordinates (Fig. 2).

Table 1. LEVELS OF ASCORBIC ACID, MG/100 G TISSUE

Hours of depletion	Lung	Adrenal	Liver	Kidney
0	7·37 ± 0·18	48·70 ± 3·10	4·86 ± 0·64	2·62 ± 0·38
24	8·40 ± 1·13	36·50 ± 2·50	3·15 ± 0·45	1·89 ± 0·06
48	5·40 ± 0·69	39·30 ± 4·63	2·76 ± 0·25	1·68 ± 0·17
72	4·18 ± 0·71	13·60 ± 1·60	1·13 ± 0·18	0·94 ± 0·19
96	2·04 ± 0·34	9·50 ± 0·81	1·26 ± 0·22	0·51 ± 0·11
120	2·21 ± 0·36	13·74 ± 1·75	1·28 ± 0·32	0·51 ± 0·05
144	1·49 ± 0·27	11·52 ± 1·75	1·07 ± 0·25	0·54 ± 0·13
240	1·83 ± 0·34	4·10 ± 1·73	0·46 ± 0·13	0·34 ± 0·05
336	0·49 ± 0·11	2·12 ± 0·42	0·19 ± 0·00	0·20 ± 0·10

* Mean ± standard error of mean.

All these investigations indicate substantial amounts of ascorbic acid in the lungs of guinea-pigs responsive to depletion states in a fashion generally similar to other organs. When comparable data from the work of Penney and Zilva are examined, the lung would appear to have levels similar to the small intestine, and possibly the spleen[1]. The lung is then a major site of ascorbic acid storage in guinea-pigs on a per 100 g weight basis. Because the lungs are a relatively light tissue (less than 1 per cent of body weight) they constitute only a small fraction of the total body stores of the vitamin.

That levels determined on a 24-h interval basis show a definite lack of uniform depletion is shown by the absolute levels in the tables and by the logarithmic plot. Definite plateaux between 72 and 144 h can be noted for adrenal, liver, and kidney, and a longer plateau is seen for the lung from 96 to 240 h. The points for the lung at zero, 72, 120 and 336 h, taken alone, would, if connected, yield an exponential plot. This would give rise to the possibly false impression of a single pool diffusing from the intracellular

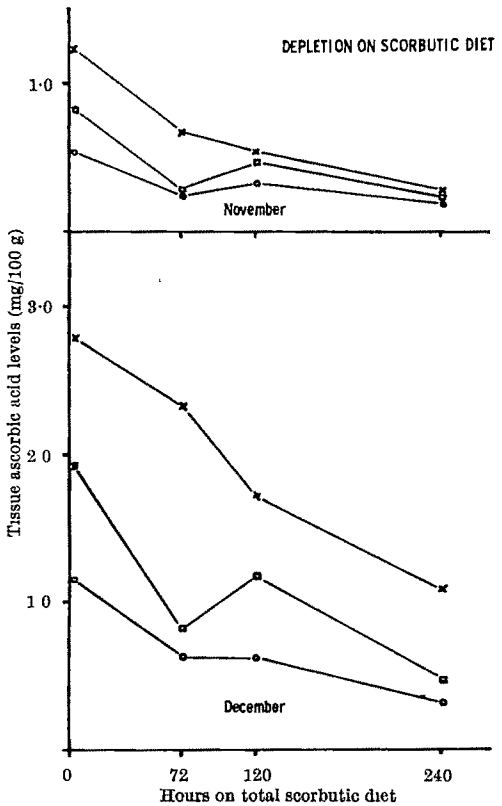

Fig. 1. Parallel linear plots of both halves of first experiment. The upper portion was determined in November, and the lower in December, 1964, after more preparation on stock diet. The 120-h lung point for December is questionable, only two samples being available; the third was lost in processing. ×, Lung; □, liver; ○, kidney

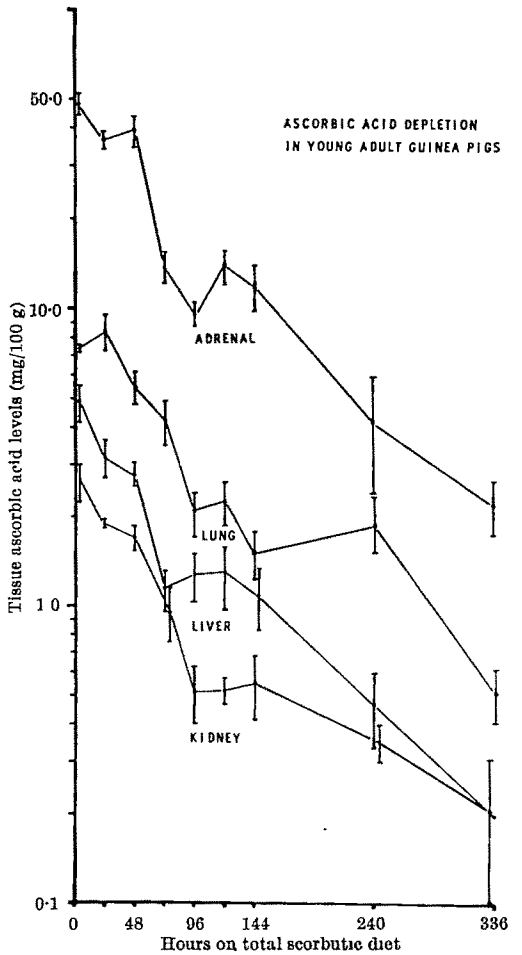

Fig. 2. Semi-logarithmic plot of the second, more extensive experiment. Four animals per point. All curves show non-exponential behaviour about 72 or 96 to 144 h; the "plateau" for lung extends to 240 h. Portions of curves before and after plateau are essentially exponential, but at slopes different one from the other. Standard error of the mean at 336 h for liver was 0·00. Higher zero h levels are attributable to greater duration of preparatory diet of good quality

and interstitial compartments. Similar plots can be constructed for the other organs investigated, yielding a picture essentially similar to that found by Penney and Zilva, who plotted TAA levels at 1, 3, 8, 15, and 23 days[1]. We cannot be sure whether the further variation between zero and 24 h represents a normal increase in the pulmonary TAA level through some mobilization and transport mechanism or simply a variation in the sampling and chemical assays. The specific values for the lung levels at zero h were: 7·15, 6·98, 7·65, and 7·68 mg/100 g; those at 24 h were: 5·45, 9·65, 10·50, and 8·00 mg/100 g.

The behaviour of the other tissue levels suggests that the phenomenon is a general one. Since the slope of the depletion curves is a reflexion of the initial levels, an effect of tissue 'flush' of ascorbic acid such as described by Penney and Zilva on loading, either by diet or by supplementation[1], must be considered an explanation for the biphasic slopes. The essential agreement between our three experiments, despite clearly different initial levels, mitigates against that possibility. The further differences between the several tissues in the duration of the apparent 'plateau' may indicate separate rates of turnover or utilization. Whether there is any order or sequence in depletion such as has been determined for the embryo during development[8] cannot be stated on the basis of this investigation.

It is tempting to consider that two forms of ascorbic acid exist in animal tissues, one in a rather loose state of association which depletes at a rapid rate, and the other in a high degree of association, or perhaps polymerization

the pool of which is entered only after the former is essentially depleted. Whether this is fully true, and whether a bound form is chemically similar to the bound fraction of plants, ascorbigen[9], remains to be established.

This work was supported by a grant from the John A. Hartford Foundation, New York.

RATE OF DISSOLUTION OF GRISEOFULVIN AND HEXOESTROL IN BILE SALT SOLUTIONS

By THEODORE R. BATES, Prof. MILO GIBALDI and Prof. JOSEPH L. KANIG
College of Pharmacy, Columbia University, New York

In order for a solid drug to be absorbed to any appreciable extent across the gastrointestinal barrier, it must be in solution[1]. Thus, for relatively water-insoluble drugs, the rate-limiting step in the absorption process is usually dissolution in the biological fluids of the gastrointestinal tract[2]. The importance of dissolution kinetics in the absorption process has been discussed in detail by numerous investigators[3–8].

Noyes and Whitney[9] derived the following equation for the dissolution rate of solid substances:

$$\frac{dc}{dt} = k(C_s - C) \qquad (1)$$

where dc/dt is the rate of dissolution, C_s is the equilibrium solubility of the solid and C is the concentration of solid in solution at time, t. The k in this equation is dependent on a number of physico-chemical factors, some of which are the surface area of the solid exposed to the dissolution media, the temperature, the intensity of agitation and the diffusion coefficient of the dissolved solid[2,10].

It can readily be seen from equation (1) that, for relatively water-insoluble drugs, the solubility term C_s is one of the more important factors governing the rate of dissolution of the drug. Since the rate of dissolution is directly proportional to C_s, any change in the nature of the dissolution media which will effectively increase C_s should, in theory, increase the rate of dissolution of the drug. One means by which this could be accomplished is by the addition of a surface-active agent to the dissolution media.

It is possible for surface-active agents to increase the dissolution rate of a relatively water-insoluble drug by either of two mechanisms: (i) by decreasing the interfacial tension between the drug and the dissolution medium, thus allowing the latter to wet the drug more completely[11]; or (ii) by means of micellar solubilization. The latter mechanism involves the incorporation of the water-insoluble material into micelles (that is, aggregates composed of monomers of the surfactant) formed above the critical micelle concentration (CMC) of the surfactant[11–13].

Very few reports have appeared in the literature concerning the influence of surfactants on the rate of dissolution of therapeutically significant drugs. The effect of the surfactant sodium lauryl sulphate on the dissolution characteristics of benzoic acid[14], salicylic acid[15] and certain crystalline forms of prednisolone[2] has been investigated. The results of these investigations show that the dissolution of these drugs is substantially increased in the presence of the surface-active agent. No reports have appeared in the literature on the effects of physiological surfactants on the dissolution characteristics of drugs.

Perhaps one of the most important groups of surfactants present in man, as well as in other animals, is the bile salts. These physiological surfactants have been shown to play an important part in both the digestion and absorption of dietary fats in the small intestine[16–19]. Their physico-chemical properties are similar to those of typical colloidal surfactants, including their ability to solubilize water-insoluble substances above their CMC (refs. 20–38).

In a previous communication[38], we have reported a portion of an extensive physico-chemical investigation, being conducted in our laboratory, to examine some of the factors which influence the micellar solubilization of relatively water-insoluble drugs in aqueous solutions of both conjugated and unconjugated bile salts. This investigation was initiated in connexion with the hypothesis that one of the steps in the gastrointestinal absorption of relatively insoluble drugs involves the preliminary solubilization of the drug by bile salt micelles normally present in the small intestine during fat absorption[38]. In view of the dynamics involved in the absorption process it was decided to consider the effect of bile salts on the rate of dissolution of poorly soluble drugs. The dissolution of both hexoestrol (obtained from Gallard-Schlesinger Chemical Manufacturing Co., New York) and griseofulvin (generously supplied by the Schering Co., Bloomfield, New Jersey) was investigated in 0·04 M solutions of the bile salts sodium cholate and sodium deoxycholate, as well as in distilled water. The bile salts, obtained enzymatically pure from Mann Research Laboratories, Inc., New York, were dried *in vacuo* for 36 h before use.

The apparatus in which the investigations of dissolution were conducted was similar to that used by Higuchi and Shefter[10]. It consisted chiefly of the following items: a 150-ml. beaker, a magnetic stirrer, a 2·3-cm fluorocarbon-covered stirring bar, and a timer.

The procedure used for the dissolution experiments was as follows: a weighed sample of the drug (20 mg griseofulvin and 100 mg hexoestrol), in excess of its predetermined equilibrium solubility in 0·04 M bile salt solution, was rapidly added to exactly 100 ml. of dissolution medium at 37° ± 1° C.

The solution was agitated by means of a magnetic stirrer. The intensity of agitation was high, but was maintained constant for all experiments performed with the individual drugs. At 2-, 5- and 10-min intervals a 5-ml. sample was withdrawn from the beaker and replaced by the same volume of dissolution medium. The sample was rapidly filtered through a 'Millipore' filter assembly (0·45μ pore size). An aliquot of the clear filtrate was diluted with anhydrous reagent methanol and the concentration of drug in solution determined spectrophotometrically from the absorbance values at 278 mμ for hexoestrol and 292 mμ for griseofulvin, using the Beer's law relationship[38]. All dissolution experiments were conducted in a constant-temperature room maintained at 37° ± 1° C. A cumulative correction was made for the previously removed samples in determining the total amount dissolved by using the formula:

$$C_n = C_{n,\,\text{meas.}} + \frac{5}{100} \cdot \sum_{s=1}^{n-1} (C_{s,\,\text{meas.}}) \qquad (2)$$

where $C_{n,\text{meas.}}$ denotes the spectrophotometrically measured concentration, and C_n is the concentration of the nth sampling expected in the medium if the previous samples had not been removed[39].

Fig. 1 shows the dissolution behaviour of griseofulvin in water, 0·04 M sodium cholate and 0·04 M deoxycholate at 37° C. A bile salt concentration of 0·04 M is considered to be the approximate molarity of the total bile salts present in the small intestine during fat absorption[40–42]. Each curve is drawn through points which represent an average of two dissolution runs. As can be seen from these curves the concentration of griseofulvin, at any time, is substantially greater than that in water. The dissolution rates in these media decrease in the following order: sodium deoxycholate solution > sodium cholate solution ≫ water. This parallels the order observed for the equilibrium solubility of griseofulvin in water and 0·04 M bile salt solutions at 37° C (ref. 38).

Table 1. RELATIVE DISSOLUTION RATES* FOR GRISEOFULVIN AND HEXOESTROL AT 37° C

Dissolution medium	Griseofulvin Time (min) 2	5	10	Hexoestrol Time (min) 2	5	10
Water	1·0	1 0	1·0	1 0	1 0	1 0
Sodium deoxycholate (0·04 M)	7 5	6·6	6·0	14·6	18·6	24 0
Sodium cholate (0 04 M)	7 2	6 1	5·5	20 3	30 4	36·0

* Ratio of the amount of drug solubilized in the bile salt medium divided by the amount of drug solubilized in the aqueous medium at the same time interval.

The dissolution curves for hexoestrol in each dissolution medium are shown in Fig. 2. The dissolution rates in these media decrease in the following order: sodium cholate solution > sodium deoxycholate solution ⋙ water. The same sequence was observed in equilibrium solubility experiments with hexoestrol in 0·04 M bile salts and water at 37° C (ref. 38).

The relative dissolution rates, that is, the amount of drug solubilized in the bile salt medium divided by the amount of drug solubilized in the aqueous medium at the same time-interval for both griseofulvin and hexoestrol, are shown in Table 1.

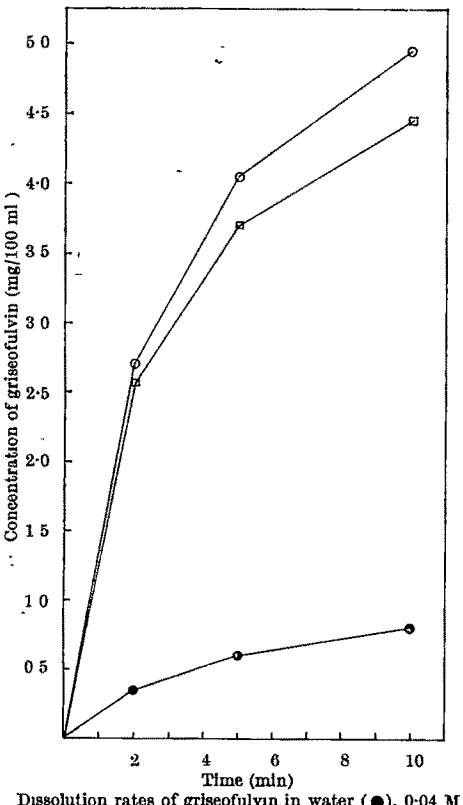

Fig. 1. Dissolution rates of griseofulvin in water (●), 0·04 M sodium deoxycholate (○), and 0·04 M sodium cholate (□) at 37° C

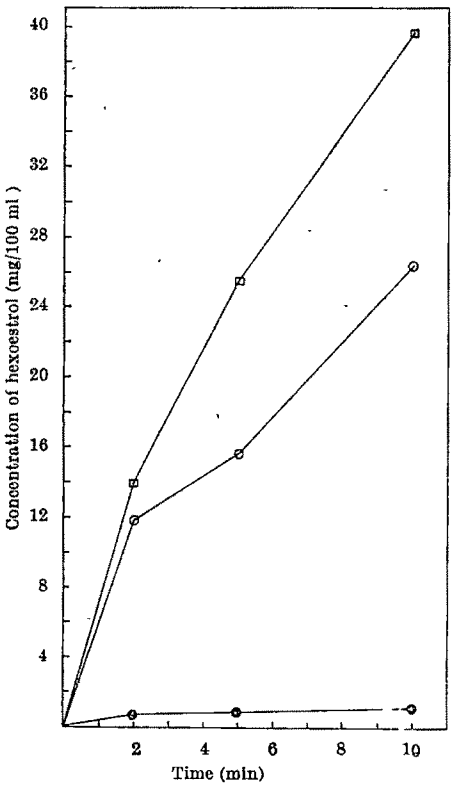

Fig. 2. Dissolution rates of hexoestrol in water (●), 0 04 M sodium deoxycholate (○), and 0 04 M sodium cholate (□) at 37° C

The enhancement in the dissolution rates of these two drugs in the presence of bile salts is probably due to a lowering of the interfacial tension between the drug and the dissolution medium as well as to micellar solubilization. The latter mechanism is probably more significant, since the bile salt concentration used in this investigation is approximately four times their CMC values.

The marked increase in the dissolution rates of the relatively water-insoluble drugs, hexoestrol and griseofulvin, in the presence of bile salts serves to strengthen the possibility that these physiological surfactants play an important part in the dissolution step of the absorption process.

We thank the Ciba Pharmaceutical Company, Summit, New Jersey, for its generous support of this investigation, and Mr. Michael Mayersohn for his technical assistance.

SEPARATION OF CHEMICALLY UNMODIFIED HISTOLOGICA LCOMPONENTS OF KERATIN FIBRES AND ANALYSES OF CUTICLES

By DR. J. H. BRADBURY, G. V. CHAPMAN, PROF. A. N. HAMBLY and N. L. R. KING
Department of Chemistry, Australian National University, Canberra

IT is well known that keratin fibres are particularly inert towards many chemicals and enzymes, and this has been ascribed to two main factors[1]: (1) The complex histological structure consisting mainly of cuticle, cell membranes and cortical cells, each of which tends to be complementary in its inertness towards chemicals (for example, formic acid, see later). (2) The high degree of cross-linking of the cuticle and cortical cells by disulphide bonds originating from cystine. The separation of the histological components of keratin fibres has thus been a major problem of keratin chemistry over the years, as shown by the many attempts to achieve separations by different methods (reviewed by Bradbury and Chapman[2]).

Probably the best method of producing essentially chemically unmodified components is ultrasonication or simply rapid shaking of the fibre in formic acid[2–5]. By this means the cell membrane complex which underlies the cuticle and surrounds each cortical cell is partly or completely dissolved in the 98 per cent formic acid and cuticle cells and afterwards cortical cells are liberated by the mechanical agitation. This mechanism, as previously reported[4], is confirmed by (i) electron microscopy which shows that the cell membrane structure is disrupted by immersion in acid, and (ii) analysis of the material dissolved by the formic acid. The latter, which amounts to about 2 per cent by weight of the fibre, consists mainly of lipid, and the amino-acid composition of the protein component is similar to that obtained by other workers[6]. In addition, it is known that immersion of proteins in formic acid at room temperature does not cause hydrolysis of peptide bonds[7–10] but only some formulation of hydroxyl groups of serine and threonine[10,11]; thus one is able to obtain samples of cuticle and cortical cells which are not appreciably modified by the method of preparation. Furthermore, the cell-membrane complex is also obtained separately as the material dissolved by the formic acid, but some possible complications are at present being investigated such as the possibility of dissolution of some protein from other parts of the fibre or lipid from the nuclear remnants of the cortical cells.

The technique of shaking in formic acid has been applied to Merino wool[4] and the amino-acid analysis of cuticle agrees nicely with that of cuticle produced by ultrasonication in various liquids[3]. In this article we show that the technique of shaking in formic acid is capable of disrupting a representative sample of keratin fibres. Furthermore, amino-acid analysis of the cuticle samples has shown the presence of the unusual amino-acid citrulline in every case and that, in general, the cuticle contains more of those amino-acids which cannot form α-helical homopolypeptides[12,13] than does the parent fibre.

The keratin fibres investigated were as follows: Merino 64's wool; bibrik, a Pakistani carpet wool; mohair; human hair; alpaca; the fur of the Australian marsupial 'brushtailed possum' (*Trichosurus vulpecula*) and rabbit fur. The fibres were cleaned by the method described previously[2], except that distilled water was substituted for the detergent solution of 'Gardinol BW', which recent work has shown cannot be completely removed from the fibres by washing with water. Samples of the cleaned, air-dried fibres (1·5 g) were cut into 0·5–1 cm lengths and agitated in 50 ml. of 98 per cent formic acid in a cylinder, 4 cm diameter, by means of a 'Vibromix' agitator (A. G. für Chemie-Apparateban, Zurich). The latter was operated with a 3 cm diameter-perforated plate oscillating at 100 c/s and at maximum amplitude. After an initial treatment for 5 min to disperse any skin flakes, the fibres were teased apart and subjected to 55 min of agitation in fresh formic acid at room temperature. The dispersed material from this second treatment was centrifuged, the formic acid solution removed and the residue washed three times with water and three times with ethanol. The cuticle cells were separated from cortical cells and residual fibre by the differential screening method of Bradbury and Chapman[2], applied to an ethanol suspension. The purity of the cuticle cells was checked by optical microscopy. Microscopic examination of the residual fibres showed that in no case was all the cuticle absent and that removal was very uneven because of partial felting. The material dissolved in the formic acid solution was recovered by lyophilization.

The yields of the components are shown in Table 1. Possum fur appears to be disrupted more rapidly than the fibres of the mammals, but in every case the liberation of cortical cells is slow. In order to obtain large quantities of the latter, it is preferable to use more vigorous mechanical agitation such as ultrasonication, by means of which 20 per cent of cortical cells can be produced in 1 h (ref. 2).

Amino-acid analyses of the cuticle samples were made using the Technicon system (column 0·63 cm diameter by 125 cm long) as described previously[3]. However, in the earlier work[3,4] the occurrence of citrulline was not noticed because of the relatively small amount present in wool cuticle and also because the peak occurs at the same position as that of proline. The neglect of this point does not make any appreciable difference to the proline figures previously reported[3,4].) Since proline has an absorption

Table 1. YIELDS FROM 'VIBROMIX' TREATMENT OF FIBRES IN FORMIC ACID

Fibre	Cuticle (per cent)	Cortical cells (per cent)	Cell membrane complex (per cent)
Merino 64's	1·0	0 1	2·5
Bibrik	2·2	0 1	3·7
Mohair	0 9	0 1	1·5
Human hair	0 8	0·1	2 8
Alpaca	4·0	0 1	3 2
Possum fur	7·0	2·8	6 0
Rabbit fur	0·7	0·1	3 2

maximum at 440 mμ and citrulline at 570 mμ, it is possible to estimate the amounts of each amino-acid present in the mixed peak from the areas under the 440 and 570 mμ peaks. Routinely, when the ratio of these areas becomes less than 6·0, there is obviously an appreciable amount of citrulline present. Under these conditions, the duplicate analysis is done in such a way that 20 min before the aspartic acid peak is recorded (as shown by the first chromatogram) the temperature of the column is reduced to 15° C. This is maintained until the proline peak has been recorded after which the temperature is returned to its normal value of 60° C. This procedure changes the order of elution; proline now appears before glutamic acid, while citrulline appears in the normal position after glutamic acid. We have also noted the occurrence of a peak between ammonia and lysine, which has been identified as ornithine. This amino-acid is known to be produced by decomposition of citrulline during hydrolysis in 6 M hydrochloric acid at 110° C (ref. 14), and preliminary results (which require confirmation) indicate that ornithine may not occur as such in the native material.

In Table 2 are given the citrulline and ornithine results for the various keratin derivatives; the complete amino-acid analyses will be reported later. In Merino wool citrulline and ornithine are not present in the cortical cells and this accounts for the negligibly small value in the whole fibre. This is probably also the case for Lincoln wool and mohair, but the other six keratins in Table 2 contain considerable amounts of medulla, in which citrulline is known to be present[14]. It is therefore clear that citrulline occurs in all the cuticle samples, but is absent from the cortical cells of Merino wool and probably also of the other keratins. Rogers has shown the presence of citrulline in the medulla and also in the inner root sheath protein of the hair follicle[14–16]. It seems likely that there is a common mechanism for the incorporation of citrulline into the protein produced by these three types of cells, but whether citrulline is incorporated as such or whether as arginine, which is later modified by an enzymatic reaction on the formed protein to citrulline, is not known[14].

There is naturally a considerable variation in the amino-acid composition of the various keratins and cuticles therefrom, but there is one regularity which has been noticed. There is very approximately the same difference between the amino-acid composition of the cuticle and the fibre from which it was derived for every keratin; the following figures represent average percentage differences over all the keratin samples. As well as the citrulline content already noted the cuticles contain more cystine 44, cysteic acid 233, proline 49, serine 31, valine 27, and glycine 26 and less aspartic acid 36, glutamic acid 19, threonine 21, isoleucine 26, methionine 29, leucine 19, tyrosine 28, phenylalanine 36 and arginine 32 than the respective whole fibres. The cuticle is deficient in acidic and basic groups and is therefore less polar than the keratin as a whole[3]. The cuticle contains more of those amino-acids which are unable to form α-helical homopolypeptides in the solid state or in solution[3,12,13]. It has been proposed that the wool fibre cuticle is amorphous, whereas the cortical cells have an α-helical component, because of the increased amount of these α-helix inhibiting amino-acids in the cuticle[3]. It is now clear that this difference in amino-acid composition between cuticle and whole fibre is of general occurrence and apparently causes the formation of an amorphous, highly cross-linked cuticle, which forms a suitably inert outer covering for the keratin fibre.

Table 2. CITRULLINE AND ORNITHINE CONTENT (μMOLES PER G DRY PROTEIN) OF HYDROLYSATES OF KERATINS AND CUTICLES THEREFROM

Type of keratin	Whole Keratin		Cuticle	
	Citrulline	Ornithine	Citrulline	Ornithine
Merino 64's wool*	0	0	30	13
Lincoln wool	0	0	15	0
Mohair	0	0	33	14
Bibrik	25	0	25	17
Human hair	11	0	45	5
Alpaca	34	0	78	41
Rabbit fur	61	9	170	78
Possum fur	8	44	297	161
Porcupine quill†	79	26	15	0

* There are negligible quantities of citrulline and ornithine in cortical cells, disrupted cortical cells (ref 3) and skin flakes (ref. 4) and a small amount in the cell membrane protein produced on immersion of Merino wool in formic acid (ref. 4)

† The cuticle was produced in this case by dissection.

We thank Mr. A. S. Inglis for advice on the separation of citrulline and proline and the following organizations for gifts of keratins: C.S.I.R.O. Wool Research Laboratories, Ryde; Returned Soldiers and Sailors Woollen Mills, Geelong; Taronga Park Zoo, Sydney. We also thank the Wool Research Trust Fund for financial support.

GLYCEROL AS A SUBSTRATE FOR BRAIN METABOLISM

By DR HENRY A. SLOVITER, PETER SHIMKIN and KUNIKAZU SUHARA

Harrison Department of Surgical Research and Department of Neurosurgery, School of Medicine, University of Pennsylvania, Philadelphia

THERE is a considerable body of evidence which indicates that under ordinary conditions the brain utilizes glucose as its metabolic substrate and that other substances are not utilized to any significant extent. Since pyruvate is one of the intermediates in the oxidation of glucose, it would be expected that the cells of the brain can readily metabolize pyruvate. Brain slices and suspensions do readily oxidize pyruvate[1,2]. However, the brain of the intact animal is apparently unable to utilize pyruvate which is present in the blood circulating through it. In animals which are hypoglycaemic as a result of hepatectomy, the abnormal electrical activity of the brain and the coma and convulsions which result are relieved by administration of glucose but are not relieved by administration of pyruvate[3,4]. This lack of utilization of pyruvate by the brain *in vivo* is probably due to the limited access of pyruvate to the brain tissue (the 'blood-brain barrier'). This relative impermeability of the brain to systemically administered pyruvate has been demonstrated experimentally in cats[5]. The impermeability to pyruvate may be due in large part to the relative impermeability of the brain to negatively charged substances[6]. Glycerol is an electrically neutral substance which can be converted by mammalian tissues to glucose

and to pyruvate. As a component of the fat molecule, it is normally produced and metabolized in mammalian tissues. It can be administered orally or parenterally without noxious effect[7] and it has been reported that injection of glycerol can relieve the cerebral symptoms of insulin hypoglycaemia[8]. However, it was not shown whether this action was due to the direct utilization of glycerol by the brain or to the prior conversion of glycerol to glucose. This article presents the results of experiments performed *in vitro* and *in vivo* which indicate that the mammalian brain can utilize glycerol as a metabolic substrate.

The *in vitro* experiments were performed with slices of guinea-pig brain. A guinea-pig was decapitated, the brain was rapidly removed, chilled in ice and thin slices of cortex were prepared with a Stadie-Riggs microtome. The slices (about 200 mg wet weight) were incubated for 1 h at 37° in 2 ml. of an isotonic saline-phosphate buffer (*p*H 7·4) medium[9] in Warburg vessels with 0·10 ml. of 10 per cent potassium hydroxide in the centre well and oxygen as gas phase. Each experiment with slices from a single brain was composed of five vessels: a blank control and four experimental vessels. To the experimental vessels were added 0·1 μc. of glycerol-1-^{14}C (New England Nuclear Corp.) and carrier glycerol in amounts increasing progressively from 56 to 448 μmoles. The total volume of fluid in each vessel was 2·3 ml. At the end of the incubation period, 0·2 ml. of 5 per cent perchloric acid which had been placed in the side arm was tipped into the vessel. The centre well and the paper in it were carefully washed three times with water and the washings were evaporated in a planchet under an infra-red lamp. The tissue slices were removed from the reaction vessels, rinsed in water and dried to constant weight at 140° C in weighing bottles.

The dried planchets were allowed to cool in a desiccator and their radioactivity was measured in a windowless gas-flow counter. A small excess of dilute hydrochloric acid was then added to each planchet and the planchets were again dried and counted. This was done to ensure that the radioactivity in the centre well material was derived from absorbed $^{14}CO_2$ and that there had been no significant contamination by material from the incubation medium. In all cases, the second measurement of radioactivity was not significantly above the background value, indicating that contamination had not occurred. The self-absorption correction factor was determined by measuring the radioactivity of carbon-14 samples with and without the addition of the same amount of alkali that had been added to the centre well. From the corrected values of the counts per minute for each planchet and the known efficiency of the counter, the number of μc. of $^{14}CO_2$ in each planchet was calculated.

Since it can reasonably be assumed that the carbon-14-labelled glycerol is being oxidized at the same rate as the carrier glycerol, the total amount of carbon dioxide produced can be calculated. Each molecule of glycerol which is oxidized gives rise to three molecules of carbon dioxide, therefore:

$$\mu\text{moles of carbon dioxide produced} = 3 \times \mu\text{moles glycerol oxidized}$$

The fraction of the total glycerol oxidized is the same as the fraction of the carbon-14-labelled glycerol converted to $^{14}CO_2$, therefore:

$$\frac{\mu\text{moles glycerol oxidized}}{\mu\text{moles glycerol added}} = \frac{\mu\text{curies } ^{14}CO_2 \text{ produced}}{\mu\text{curies glycerol-}^{14}\text{C added}}$$

$$\mu\text{moles of } CO_2 \text{ produced} = 3 \times \mu\text{moles glycerol added} \times \frac{\mu\text{curies } ^{14}CO_2 \text{ produced}}{\mu\text{curies glycerol-}^{14}\text{C added}}$$

The experimental results and the calculated values for one experiment are shown in Table 1. The production of carbon dioxide as a function of the initial quantity of glycerol for this experiment is shown graphically in Fig. 1.

Table 1. PRODUCTION OF CARBON DIOXIDE FROM GLYCEROL BY GUINEA-PIG BRAIN SLICES (EXPERIMENT 4)

Brain slices, dry weight (mg)	μmoles glycerol	corrected c.p.m.	$^{14}CO_2$ (mμc./h)	Carbon dioxide (μmole/h)	Carbon dioxide (μmole/h/mg)
15·4	56	956	0·96	0·16	0 011
12 0	112	652	0·65	0·22	0·018
15 8	224	736	0·74	0 50	0 032
14·7	448	732	0·73	0·99	0 068

Table 2. PRODUCTION OF CARBON DIOXIDE FROM GLYCEROL BY GUINEA-PIG BRAIN SLICES

Expt. No.	μmoles of glycerol added	56	112	224	448
		Carbon dioxide (μmoles/h/mg dry weight)			
1		0 031	0 036	0·058	0·102
2		0 010	0 017	0·024	0·046
3		0 017	0·026	0·036	0·056
4		0 011	0 018	0·032	0 068

It is apparent that the rate of production of carbon dioxide is an approximately linear function of the initial glycerol concentration. The individual values for all the experiments are listed in Table 2.

McIlwain[10] reported that guinea-pig brain slices in a 2-mM glucose medium consume oxygen at the rate of 60 μmoles/h/g (wet weight). Assuming that the respiratory quotient was unity and that about 80 per cent of the wet weight is water, this means that, with glucose as substrate, carbon dioxide production is about 0·012 μmoles/h/mg (dry weight). In our experiments with glycerol as substrate, carbon dioxide production of the same order of magnitude was obtained (Table 1) when the glycerol concentration was about 25 mM (56 μmoles/2·3 ml.). Thus, glycerol is required at levels more than ten times that of glucose to produce a similar respiratory rate. In this respect, glycerol is similar to fructose as a substrate for brain slices[10].

The *in vivo* experiments were performed in adult male albino rabbits, weighing about 3 kg. Each rabbit bore a chronically implanted catheter through which injections were made directly into the right internal carotid artery. The implantation and testing of such catheters have been described[11]. Silver coil electrodes had been implanted into the skull in the frontal, parietal and occipital areas on both sides. Bipolar electroencephalograms (EEG) were recorded with a Grass 'Polygraph' recorder. The rabbits were fasted about 18 h before the experiment and were un-anaesthetized, unrestrained and quiet throughout the experiments. At the start of the experiment dihydroergotamine methanesulphonate (0·3 mg/kg) was injected to block the hyperglycaemic action of epinephrine which is released during insulin hypoglycaemia. 30 min later, regular insulin (1·5 U/kg) was injected intravenously. During the period of 30–60 min after the injection of insulin, the blood glucose level of the rabbit dropped from about 50 to 20 mg/100 ml. and the changes in the EEG which are characteristic of hypoglycaemia appeared. These changes consisted of a decrease in the amplitude of

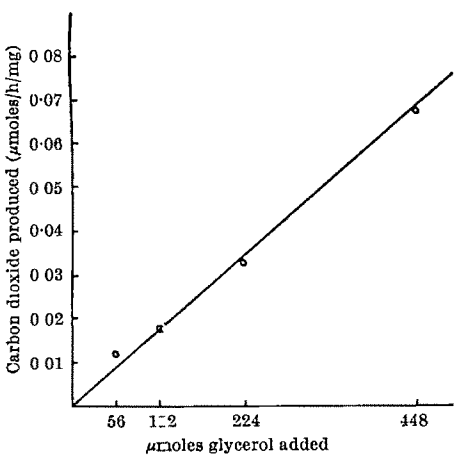

Fig. 1. The effect of glycerol concentration on the production of carbon dioxide from glycerol by guinea-pig brain slices

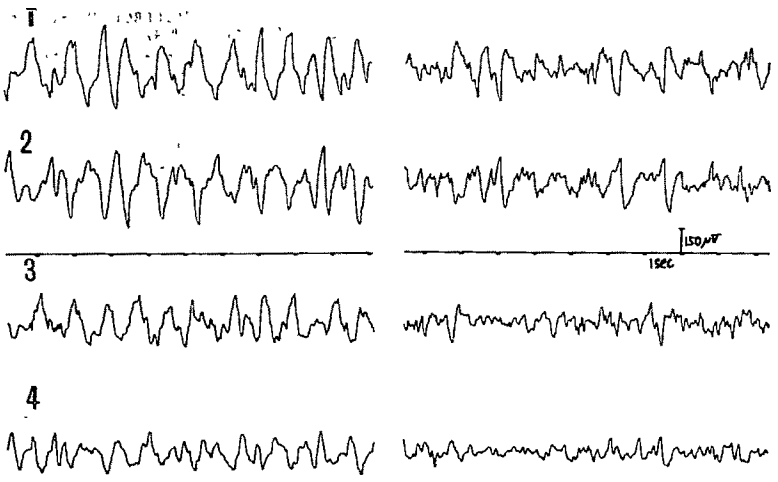

Fig. 2. The effect of infusion of a 10 per cent solution of glycerol by way of the right internal carotid artery on the bipolar electroencephalogram of the hypoglycaemic rabbit. The recordings are from the following electrode pairs (top to bottom): No. 1, left frontal–left parietal; No. 2, left parietal–left occipital; No. 3, right frontal–right parietal; No. 4, right parietal–right occipital. The recordings on the left were made 1 min before the start of the infusion and those on the right were made after 5 min of infusion at the rate of 0·2 ml./min. The decrease in number and amplitude of the high voltage, slow waves on the right (ipsilateral) side after infusion is quite definite

the normal fast activity (4–5 c/s, corresponding to alpha waves of human EEG) and the appearance of spindles (2·5–4 c/s, corresponding to theta spindles of human EEG) and high-voltage, slow waves (0·5–1·5 c/s). During this period when there were definite EEG signs of hypoglycaemia, infusions were made of either glucose or glycerol solutions by way either of the internal carotid artery or intravenously.

Infusion of a 10 per cent glucose solution in 0·45 per cent sodium chloride at the rate of 0·2 ml./min by way of the internal carotid artery was followed by a reversal of the EEG pattern toward normal within 1 min of the start of the infusion. In twenty-three of thirty-one such infusions, there was definite ipsilateral improvement of the EEG and the average amount of glucose required to produce this improvement was 14 mg. The nature of the effects on the EEG are the same as those shown in Fig. 2. When the glucose was administered intravenously, improvement in the EEG was always bilateral, and occurred 2–3 min after the start of the infusion when about 40 mg of glucose had been administered.

Infusion of a 10 per cent glycerol solution in 0·45 per cent sodium chloride at the rate of 0·2 ml./min was followed by ipsilateral improvement of the EEG of the hypoglycaemic rabbit in seventeen of forty-four cases. This improvement (shown in Fig. 2) first appeared after 4–5 min of infusion when an average of about 105 mg of glycerol had been administered. In four additional cases bilateral improvement in the EEG was seen. When the glycerol solution was administered intravenously no significant change in the EEG of the hypoglycaemic rabbit was seen. The infusion of physiological saline solution at the same rate by way of the internal carotid artery or intravenously had no effect on the EEG.

The unilateral nature of the change in the EEG is fairly good evidence that the change is caused by the agent being infused. The abnormalities of the EEG caused by hypoglycaemia are presumably due to the inadequate energy available to maintain the normal activity of the brain. The reversion of the EEG toward normal, when glycerol is made available to the brain, indicates that glycerol is being metabolized and is providing some of the energy requirement of the brain. It is evident from the results of these *in vivo* experiments and from the *in vitro* experiments described above that glycerol is utilized, but at a considerably slower rate than is glucose. The results of our *in vivo* experiments will be reported in greater detail elsewhere.

One previous report[3] indicated that the intact brain does not utilize glycerol. This was based on the inability of systemically administered glycerol to eliminate the symptoms of cerebral hypoglycaemia in hepatectomized dogs. In view of our results with glycerol solutions administered intravenously, it seems unlikely that such an experiment would detect the relatively slow rate at which glycerol is used by the brain. Elliott[12] in a reference to his unpublished results stated that glycerol is not oxidized by brain slices. This observation is probably based on measurement of oxygen consumption, which might be inadequately sensitive if low concentrations of glycerol were used. Pritchard[13] has shown that glycerol-^{14}C is incorporated into the lipids of brain slices. Although this does not indicate that glycerol can provide energy for the brain, it does demonstrate that brain tissue can metabolize glycerol.

The present investigation was supported by a research grant from the U.S. National Institutes of Health.

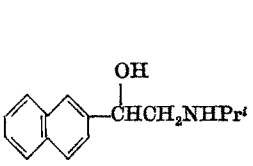
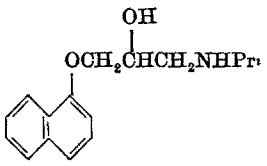
OPTICAL ISOMERS OF PROPRANOLOL



By DR. R. HOWE and DR. R. G. SHANKS

Imperial Chemical Industries, Ltd., Research Department, Pharmaceuticals Division, Alderley Park, Macclesfield, Cheshire



THE β-adrenergic receptor antagonist, pronethalol ('Alderlin'), has anti-arrhythmic properties in experimental animals. It has been shown to prevent or abolish ouabain-induced arrhythmias in guinea-pigs[1], and dogs[2–4], and anaesthetic adrenaline arrhythmias in dogs[2–4]. It has been suggested that some of these effects are not the result of blockade of β-adrenergic receptors[2,4]. (+)-Pronethalol, which has about one-fortieth the β-adrenergic blocking activity of racemic pronethalol[5], has also been shown to be effective in abolishing ouabain and anaesthetic adrenaline arrhythmias in dogs[4].

A new compound, propranolol ('Inderal'), has been described which is at least ten times as active as pronethalol as a β-adrenergic blocking agent[6–8]. This article reports

its resolution, the physical constants, and some of the pharmacological properties of its optical isomers:

Pronethalol
2-Isopropylamino-1-(2-naphthyl)ethanol.

Propranolol
1-Isopropylamino-3-(1-naphthoxy)-2-propanol.

(−)-Di-*O*,*O*-*p*-toluoyltartaric acid[9] was used as a resolving agent. By a tedious fractional crystallization from methanol, the two salts (+)-propranolol hydrogen (−)-di-*O*,*O*-*p*-toluoyltartrate hydrate, m.p. 170° C, $[\alpha]_D^{21}$ −62·0° (*c*, 1·01 in ethanol), and (−)-propranolol hydrogen (−)-di-*O*,*O*-*p*-toluoyltartrate hydrate, m.p. 166°–167° C, $[\alpha]_D^{21}$ −89·0° (*c*, 1·0 in ethanol)[10] were obtained optically pure. Physical data for propranolol and its isomers are given in Table 1.

Table 1. PHYSICAL DATA FOR PROPRANOLOL AND ITS ISOMERS

	(±)-Propranolol m.p. (° C)	(+)-Propranolol m.p. (° C)	(+)-Propranolol $[\alpha]_D^{21}$	(−)-Propranolol m.p. (° C)	(−)-Propranolol $[\alpha]_D^{21}$
Base	96	73	+10·6° (*c*, 1·02)*	73	−10·2° (*c*, 1·02)
Hydrochloride	163–164	192	+22·2° (*c*, 0·99)	192	−22·7° (*c*, 1·0)

* Ethanol was used as solvent.

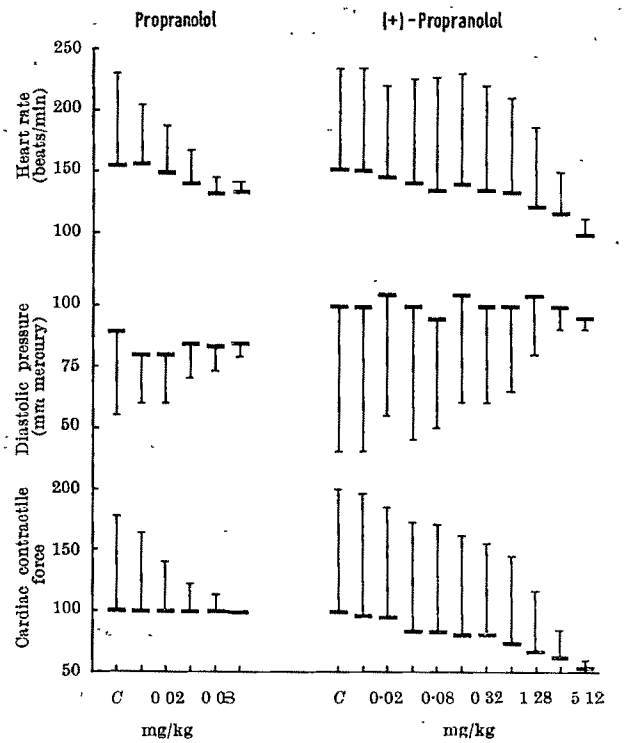
Pharmacological studies. (Doses are all expressed in terms of the salt used. Propranolol and its isomers were used as the hydrochloride.) Observations were made in cats anaesthetized with chloralose 80 mg/kg given intravenously. Spontaneous breathing was assisted by the insertion of a tracheal cannula. Heart rate was recorded by means of a cardiotachometer triggered by the cardiac *QRS* voltage. Femoral veins were cannulated for the injection of drugs. Increases in heart rate were produced by the intravenous infusion of isoprenaline at 0·2 μg/kg/min for 10 min before and 30 min after commencing the intravenous infusion of (+)- or (−)-propranolol. It has previously been shown that the intravenous infusion of propranolol reduces or abolishes the increase in heart rate produced by isoprenaline[7]. The effect of the intravenous infusion of (+)-propranolol at 20 and 100 μg/kg/min and of (−)-propranolol at 0·5, 1·0 and 5·0 μg/kg on the isoprenaline tachycardia are given in Table 2. These are the averaged results from groups of cats. Table 2 also contains previously published results for propranolol[7]. The administration of (+)-propranolol at 20 μg/kg/min had no effect on the isoprenaline tachycardia but at 100 μg/kg/min reduced the isoprenaline response slightly. The infusion of (−)-propranolol at 1 μg/kg/min reduced the isoprenaline tachycardia while the larger dose almost completely abolished it. These results indicate that the (−)-isomer is more active than racemic propranolol in blocking the isoprenaline tachycardia. The (+)-isomer had little effect on the isoprenaline tachycardia and has probably less than a hundredth the activity of racemic propranolol.

Further observations have been made with racemic propranolol and (+)-propranolol in dogs anaesthetized by the intravenous injection of thialbarbitone, 30 mg/kg. followed by chloralose, 50 mg/kg. Cardiac contractile force was measured by suturing a strain gauge arch on the right ventricle. Arterial pressure was recorded from a cannula in the left femoral artery with an inductive type differential pressure transducer, and heart rate by means of a cardiotachometer. Drugs were injected through catheters in the femoral veins. Isoprenaline, 0·4 μg/kg, was administered every 10 min and the maximum changes in heart rate, cardiac contractile force and diastolic arterial pressure were recorded. When control responses to isoprenaline had been obtained, 0·01 mg/kg racemic propranolol or (+)-propranolol was injected intravenously and 3 min later the isoprenaline administration was repeated. Geometrically increasing doses of racemic propranolol or (+)-propranolol were given at 10 min intervals followed each time by isoprenaline, 0·4 μg/kg. The effects of these two compounds on the increases in heart rate and in cardiac contractile force and on the fall in diastolic pressure produced by isoprenaline are shown in Fig. 1. These are the averaged results from three dogs for propranolol and two for (+)-propranolol.

Propranolol reduced the increase in heart rate, the fall in diastolic pressure and the increase in cardiac contractile force produced by the intravenous injection of isoprenaline. A total cumulative dose of 0·31 mg/kg propranolol abolished these responses. Much larger doses of (+)-propranolol were required to reduce the responses to isoprenaline; a total cumulative dose of 10·23 mg/kg reduced the responses to the same extent as a total dose of 0·15 mg/kg racemic propranolol. Consequently (+)-propranolol has about one-sixtieth the activity of racemic propranolol in blocking these effects of β-receptor activation. In these experiments propranolol produced a slight reduction in resting heart rate; the comparable blocking doses of (−)-propranolol produced a greater bradycardia and had a negative inotropic action.

Table 2. EFFECT OF PROPRANOLOL AND ITS ISOMERS ON THE ISOPRENALINE TACHYCARDIA EXPRESSED IN BEATS/MIN IN ANAESTHETIZED CATS; AVERAGED RESULTS FROM GROUPS OF CATS

Compound	Dose (μg/kg/min)	No. of cats	Isoprenaline tachycardia Control	Isoprenaline tachycardia Treated
(±)-Propranolol	1	3	30	19
	5	3	49	12
	25	3	54	7
(+)-Propranolol	20	4	61	63
	100	3	67	50
(−)-Propranolol	0·5	3	38	34
	1·0	4	42	10
	5·0	3	59	5



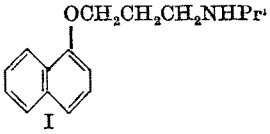


Fig. 1. Observations in dogs anaesthetized with thialbarbitone and chloralose. Heart rate, beats/min, femoral diastolic arterial pressure, mm mercury, and right ventricular contractile force, expressed as percentage of initial control value, were recorded. Resting level of each parameter is represented by (−) and the maximum response to isoprenaline (0·4 μg/kg) by (−). The effect of increasing doses of propranolol and (+)-propranolol on resting levels and on the responses to isoprenaline are shown, averaged results from three and two dogs, respectively.

Effect on experimental cardiac arrhythmias. The effects of propranolol and its isomers have been studied on halothane-adrenaline and on ouabain arrhythmias in anaesthetized cats. Multifocal ventricular extrasystoles were produced in cats anaesthetized with chloralose and spontaneously breathing oxygen and 1 per cent halothane, by the intravenous injection of adrenaline 1–5 μg/kg. When control responses to adrenaline had been obtained, propranolol or one of its isomers, 0·1 mg/kg, was injected intravenously, and 5 min later the administration of adrenaline was repeated. Propranolol and (−)-propranolol, 0·1 mg/kg, prevented the development of arrhythmias; it was necessary to increase the dose of (+)-propranolol to 1·0 mg/kg before it prevented the development of the adrenaline-induced arrhythmias.

Ouabain, 60–110 μg/kg, was injected intravenously in divided doses into cats, anaesthetized with pentobarbitone and artificially respired, to produce a ventricular tachycardia. When this arrhythmia was established, propranolol or one of its isomers was infused intravenously at 2 mg/kg/min until the return of sinus rhythm or death of the animal. Propranolol was administered to nine cats; there was a return to sinus rhythm in seven animals after the intravenous infusion of a mean amount of 10·3 ± 2·3 mg/kg; the remaining two cats died from ventricular fibrillation. (+)-Propranolol abolished the ouabain-induced arrhythmia with a return to sinus rhythm in nine out of nine cats after the administration of a mean dose of 8·4 ± 2·0 mg/kg. (−)-Propranolol was given to six cats; in one animal there was a return to sinus rhythm after 4·0 mg/kg; in the remaining five cats the arrhythmia was unaffected by (−)-propranolol which was given until death occurred from ventricular fibrillation. In these five cats death occurred after the intravenous infusion of a mean amount of 16·4 ± 2·1 mg/kg (−)-propranolol.

These experiments in anaesthetized dogs and cats show that the (−)-isomer of propranolol is 60–100 times more active than the (+)-isomer in blocking the inotropic, chronotropic and vasodepressor actions of isoprenaline. A similar ratio of activity was found for the isomers of pronethalol[5]. In man[11] the (−)-isomer of isoprenaline was about fifty times more active than the (+)-isomer in stimulating β-adrenergic receptors, while in animals the ratio was about 600 : 1 (ref. 12). These variations in activity of the two isomers may result from slight contamination of the (+)-isomer with the (−)-isomer. This may account for the β-blocking activity of high doses of (+)-propranolol; it may, however, be the result of low specific activity of the compound itself. Support for the latter view is gained from the observation that the compound 1-(3-isopropylaminopropoxy)naphthalene (I), which lacks the side-chain hydroxyl group of propranolol and which has no asymmetric centre, is about as active as (+)-propranolol in blocking isoprenaline-induced tachycardia. Ariens has shown[13] that the β-mimetic activities of (+)-noradrenaline and (+)-adrenaline, the isomers with least activity on β-receptors, are about the same as those of the corresponding compounds which lack the side-chain hydroxyl group.

I

Propranolol and its (+)-isomer are equally effective in abolishing ouabain-induced arrhythmias while the (−)-isomer had little effect. These results suggest that the action of propranolol in these arrhythmias does not result from blockade of β-adrenergic receptors and support Lucchesi's observations with pronethalol. The compound I does not abolish ouabain-induced arrhythmias. This highlights not only the need for the side-chain hydroxyl group of (+)-propranolol for the effect on ouabain-induced arrhythmias, but also the requirement that the steric arrangement at the asymmetric centre should be the mirror image of that required for maximum β-blocking activity. Propranolol and its (−)-isomer are equally effective in preventing halothane–adrenaline arrhythmias and are at least ten times more active than (+)-propranolol. The protective action of propranolol in these arrhythmias probably results from blockade of β-adrenergic receptors. These observations do not agree with those of Lucchesi[4], who showed that pronethalol and its (+)-isomer were equally effective in preventing anaesthetic adrenaline arrhythmias.

VARIABLE SIZE OF THE SEPTAL NUCLEI IN MAN

By ELISABETH BECK

Institute of Psychiatry, The Maudsley Hospital, London

AND

DR. D. CARLETON GAJDUSEK

National Institutes of Health, Bethesda, Maryland

THE septal nuclei, which form part of the limbic system, are discrete, well-developed nuclear masses in lower forms but become increasingly smaller and ill-defined in the ascending mammalian scale. They are included in the so-called 'septal area' lying anterior and lateral to the descending fibres of the fornix. A large-celled medial and a small-celled lateral or principal septal nucleus can be distinguished, the latter being continuous posteriorly with nucleus septo-fimbrialis. While both the medial and the lateral nucleus are associated with fibres of the precommissural fornix, nucleus septo-fimbrialis is related to fibres of the postcommissural fornix[1]. Microscopically, the septal nuclei are composed of neurones similar in type to the 'dominant elements in the corpus striatum'[2].

In man, the septal nuclei are small and ill-defined and a division into a medial and a lateral nucleus is often difficult[3] as is delimitation from some of the adjacent

structures. In his cyto-architectonic investigation of this region in man, Brockhaus[4] distinguishes between a principal nucleus, his nucleus septoventricularis, and smaller nuclei septofornicatus, interfornicatus and parvocellularis; together he designates them 'nuclei septi proprius'. Over their whole antero-posterior extent these nuclei are demarcated medially by descending fibres of the fornix and laterally by the ventricular wall.

In the course of our investigations on the central nervous system in cases of Kuru, a neurological disease confined to the Fore people and their close neighbours in the Highlands of New Guinea[5], we were impressed by the relatively large size of the septal nuclei in these brains. In all the eleven cases investigated so far the septal nuclei not only had an unusually long antero-posterior extent, but they also protruded markedly into the medial wall of the lateral ventricle (Fig. 1), causing a surface configuration reminiscent of that produced by the caudate nucleus on the opposite side. A similar phenomenon has not previously been observed in any of the brains dealt with in this laboratory. Microscopically, the nuclei appeared normal and showed none of the pathological changes associated with Kuru[6,7]. They were composed of the typical, irregularly shaped neurones (as described by Cajal[2]) interspersed with thin fascicles of myelinated fibres.

The septal nuclei were measured in eight cases of Kuru and in seven normal cases used as controls, and matched, as far as possible, for age and sex. A further three controls of an older age group are included. Controls 3 and 4 are taken from African negroes and the remainder from Europeans. The area measured corresponds approximately to Brockhaus's[4] 'nuclei septi proprius' with the exception of the most anterior tip which is so diffusely arranged that it does not lend itself to measurement.

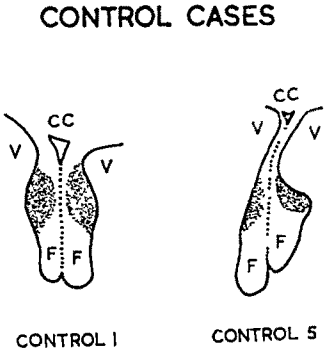

Fig. 1. Projection drawings of representative examples of the septal nuclei (stippled area) taken at a coronal level about 0 75 mm behind the descending columns of the fornix. Note the difference in size and shape between the nuclei of the control and Kuru cases; the latter are much larger and protrude markedly into the wall of the lateral ventricle. CC, Corpus callosum, F, fornix; V, lateral ventricle

The processing of all but two of the brains followed standardized procedures in order to obtain comparable coronal levels and to minimize a variation in shrinkage during dehydration and subsequent embedding in celloidin. The measurements were obtained from projection diagrams drawn at intervals of 0·375 mm from serial sections through the septal nuclei, stained by the method of Nissl. (The outlines of the nuclei were checked under the microscope.) At each level, the area of the nucleus was measured planimetrically and the reading was converted into mm². With a known interval of 0·375 mm between each level the final volume was calculated in mm³ by simple addition of the separate areas multiplied by 0·375.

Table 1

Case No.	Sex	Age at death	Volume of septal nuclei in mm³ left	right	Brain weight‡ (g)
Kuru 1	M	10	57·3	46·5	1025
Kuru 2	F	11	—	41·8	900
Kuru 3	M	11	43·0*	—	983
Kuru 4	F	12	64 0	71·0	873
Kuru 5	F	12	—	54·5*	905
Kuru 6	F	16	38·0*	—	1080
Kuru 7	F	29	46·8*	45·0*	1035
Kuru 8	M	30	—	43·0*	—
Control 1	F	11	16·7	16·5	1350
Control 2	F	15	22·0	25·0	1245
Control 3	M	25	12·0	16·0	1380
Control 4	F	32	12·0	16·0	1320
Control 5	M	40	12·0	13·5	1330
Control 6	F	45	13·5	14·6	1360
Control 7	F	49	14·6	16·0	1460
Control 8	F	53	14·0	13·5	1350
Control 9	F	61	9·4	13·5	—
Control 10	M	69	12·4†	16·5	1370

* Kuru cases 5 and 7 went through a process of double embedding which causes a higher degree of shrinkage; Kuru cases 3, 6 and 8 were damaged at post-mortem—small portions of the septum were missing. The absolute measurements for these five cases should therefore be higher.

† The average volume in the control group amounts to 13·9 mm³ on the left and 16 1 mm³ on the right side. Similar figures would be representative of the large numbers of other European brains seen in this department.

‡ The low brain weight in the cases of Kuru was not due to atrophy. These were all small but perfectly normal-looking brains. Kuru cases 1, 2, 3, 4 and 6 had 10–20 g of tissue removed for virus isolation investigations before fixation and weighing.

A comparison between Kuru cases 1–6 and control cases 1 and 2 shows that the volume of the septal nuclei is, in every instance, considerably larger in the Kuru brains than in the controls. Likewise, Kuru cases 7 and 8 have measurements far exceeding those of control cases 3–10 (this includes the two African negroes). If, in addition, the smallness of the brain in the cases of Kuru, as compared with the controls, is taken into account and thus the size of the septal nuclei is seen in proportion to the total size of the brain, then the difference becomes even more marked.

It is of interest to note that a certain variation also exists between the measurements within the control group and that the two children especially tend to have larger septal nuclei than the adults (though a further correlation with age does not seem obvious within the adult group). However, even the largest volume of 25·0 mm³ (control case 2, right) is far exceeded by the lowest absolute measurement of 41·8 mm³ in Kuru case 2.

The present are preliminary investigations; an investigation of the septal nuclei on a larger scale is planned especially to include the brains of natives belonging to the East New Guinea Highlands stock who did not suffer from Kuru and from other linguistic groups, in particular in Lowland regions of New Guinea and in other parts of Australasia. Apart from the septal nuclei, it is intended

to investigate: (1) the size of the massa intermedia of the thalamus which is large in all cases of Kuru, but, though it may be large in an occasional control, is absent in up to 27·9 per cent of normal brains[8]; (2) the occurrence of a substantial accessory paraventricular nucleus in the hypothalamus which was present in four out of seven cases of Kuru but in none of the ten controls; and (3) the shape of the frontal poles which tend to be rather pointed with a concave orbital surface.

It remains to be seen whether such unusual features are found only in the brains of Kuru patients or whether they are a characteristic of the Melanesian population as a whole.

PRODUCTION OF ANTIBODY AGAINST "AUSTRALIA ANTIGEN" IN RABBITS

By DR. LIISA MELARTIN and PROF BARUCH S. BLUMBERG

The Institute for Cancer Research, Philadelphia, Pennsylvania

TRANSFUSED haemophilia patients often have an isoprecipitin in their sera which reacts with an antigen not found in the sera of normal individuals in the United States but not uncommon in the sera of patients with leukaemia (10 per cent)[1] and mongolism (28 per cent)[2] patients. It is also found in the sera of 5 per cent or more of several populations outside the United States[1]. The antigen has not been identified with any of the known serum proteins or cell constituents and, since the original studies were done using the serum of an Australian Aborigine, this "new" isoantigen has tentatively been called Australia antigen.

It has been taken as a working hypothesis that the isoprecipitin is present in the blood of the haemophilia patients as a result of the transfusions the patients have received. The high frequency (29 per cent) of antibody against Australia antigen in haemophilia patients as opposed to the antibody frequency in other transfused patients (approximately 3 per cent) is thought to be due to the fact that the former receive large amounts of fresh frozen plasma. It is postulated that freezing results in the partial denaturation of the plasma with a resulting revelation of an ordinarily occult Australia antigen specificity site. Other evidence consistent with the hypothesis that the isoprecipitin is an antibody is (1) its identification as an IgG immunoglobulin, and (2) the fact that it forms specific precipitins by double diffusion in agar gel in the same manner as other antigen–antibody systems. It was felt, however, that this did not constitute firm proof that the anti-Australia antigen isoprecipitin was indeed a specific antibody. In the present article, experiments are described in which rabbits were immunized with the whole serum containing Australia antigen. Specific antiserum against Australia antigen was produced after absorption with the sera of normal persons which did not contain Australia antigen. The results provide clear support for the antibody hypothesis. This technique also provides a more reliable source of antisera than that available from sick transfused patients.

Blood was collected by venepuncture and allowed to clot at room temperature for 4 h and at 4° C overnight. The serum was separated from the red blood cell clot by centrifugation and stored in glass containers at −20° C until ready for use. The immunizations were performed within 1 month of blood collection. Specimens from three different individuals were used in the experiments. (1) C. F., a 54-year-old white male with chronic reticuloendotheliosis of 2 years duration. This serum contains Australia antigen. (2) C. De S., a 60-year-old white female with chronic lymphocytic leukaemia of 5 years duration. This serum contains Australia antigen. (3) L. M., a normal blood donor. This serum does not contain Australia antigen and is used as a control.

Absorptions were performed with a pool of two sera from normal white United States blood donors. We are indebted to Dr. R. Donato of the Jeanes Hospital, Philadelphia, for these samples. Male rabbits (Laboratory Animals Corp., Plainfield, New Jersey) weighing 2·7–3·2 kg at the beginning of the experiment were used for the immunizations. None showed any signs of illness. The sera of all of the rabbits were tested for the presence of human serum protein antibodies before the immunizations were begun, but none was found.

Rabbits 1 and 2 were immunized with reticuloendotheliosis serum C. F.; rabbits 3 and 4 with leukaemia serum C. De S.; and rabbits 5 and 6 with normal serum L. M., using the schedule of Hirschfeld[3]. Briefly, this consists of a first intramuscular immunization with alum-precipitated serum followed by a similar immunization 2 weeks later. 10 days after the second immunization, 1 ml. of serum was injected intraperitoneally. After a 7–10-day rest period, the rabbits were bled and the antiserum used in the experiments (see Table 1, "after 6 weeks"). After a 2-week rest, the immunization schedule was repeated (Table 1, "after 14 weeks"). The antisera produced contained antibodies against normal serum proteins as well as Australia antigen. In order to produce antisera specific for Australia antigen, the sera from each of the rabbits were absorbed in a test-tube using the pool of two normal sera described above. To establish the proper ratio of antiserum to absorbing sera, various concentrations were tried until the minimum amount of "normal" serum (not containing Australia antigen) necessary to absorb the antibodies against the normal non-Australia antigen proteins was determined. The technique eventually adopted after these experiments consisted of the following: two parts of rabbit serum was mixed with one part of the pool of absorbing (Australia antigen negative) serum and the resulting mixtures incubated at 4° C for 48 h. The precipitate was then centrifuged and the supernatant used in the diffusion experiments. For comparison with the antisera produced in the rabbits, the serum of a haemophilia patient containing antibody against Australia antigen was used.

In some of the experiments, absorption was carried out by the "in basin" technique. In this the antiserum well was first filled with the absorbing serum and after it had diffused into the gel (approximately 30 min), the antiserum to be absorbed was added. Double diffusion in agar gel, using the Ouchterlony micro-pattern, was carried out by a method previously described[4]. Double diffusion in agar tubes was done by the method of Preer and Preer[5]. We are indebted to Dr. Anne S Jones for performing these experiments.

Table 1. DEVELOPMENT OF ANTIBODY AGAINST AUSTRALIA ANTIGEN IN RABBIT NO 4 AFTER 6 AND 14 WEEKS OF THE IMMUNIZATION PROGRAMME (The Table gives the reactions with forty sera known to contain Australia antigen)

	Total	Positive	Percentage positive
After 6 weeks	40	30	75
After 14 weeks	40	39	98

After the 6-week immunization period, the absorbed antiserum produced in rabbits 3 and 4 (which had been immunized with the serum of patient C. De S.) reacted to form what appeared to be a single precipitin band with the sera of normal individuals and patients with leukaemia known to contain Australia antigen, but not with the serum of patients or normals in which Australia antigen had never been found. 75 per cent of the known Australia antigen positive individuals gave a detectable precipitin reaction with the rabbit antiserum (Table 1). After the 14-week immunization period, 98 per cent of the known Australia antigen sera gave a detectable reaction (Table 1). The precipitin lines stained only faintly with Sudan black but gave an intense stain with azo carmine. These were the same staining characteristics exhibited by the human Australia antigen iso-precipitins.

The precipitin line formed against the rabbit antiserum gave a reaction of identity with the precipitin line formed against the human antiserum (Fig. 1). A well-defined single band was also seen using the Preer tube technique (Fig. 2).

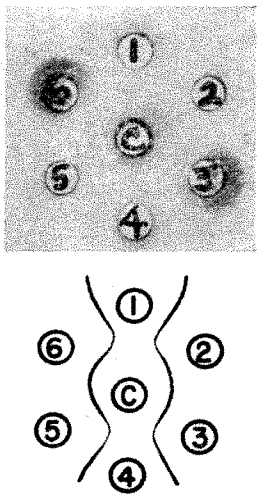

Fig. 1. Photograph and diagram of an experiment designed to show that human serum containing Australia antigen can absorb the antibody against Australia antigen developed in rabbits, and that serum which does not contain Australia antigen does not do so. The following sera are placed in the indicated wells: (*C*) serum from a leukaemia patient which contains Australia antigen; (1) Rabbit-anti-Australia antigen (Rabbit No. 4) absorbed with Australia antigen positive sera from two patients with Down's syndrome (Mongolism). The antibody is absorbed and no precipitin is seen between the central and No. 1 wells; (2) Rabbit anti-Australia antigen serum (rabbit No. 4) absorbed with Australia antigen negative sera from a normal person. The antibody is not absorbed and a precipitin line is seen; (3) Serum from a patient with haemophilia with an antibody against Australia antigen. There is a reaction of identity between this and the rabbit line; (4) same as 1; (5) same as 2; (6) same as 3. The lines between 1 and 2, 3 and 4, 4 and 5, and 6 and 1, are the reactions between the anti-Australia antigen and the Australia antigen in the excess absorbing sera

In another experiment, all the wells contained the same sera except the central well which contained an Australia antigen negative serum. In this case, there were no reactions between the central and peripheral wells

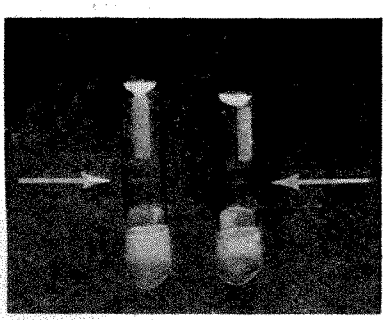

Fig. 2. Double diffusion in agar gel using the Preer tube technique (ref. 5). The reaction of two sera containing Australia antigen with rabbit anti-human Australia antigen is shown

Table 2. PATTERN OF REACTIONS WITH RABBIT ANTI-AUSTRALIA ANTIGEN SERUM AND HUMAN ANTI-AUSTRALIA ANTIGEN SERUM IN THREE POPULATIONS (Antisera from human and rabbit are tested with the same panel of Australia antigen positive and negative human sera)

Antiserum reaction	Normal (Utirik Atoll*) Human +	Normal (Utirik Atoll*) Human −	Down's syndrome Human +	Down's syndrome Human −	Leukaemia Human +	Leukaemia Human −
Rabbit +	15	0	19	0	4	0
Rabbit −	0	96	0	56	1	78
Total	11		75		83	

* U.S. Trust Territory of the Pacific Islands.

After absorption with an Australia antigen positive serum (using the "in basin" method) the rabbit antisera did not give a precipitin reaction. Absorption with an Australia antigen negative serum has no effect on precipitin formation (Fig. 1).

In order to compare the specificity of the rabbit anti-Australia antiserum with that found in the human haemophilia patients, both were tested side by side with the sera from members of three populations in which Australia antigen is relatively common (Table 2). There was very nearly complete agreement, with the exception of a single patient with leukaemia who reacted with the human antiserum, but not with the rabbit antiserum. This is the same serum which did not react with the "after 14 weeks" antiserum (Table 1). There is reason to believe that this patient has an unusual Australia antigen and this interesting possibility is being investigated. There is, in fact, evidence that there is more than one Australia antigen specificity and this will be described elsewhere.

When the rabbit antiserum produced in the rabbit (No. 6) which had been immunized with the normal serum (L. M.) was absorbed and tested in the same manner as the other antisera, it gave no precipitin line with the sera containing Australia antigen, or with other sera. One of the control rabbits (No. 5) died before the end of the immunization schedule.

An observation presumably unrelated to Australia antigen was made using the antisera produced in rabbits 1 and 2. Rabbits 1 and 2 produced a strong antibody against a blood protein present in individuals with and without disease which was different to the antibody against Australia antigen. Using immunoelectrophoresis and commercial specific human antisera, it was shown that this was an antibody against soluble fibrinogen[6,7]. These rabbits also produced a weak antibody against Australia antigen after 6 weeks, which increased in intensity after 14 weeks.

The production of the specific anti-Australia antigen antibody in rabbits by immunization with serum containing Australia antigen shows that the precipitation obtained with haemophilia sera is indeed caused by an antibody and lends considerable support to the hypothesis that this antibody is a result of immunization by transfusion with human plasma containing Australia antigen. It also adds support to the impression (gained from the high frequency of antibody formers among the transfused haemophilia patients) that Australia antigen is a "good" antigen, since there was no difficulty in developing antibodies in all the rabbits immunized after a relatively short period of immunization.

This method of producing antisera will make available much larger amounts than was possible from human sources and should help advance the studies on the significance of the Australia isoantigen system.

This work was supported in part by grants from the National Cancer Institute, U.S. Public Health Service.

CELLULAR TRANSMISSION OF LYMPHOSARCOMA IN DOGS

By DR. G. MOLDOVANU, DR. A. E. MOORE, DR. M. FRIEDMAN and DR. D. G. MILLER
Sloan-Kettering Institute for Cancer Research, New York

ALTHOUGH leukaemias and lymphosarcomata of fowls and rodents can often be transferred easily by inoculating cells into the same species, cellular transfer of the disease in domesticated animals has proved difficult. Rosenberger[1] has reported producing leucosis in cattle by inoculation of blood, milk, urine, faeces and suspensions of leucotic tumours as well as cell-free material, but details are not given. Hofland, Thorell and Winqvist[2] reported successful transfer to one of two very young calves inoculated with 10^8 leucotic cells after an interval of 4 years. Using a presumably cell-free extract of a lymphomatous node from a cat, Jarrett *et al.*[3] have recently reported the appearance of the disease in all of four kittens inoculated at birth. Nielsen and Cole[4] were unsuccessful in transferring canine lymphoma by the inoculation of cells into irradiated pups. This is a report of the cellular transfer of lymphosarcoma to three irradiated puppies. One clear case appeared 26 days and the second 90 days after the inoculation of cells from lymphosarcomatous dogs. The third animal developed the disease 44 days after the inoculation of a canine lymphosarcoma cell line, *LS* No. 30, which had been in tissue culture for almost 1 year. In previous attempts, thirty-five adult dogs inoculated with lymphosarcoma cells failed to develop the disease.

Three dogs (Table 1) with advanced lymphosarcoma provided the starting material. The first two were treated intermittently with *cyclo*phosphamide in an effort to control their disease. Cell suspensions were prepared either from surgically removed spleen or from lymph nodes on the day the pups were born. After mincing the tissue, the cells were freed by blending at a low speed in 1 per cent heparinized saline. The cells were sedimented by centrifugation at 1,000 r.p.m., re-suspended in balanced saline, and counted in a haemocytometer.

Filtrates were made in the following manner: lymphomatous tissue was weighed, ground in a mortar with sand, and sufficient Eagle's basal medium[5] was added to make a 20 per cent extract. After spinning at 4,000 r.p.m. for 15 min to sediment the coarse particles, the decanted fluid was again spun at 6,500 r.p.m. for 30 min before passage through a 3-μ 'Millipore' filter. The filtrate was then passed through a 0·65-μ, 0·4-μ and finally twice through 0·22-μ 'Millipore' filters.

The *LS* No. 30 cell line was developed from the spleen of an 11-year-old male dog with advanced lymphosarcoma after splenectomy in July, 1964. The trypsinized cells were implanted in milk dilution bottles in Eagle's basic media with 10 per cent agammaglobulinaemic calf serum. In one month the cells had grown out sufficiently to be trypsinized. The cultures then began to grow rapidly, so that they are now subcultured at 3-day intervals. The cells are neither epithelial nor fibroblastic in appearance but resemble those sometimes called reticular. Small, round cells and both multi- and mono-nucleated giant cells are seen. The cells inoculated into dog M.B. were those from the thirty-fifth to thirty-seventh transfers and were prepared by freeing the cells from the glass by trypsinizing and scraping. After centrifugation they were re-suspended in a small amount of medium and counted in a haemocytometer.

All recipients were mongrel new-born dogs of unknown origin. As soon as possible after birth they were given total-body irradiation delivered by a 180 kV dual tube X-ray machine, 25 m.amp, *TSD* 40 cm, at a dose rate of 85·4 r./min (air). Litters 1 and 3 received 85·4 r. immediately after birth, while litter 2 received 128 r. 24 h after birth. The pups were inoculated subcutaneously in the nape of the neck and intramuscularly in the leg 10–24 h after irradiation. Repeated inoculations were given at weekly intervals as outlined in Table 1. Fresh cell suspensions made from biopsy specimens were used except for three animals in litter 1 which received the original suspension after storage in the refrigerator for 1 week. Counts with trypan blue showed that the cells were 65 per cent viable. The *LS* No. 30 cells were administered immediately after trypsinization. Cell filtrates were kept frozen at −80° C during the interval between the inoculations.

As shown in Table 1, lymph nodes became palpable and visibly enlarged 26–58 days after inoculation. The first to appear were the mammary or peripenal nodes, followed by suprascapular, popliteal and cervical. The later appearance of the nodes in litter 2 may be a result of the smaller numbers of cells inoculated or of the fact that they were inoculated 1 day later than the other litters. Biopsies were done on all animals and have been reported as showing hyperplasia, except in the case of

Table 1

Donors of malignant lymphoma material	Recipients	Sex	Material injected	Amount	Appearance of lymph nodes	Death	Confirmed diagnosis of lymphosarcoma

Litters 1 and 3 irradiated immediately after birth (85·4 r. total body irradiation).
Litter 2 irradiated 24 h after birth (128 r. total body irradiation).

Fig. 1. Suprascapular lymph nodes removed from dog M.B. at autopsy (actual size)

D.B., where the nodes showed lymphosarcoma at 26 days, and M.B., which had one negative biopsy at 26 days, but the next specimen from which showed the beginnings of lymphosarcoma at 44 days. Similarly, dog *D*2 showed no lymphosarcoma in a biopsy taken at 26 days but was reported positive for the disease in a specimen taken at 90 days. The litters are now 3·5, 3 and 2·5 months of age and still have palpable nodes which have not increased in size for the past month. Four dogs in litter 3 died of inter-current infection and although abnormal lymphocytes were seen, a positive diagnosis of lymphosarcoma could not be made.

Recipient D.B. died at 6 weeks of age with generalized lymphosarcoma involving the spleen and lymph nodes. A cell suspension containing $1{\cdot}3 \times 10^9$ lymph node cells from this animal was immediately administered to two new-born irradiated puppies. One died of malnutrition 2 days later and the other died in 14 days of generalized lymphosarcoma, thus achieving the second passage. Cell suspensions from this dog were processed as before and inoculated into three irradiated new-born puppies. Two of these died of inter-current infection and the one remaining pup shows no sign of disease at 50 days of age.

In the cell filtrate recipients *D*3 and M.B.W., lymph nodes appeared as stated in Table 1 and are still present. Biopsy of these lymph nodes showed hyperplasia with an increased number of reticulum cells, but the appearance at this time is not that of a lymph node malignancy.

We believe the following factors are important in the cellular transmission of this disease: (1) Timing of irradiation of new-born pups: irradiation should be given as soon as possible after birth in order to prevent further development of immunological competence. (2) Amount of radiation: total-body irradiation with 85–128 r. (in air) has been sufficient. No haematological changes were encountered at this dose. Puppies are very susceptible to pneumonia and doses which cause leukopenia could be deleterious. (3) Amount of material: this seemed to be a very important factor. When we injected the second litter with little material, lymph node enlargement was temporary and disappeared in a few weeks. After the last two injections of large quantities of cells the lymph nodes reappeared.

In summary, cellular transmission of canine lymphosarcoma has been accomplished by injecting material from adult dogs and a tissue culture line into irradiated new-born puppies. Lymphadenopathy is present in puppies which received cell-free filtrate and their lymph node architecture is abnormal, but the disease has not yet unequivocally appeared.

Since the preparation of this manuscript, Dr. Charles Rickard of the New York State Veterinary College at Cornell has informed us that he, too, has been successful in transferring lymphosarcoma to new-born puppies with cell suspensions.

We wish to thank Mr. Alan Kaplan for his technical assistance.

TRANSFORMATIONS IN HAMSTER CELLS MEDIATED BY MYCOPLASMAS

By Dr. I. MACPHERSON and Dr. W. RUSSELL

Medical Research Council Unit for Experimental Virus Research, University of Glasgow, and National Institute for Medical Research, London

RECENT investigations have shown that mycoplasmas mimic viruses in many of their activities[1]. In tissue culture, for example, mycoplasmas may establish inapparent infections or cause complete cytolysis. This article describes a further similarity. Like polyoma and Rous sarcoma viruses[2,3], certain mycoplasmas have been shown to be capable of mediating changes in the *BHK*21 line of hamster fibroblasts such that the cells will form colonies in agar suspension culture and also grow on glass with altered colonial morphology.

The *BHK*21 cells used in this investigation were low-passage clone 13 cells cultured on glass according to methods previously described[4]. They had been carefully examined for mycoplasma by ourselves and others[5,6]. All tests were negative. Mycoplasma cultures were obtained through the courtesy of Dr. Ruth Lemcke, Lister Institute of Preventive Medicine, London, Dr. D. Taylor-Robinson, Medical Research Council Common Cold Research Unit, Salisbury, and Dr. R. Fallon, Ruchill Hospital, Glasgow, as broth cultures and frozen-dried broth cultures. They were routinely passaged in Difco PPLO broth containing 20 per cent unheated horse serum (Burroughs-Wellcome) and 10 per cent yeast extract. Cells were infected in suspension by shaking 10^6 cells in 1–2 ml. of medium containing a 1 in 10 dilution of a broth culture of mycoplasmas at 37° C for 1 h. Controls consisted of cells shaken with medium plus uninoculated broth and also mycoplasma broth cultures heated at 56° C for 1 h.

Agar suspension cultures were prepared as previously described[2]. Individual cultures contained 10^4–10^5 cells incorporated in top layers of 0·25 per cent or 0·33 per cent agar medium and were incubated at 37° C for 10 days to 6 weeks in a humidified carbon dioxide incubator. Cultures were examined after 10 days, then at weekly intervals for the appearance of macroscopic colonies (> 0·5 mm). Colonies were removed from the agar with finely drawn Pasteur pipettes and transferred to small bottles with 1 ml. of tissue culture medium. After pipetting the colony in the medium to free it from the agar and break it up, the cells attached to the glass and grew out during the course of the following week. The culture was then dispersed with trypsin and passed or plated to produce discrete colonies in Petri dishes.

In the first series of experiments carried out by one of us (I. M.), cells were infected with *Mycoplasma hominis* type 1 (*H* 34) and plated in 0·33 per cent agar. The controls produced colonies at a frequency of 0·005 per cent of the cells plated. The infected cells formed colonies with an efficiency of 0·4 per cent. When colonies were picked from the plates seeded with infected cells and grown on glass, a remarkable range of altered cells was obtained. Multinucleated giant cells, epithelioid cells,

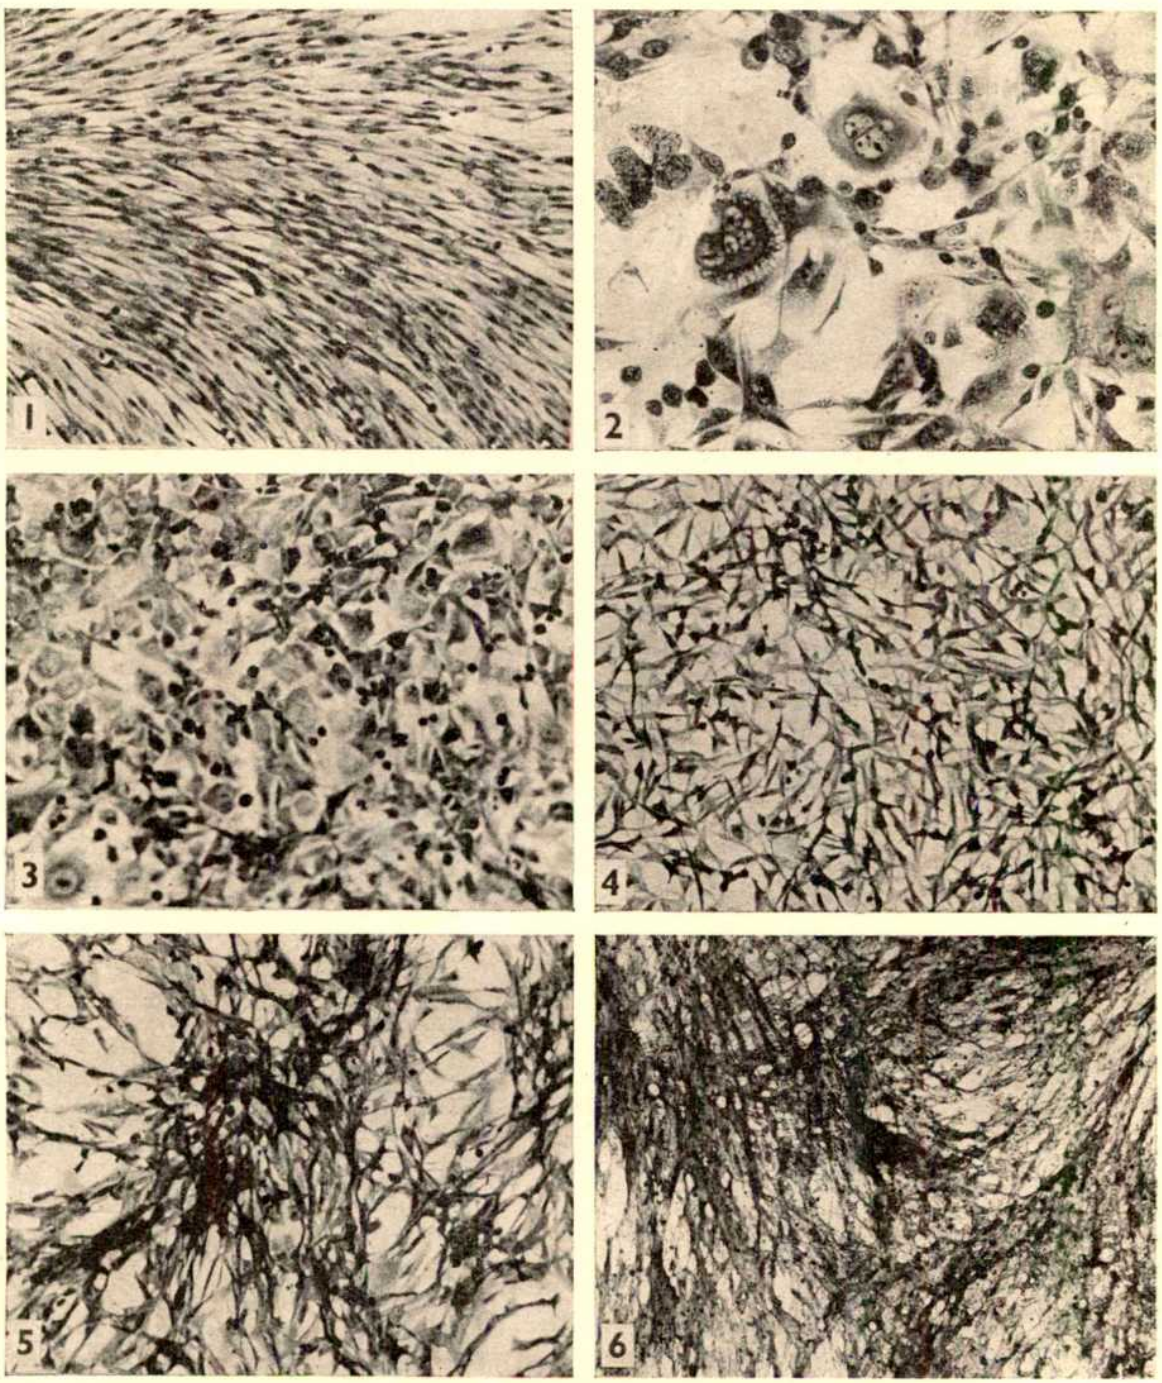

Fig. 1. Uninfected *BHK*21/13 cells. (× 75)

Figs. 2–4. *BHK*21/13 cells following infection with *M. hominis* type 1 (*H*34). Note: Giant cells in Fig. 2, epithelioid cells in Fig. 3, and the random arrangement of the cells in Fig. 4. (× 75)

Figs. 5 and 6. *BHK*21/13 cells following infection with *M. fermentans*. (× 75)

round cells, and long spindle-shaped cells growing in disarray like polyoma transformed cells, were all seen. (See Figs. 1–4.)

Mycoplasmas were regularly isolated from these cultures on agar medium. When the cells were plated to form colonies in Petri dishes and left for more than 7 days without medium changes, the cells in the centre of the colonies degenerated and came off the glass leaving a ring of viable cells. The cytopathogenic changes in such cultures could be delayed by changing the medium each day. In many cultures left for more than 6 or 7 days without medium changes, corynebacteria appeared in association with the cells. The relationship between these bacteria and the mycoplasmas is not known. Similar associations have been previously described[7,8]. No other tissue cultures carried in the laboratory at the same time and cultured in the same medium were contaminated with corynebacteria, and they could not be detected in the broth cultures of mycoplasma by plating on agar media.

Cultures derived from seven colonies with different morphologies, and in culture for 3 weeks since infection, were grown for 5 days in medium containing 500 μg 'Kanamycin', 50 μg 'Novobiocin' and 5 μg 'Aureomycin'/ml. The medium was changed each day. On the sixth day the medium was changed to one without the additional antibiotics and medium changes continued each day for a further 5 days. The cells of each clone were subcultured with trypsin three to four times during the course of this treatment. Each subculture received one-twentieth of the cells in the previous pass. At the end of this period no mycoplasmas or bacteria could be detected in the cells. The cells had in all cases retained their altered growth characteristics on glass and when two lines of cells with fibroblastic and epithelioid morphologies were cultured in agar they plated with efficiencies of 0·3 and 0·7 per cent respectively.

In the second series of experiments (carried out by one of us (W. R.)), *BHK*21/13 cells (obtained from Dr. W. I. H. Shedden, Department of Virology, University of Birmingham, and free from detectable mycoplasmas) were infected with the strains of mycoplasmas shown in Table 1 and plated in 0·25 per cent and 0·33 per cent agar medium. It will be seen from Table 1 that colonies appeared in all cases except with *M. salivarium* and the control cells. With the higher concentrations of agar, no colonies were obtained with cells infected with *M. pneumoniae*. As in the first experiment the cells picked from these colonies were initially morphologically altered but in all cases except cells derived from the *M. fermenians* infection, the cells gradually returned to the fibroblastic shape and the parallel alignment of uninfected *BHK*21 cells.

Table 1. Colony Formation by *BHK*21/13 Cells in Agar Suspension Culture following Infection with Various Mycoplasmas

Mycoplasma	No. of colonies in 0·25 per cent agar (10^5 cells plated)	No. of colonies in 0·33 per cent agar (5×10^4 cells plated)
*M. fermentans PG*18	20	2
M. hominis I *PG*21	31	4
M. hominis II *PG*27	50	6
M. orale I *CH*19299	5	1
M. orale II *CH*20247	17	9
M. pneumoniae Eaton *CH*	10	0
*M. salivarium PG*20	0	0
None	0	0

Cells cultured from agar colonies obtained after infection with *M. fermentans* were initially very elongated in appearance, but after further sub-cultivation they assumed the appearance shown in Figs. 5 and 6. The cells pile up on each other at random, unlike their uninfected precursors, which grow in parallel array (Fig. 1). In very dense cultures the cells eventually assume some degree of parallel orientation. The cells have retained this characteristic morphology and growth pattern for fifty generations. They grow as rapidly as *BHK*21 cells but produce more acid in the medium. Their plating efficiency on glass is 40 per cent—more than twice that of uninfected *BHK*21 cells. Many attempts have been made to recover mycoplasmas from the cells both by direct plating of tissue culture media and cells on agar media and after pre-incubation in broth. No positive isolations have been obtained. After growing the cells in medium containing 50 μg 'Aureomycin' and 50 μg 'Kanamycin' per ml. for 3 days, the medium being changed every day, the cells retained their characteristic morphology.

Cells transformed by *M. fermentans* and cells derived from a colony obtained from *M. hominis* II infection (with unaltered morphology on glass and containing no demonstrable mycoplasmas) were grown in medium containing aureomycin and kanamycin, as already described, and then plated in agar suspension culture. The cells plated with efficiencies of 3 per cent and 0·2 per cent respectively, that is, 150 and 10 times higher than the colony-forming efficiency obtained after the initial infection of the cells.

The experiments indicate that some mycoplasmas, like some oncogenic viruses, are capable of mediating inheritable changes in cells *in vitro*. It seems unlikely that our results can be explained on the basis of selection of pre-existing cells. However, it is possible that mycoplasma infection of some cells stimulates them to grow in agar or acts as a 'co-carcinogen' for some other undefined factor in our system.

It has been reported that cells infected with mycoplasmas may show chromosome abnormalities[9,10]. Mycoplasmas are known to be capable of cleaving thymidine to thymine and deoxyribose[11], and Randall *et al.*[12] have found that in HeLa cells infected with mycoplasmas the host-cell DNA is unstable as detected by incorporation of tritium- and carbon-14-labelled thymidine into DNA and there subsequent release into the medium as acid-soluble radioactivity. The effects reported here may well be the manifestation of a permanent change in the genetic apparatus of the cell induced directly by the mycoplasmas.

Our observations suggest a possible mechanism for the 'spontaneous' conversion of euploid cell lines into aneuploid lines capable of continuous propagation *in vitro*. As we have noted here some of our *BHK*21 cultures, apparently transformed by mycoplasmas, no longer release mycoplasmas in detectable numbers. Perhaps mycoplasmas, like Rous sarcoma virus[13], can exist in 'defective' forms as an obligate cell parasite.

In our hands, *BHK*21 cells in agar suspension culture have a very low plating efficiency. It is possible that the high plating efficiencies of *BHK*21 cells in agar reported by some workers[14,15] may have been due to mycoplasma infection of the cells.

So far, investigations designed to test the oncogenic activity of mycoplasmas in new-born hamsters have yielded negative results[16,17]. Work is in progress to test the transplantability of the *BHK*21 cells transformed by mycoplasmas and also the effect of mycoplasmas in other cell systems.

LETTERS TO THE EDITOR

ASTRONOMY

Relation between the Red-shifts of Quasi-stellar Objects and their Radio and Optical Magnitudes

TOGETHER with E. M. Burbidge and C. R. Lynds, we have recently given a table of more than forty quasi-stellar objects which includes red-shifts, optical magnitudes, and line spectrum data[1]. Radio fluxes are available for nearly all these objects. Provided we restrict ourselves to objects with flux values $> 8 \times 10^{-26}$ W m^{-2} (c/s)$^{-1}$ at 178 Mc/s, the list is sufficiently complete (over the portion of the sky available to Palomar, Lick and Kitt Peak, the observatories from which the red-shift measurements have been made) for approximate number counts to be made. There are thirty such objects. It happens that $30 = 2 + 2^2 + 2^3 + 2^4$, which provides the following simple way of making a number count. Write $N(S)$ for the number of objects with flux density $\geq S$ and define S_1, S_2, S_3, S_4 to be the smallest values of S such that $N(S_1) = 2$, $N(S_2) = 2 + 2^2$, $N(S_3) = 2 + 2^2 + 2^3$, $N(S_4) = 30$. This permits four points to be plotted in the log N–log S plane. These points are shown in Fig. 1. Joining them gives a slope close to $-1{\cdot}5$, not quite as steep as the value of $-1{\cdot}85$ obtained from the counting of all radio sources, and not as steep as the value of about $-2{\cdot}2$ obtained by Véron[2] for all quasi-stellar objects contributing to the 3C catalogue. However, the slope of the points in Fig. 1 is evidently influenced by the two lower points which must be subject to a considerable statistical scatter. So no undue significance should be attached to the particular value of the slope which these points happen to give. What does appear to be significant, however, is that even this small sample of quasi-stellar objects shows the usual relation between N and S, $NS^{3/2}$ approximately constant. The result $NS^{3/2}$ approximately constant has always been interpreted in terms of distances and volumes—for example, for a Euclidean universe and for objects all with the same intrinsic emission, $N \propto r^3$, $S \propto r^{-2}$ (r being the distance). A similar interpretation for our sample of quasi-stellar objects requires the objects with smaller S to be at the greater distance, in any event statistically. Objects with $S \approx S_4$ should be statistically farther away than objects with $S \approx S_3$, and so on. If we make the assumption that the red-shifts z of the quasi-stellar spectra arise from the cosmological expansion of the universe, then small S must be correlated with large z. In Fig. 2 it is shown emphatically that this is not so. Thus if we adopt the usual distance-volume interpretation of the result $NS^{3/2} \approx$ constant, we must conclude that the red-shifts have nothing to do with distances.

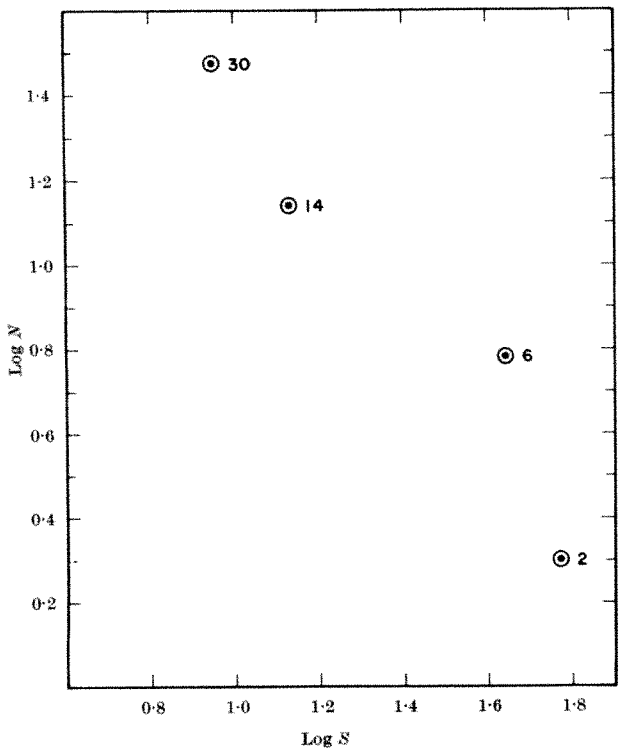

Fig. 1. Log N–log S plot for thirty quasi-stellar objects with radio fluxes $> 8 \times 10^{-26}$ W m^{-2} (c/s)$^{-1}$

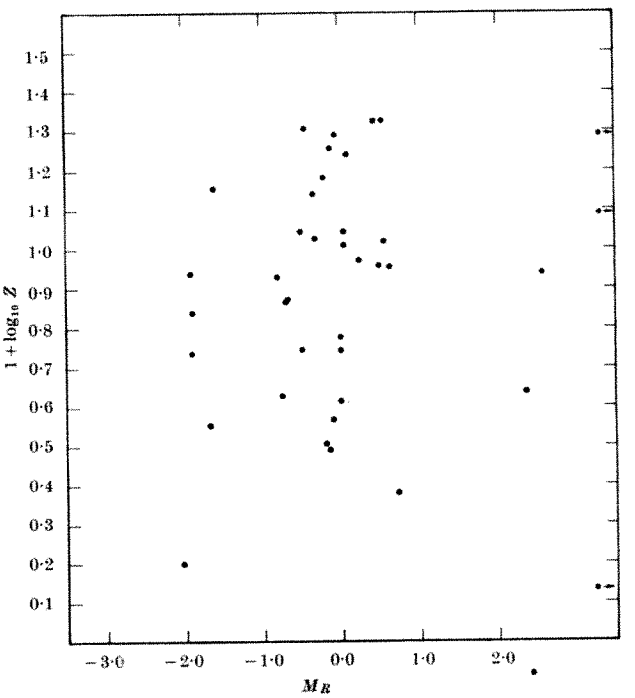

Fig. 2. Red-shift versus radio magnitude for quasi-stellar objects used in Fig. 1, together with several objects having smaller values of S. ($S = 10$ equals $M_R = 0{\cdot}00$)

In Fig. 3 we show log z plotted against visual optical magnitudes, M_v. This is for the full list of quasi-stellar objects[1]. These objects are indicated by filled circles. The open circles show the positions of N-type galaxies. The scatter in the points of Fig. 3 is large compared with the difference between M_v and the bolometric magnitude $M_{\text{Bol.}}$ the latter difference usually lying within $\pm 0{\cdot}3$ magnitudes. To sufficient accuracy, Fig. 3 can therefore be taken as representing the log z–$M_{\text{Bol.}}$ plane. The

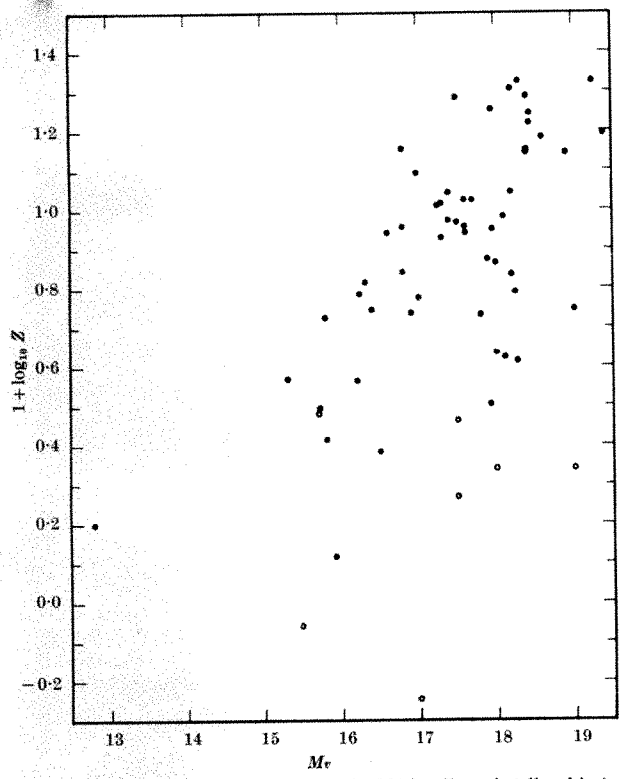

Fig. 3. Red-shift versus optical magnitude (M_v) for all quasi-stellar objects and *N*-type galaxies for which data are available. The list is compiled from published data from the observers working at Kitt Peak Observatory, Lick Observatory and Palomar Observatory. A large proportion of the objects are given in ref. 1. Others have been obtained from a list compiled by Burbidge, E. M., Lynds, C. R., and Schmidt, M., at the International Astronomical Union symposium in Erevan in May 1966

scatter is evidently so large that nothing useful, from a cosmological point of view, can be inferred. Indeed, as new red-shift values have become increasingly available, the plot of the observed quasi-stellar objects has assumed more and more the aspects of a scatter diagram. This can be seen by comparing Fig. 3 with a similar plot given by Sandage[3] about a year ago.

Origin of the Lunar Maria

THE hypothesis proposed by Kopal[1] concerning the origin of the lunar maria is very interesting. However, it is important to note that the distribution of lunar craters on the Earth-turned hemisphere is far from uniform. There are significant, well-marked chains approximately aligned with the central meridian as seen from Earth; in the west (classical sense) the chain to which Vendelinus and Langrenus belong; near the centre, the Walter and the Ptolemaeus chains; in the east, the Grimaldi chain, and so on. The suggestion by Baldwin[2], according to which the alignments are not real and are due to lighting effects, does not fit the facts. I have discussed this matter elsewhere[3,4]. Particularly important, however, is the conclusion that the well-formed maria fit in to the general pattern; it is difficult to avoid the conclusion that, for example, the Mare Crisium is simply a large member of the Vendelinus chain. To introduce a separate origin for the maria presupposes that they are of a nature basically different from that of the craters.

GEOLOGY

Age Determinations on Granites, Pegmatites and Veins from the Kibaran Belt of Central and Northern Katanga (Congo)

THE Kibaran–Burundi–Karagwe-Ankolean fold belt is one of the major geological features of eastern central Africa. It is perhaps best known as the seat of important tin and niobium–tantalum mineralizations, occurring in association with post-tectonic granites, pegmatites and veins[1,2]. In the Kibaran portion of the belt, geochronological studies have been carried out by the rubidium–strontium method on tectonically deformed granites, on non-deformed granites, and on pegmatites and veins, from four granitic batholiths: Bia Mountains, Kibara Mountains, Bukena-Manono and Mwanza.

The oldest granitic rocks recognized in both field and petrographic studies are pre- or early-tectonic granites emplaced in Kibaran metasedimentary rocks. The granites were modified during the Kibaran orogeny and are, at present, gneissic biotite granites with or without prominent microcline phenocrysts. The porphyric variety exists in all four of the massifs studied. The age of this type of granite from the Mwanza massif (Table 1, Nos. 1, 2, 4–6) is 1,310 ± 40 m.y., yielded by the closely fitting isochron of Fig. 1, with an initial strontium-87/strontium-86 ratio of $0{\cdot}708_5$. The apparent age of a non-porphyric whole-rock sample from the Bia Mountains (Table 1, No. 7) falls on the same isochron and, if the same initial ratio is assumed, is therefore the same age. It is note-

* Ages obtained by isochron (Fig. 1).
† All ages under 1,000 m.y. are rounded off to the nearest 5 m.y.; those above 1,000 m.y., to the nearest 10 m.y.

worthy that rubidium–strontium (Table 1, Nos. 3 and 8) and potassium–argon (905 ± 40 m.y.)[4] dating of biotites from this type of granite gives apparent ages which are as young as or younger than those of minerals from post-tectonic pegmatites (Table 1, Nos. 16–23). This is a clear case of 'rejuvenation' of biotites from a geochronological point of view, and it is not caused by a superimposed ulterior orogeny, which is entirely non-existent in this area.

During the same deep-seated phase which produced the aforementioned gneisses, granitization occurred, forming rocks which are now gneissic biotite granites, with some muscovite. This syntectonic granitization is, on geological and petrographical grounds, somewhat younger than the pre- or early-tectonic granites mentioned earlier; it is, however, still inadequately dated. Apparent ages of one whole rock and one microcline from a specimen from the Bukena massif are shown in Table 1, Nos. 9 and 10. Assuming an initial strontium-87/strontium-86 ratio of 0·709, the apparent age of this granitization is 1,240 ± 70 m.y.

Post-tectonic manifestations comprise various types of granites, pegmatites and veins. Of the various granites, only specimens belonging to one type, the so-called 'tin-granite', equigranular and rich in muscovite, have been dated (Table 1, Nos. 11, 12 and 14). Fig. 2 concerns these three specimens from the Bia, Bukena-Manono and Mwanza massifs and also a supplementary specimen from Kivu, further north in the same belt[5]. There is no line which fits all four points, or for that matter the three points representing whole rock analyses from the Katanga granites, even when the margins of error are taken into account. The situation is not improved when the data for two muscovites (Table 1, Nos. 13 and 15) are projected on Fig. 2. The six points fall in the vicinity of an 'isochron' of 965 m.y. with an initial strontium-87/strontium-86 ratio of $0{\cdot}708_5$, but it is thought that the lack of a close fit simply reflects, as was expected, the fact that there is no reason or necessity why these granites from four different massifs should have precisely the same age, although they are approximately contemporaneous. The results (Nos. 11–15), listed in Table 1, assuming an initial ratio of 0·709, can thus only be considered as apparent ages despite the excellent agreement between whole rock-muscovite pairs (Nos. 12–15).

As has already been found for a northern portion of the same belt, in Kivu[6], the ages and apparent ages of pegmatites and veins fall into two groups. This is the result

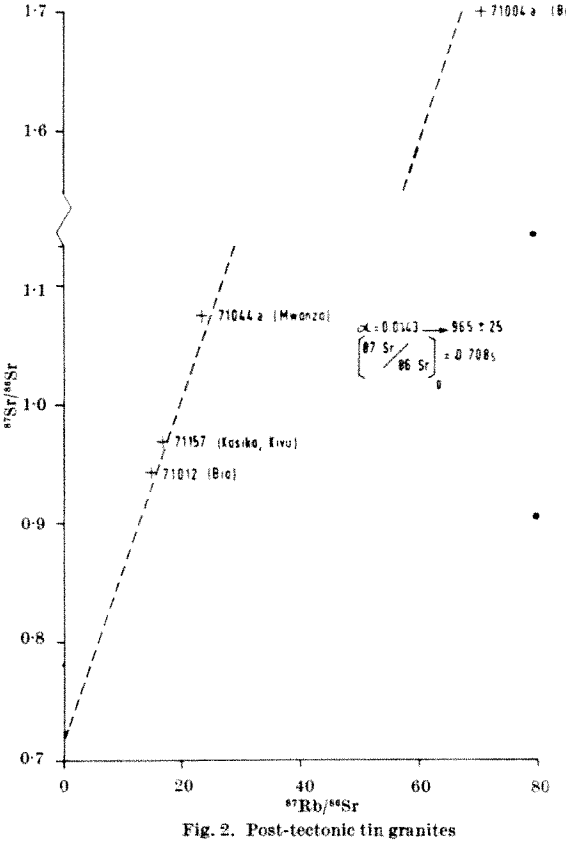

Fig. 2. Post-tectonic tin granites

of geochronological work and was not suspected in the field. The older group is represented by three concordant apparent ages for priorite from a vein cutting through the Kibara massif[7–9]. The results, recalculated with more recent constants[10], are given here and concur at about 1,104 m.y.

t (lead-207/lead-206) = 1,054 ± 50 m.y.; t (lead-206/uranium-238) = 1,133 ± 30 m.y.; t (lead-207/uranium-235) = 1,106 ± 30 m.y.

This is in keeping with the concordant apparent ages obtained by rubidium–strontium analyses of muscovite and microcline from Lugusha 1 pegmatite, Kivu[6]. Assuming an initial strontium-87/strontium-86 ratio of 0·709, these give an age of 1,120 ± 30 m.y. This older group is not usually tin-bearing.

A younger, generally tin-bearing group (Table 1, Nos. 16–23) comprises apparent ages of 965 ± 29 m.y. and 945 ± 28 m.y. for pegmatite minerals from the Bia massif, the tin granite of which has an apparent age of 1,010 ± 50 m.y.

The large pegmatite body of Manono mine, which belongs to, or is linked with, the Bukena massif, the tin granite of which is about 925 m.y. old, carries minerals of apparent ages between 930 ± 28 m.y. and 905 ± 27 m.y. (Table 1, Nos. 18–20). Other minerals from the same pegmatite (Nos. 21–23) have apparent ages which may be too young as one of these is from a demonstrably crushed microcline (No. 21) and the others, on muscovite, are similar both to the apparent age of the mylonitized microcline and to those of some of the rejuvenated biotites.

All these results are from rocks which are geographically and structurally linked to the Kibaran belt. Similar rocks with similar ages occur occasionally as post-tectonic features in older belts but never in the younger, neighbouring Katangan[11]. This important spread of ages characterizes successive events of the history of the Kibaran fold belt. Further work is needed in order to date other events, not mentioned here, and to obtain more definitive ages for some of the events which are at present characterized by apparent ages only.

The majority of the age determinations were made in the Service de Géologie et Géochimie Nucléaires, University of Brussels, under the general direction of Prof. E. Picciotto. Some mass-spectrographic measurements were made in the Laboratorio di Geologia Nucleare, University of Pisa, with the kind permission of Prof. E. Tongiorgi. Petrographical studies and mineral separation were carried out in the Geological Department, Musée Royal de l'Afrique Centrale, Tervuren. This work was supported by the Institut Interuniversitaire des Sciences Nucléaires (Belgium) and by the Fonds de la Recherche Scientifique Fondamentale Collective (Belgium).

Sedimentation in Subsiding Basins

BARRELL'S[1] concept of base-level control is a well-known theory to explain sedimentation in subsiding basins. In its original definition the base level is a critical depth below which wave action ceases and therefore no erosion occurs. According to Barrell, sedimentation builds up to this level and then erosion keeps the water depth constant. Further sedimentation can only occur if the basin subsides. This mechanism is certainly applicable to some environments; however, other environments, in particular some limestone formations, show little or no evidence of extensive erosion but are nevertheless sediments which have formed at relatively constant water depth. Such equilibrium conditions can be obtained by making certain reasonable assumptions.

The amount of sedimentation, S, is a function of Q, the quantity supplied per unit time, R, the receptor value, D, the dispersal, and M, the type of material[2]. The effect of a base-level control can be obtained by assuming Q and R constant and making D proportional to the water depth w (M is ignored for simplicity) (see Fig. 1). This may be expressed as:

$$\frac{dD}{dt} = D_0 + aw(t)$$

$$D_{(t)} = Qt - (w + w_0) \qquad (1)$$

Assuming $D = 0$ at $w = w_0$, $t = 0$, we find the solution:

$$w(t) = \frac{Q - D_0}{a} + \left(w_0 - \frac{Q - D_0}{a}\right) e^{-at} \qquad (2)$$

The various constants have to be chosen in such a way that deposition does in fact occur, that is, $\frac{Q - D_0}{a} \leqslant w_0$ and $D_0 \leqslant aw_0$ ensures that the dispersal does not exceed the assumed constant Q.

We obtain the case for the lowest permissible dispersal rates by setting $\frac{dD}{dt} = 0$ at $t = 0$ and the solution then simplifies to:

$$w = \left(\frac{Q}{a} + w_0\right) - \frac{Q}{a} e^{-at} \qquad (3)$$

under the condition that $\frac{Q}{a} \leqslant -w_0$.

The system approaches a constant water depth of $\frac{Q}{a} + w_0$, which is determined by the quantity of sediment introduced and the constant 'a' which may be regarded as typical for the environment. If any crustal movement should occur, this will enter as its derivative and is thus exactly equivalent to Q with opposite sign.

For non-clastic sediments and some limestone accumulations, the model can be slightly modified. We assume the sedimentation rate to be directly proportional to the water depth and in addition consider a crustal movement $c(t)$ causing subsidence (see Fig. 2). Thus:

$$\frac{dS}{dt} = aw(t)$$

$$S(t) = c(t) - w(t) \qquad (4)$$

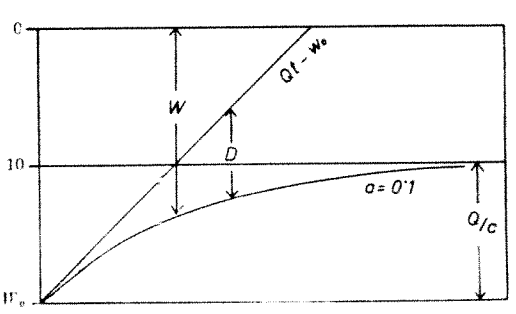

Fig. 1

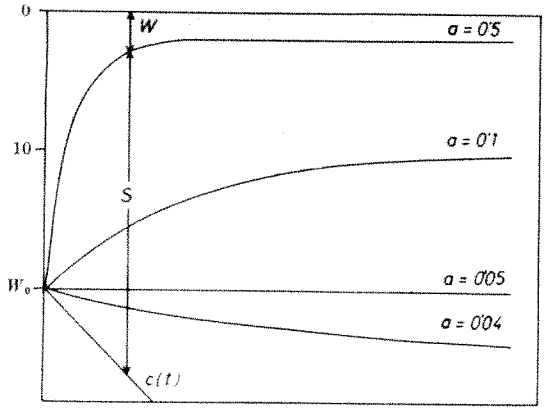

Fig. 2

If we assume $\dot{c}(t) = c$ (that is, constant sinking) the solution has the same form as equation (2). An equilibrium surface is established at a depth $\frac{c}{a}$ which is determined by the rate of sinking and an environmental constant 'a'. It is interesting to note that this equilibrium will always be obtained as long as sedimentation exists. In the example (Fig. 2), an initial water depth of 20 m is assumed and the constant rate of subsidence is 1 m per unit time. The effect of different values of 'a' is shown. Naturally, if $\frac{c}{a} = w_0$ no change of water-level occurs; for $\frac{c}{a} < w_0$ the cumulative curve of sediment laid down in time is convex; for $\frac{c}{a} > w_0$ the curve becomes concave; such features can be checked from the stratigraphical record. The assumption (4) seems reasonable as a first approximation for the behaviour of sediments in shallow basins, but this can be elaborated. Thus, it should be possible to introduce ecological depth distributions of lime producing organisms or other physical or chemical factors. One would then use a numerical or graphical method to solve the resulting differential equations.

It is not claimed that the outlined procedure can solve geological problems in quantitative terms, but it is hoped that it contributes to the clearer understanding of the 'subsidence–sedimentation' relationship.

PHYSICS

A Precision Femtofarad Capacitor

A CAPACITOR has been investigated which consists of six spheres, a, b, c, d, e and f, each with its centre on an axis of an orthogonal co-ordinate system and equidistant from the origin (see Fig. 1). The capacitance is measured between any two opposite spheres, while the remaining four and the shield are always at ground potential. This makes a three-terminal capacitor; the third terminal is the ground to which the shield and the non-active spheres are connected. This sphere configuration, which has three-dimensional symmetry, is somewhat related to the four-cylinder system having two-dimensional symmetry, described by Thompson and Lampard[1].

The mean value:

$$\frac{C_{ab} + C_{cd} + C_{ef}}{3}$$

of the cross-capacitance values of the three pairs (a–b, c–d and e–f) of opposite spheres exhibits several useful characteristics. The dimensional asymmetries of the configuration are reflected in the mean value to a much lesser degree and, at certain values of sphere spacing, the capacitance is invariant to the first order with sphere diameter and sphere spacing. These properties make it possible to achieve a precise capacitor with moderate requirements on the dimensional tolerances, which is stable in the presence of external disturbances.

The dependence of capacitance (which is in the order of a few to a few tens femtofarad; 1 femtofarad = 10^{-15} farad) on sphere spacing and diameter is shown in Fig. 2. The capacitance increases linearly with sphere spacing when the spacing is small, but as the spacing increases new effects become prominent. At very large spacing, the capacitance decreases, since the field is nearly the same as between two spheres only. In the intermediate region, there is a reversal of the capacitance versus spacing curve which approximates a parabola quite well. At the vertex, for the spacing X_S, the capacitance is invariant with spacing to the first order.

Inspection of the family of curves of Fig. 2 shows that each ascending branch of a parabola is intersected just before the vertex by an ascending branch of a parabola of the next larger sphere size. The triangle formed, for example, by the intersection of the parabolas of the 1-in. (2·54 cm), 15/16-in. (2·38 cm) and 7/8-in. (2·22 cm) diameter spheres is of interest. To the right of this triangle, the capacitance increases with sphere diameter and to the left it decreases. It can be demonstrated that at a spacing X_D, approximately in the centre of this triangle, the capacitance is invariant to the first order with sphere diameter for the 15/16-in. sphere capacitor system.

For every system there is a spacing X_S and a spacing X_D at which invariance with spacing or diameter, respectively, is realized. It can be shown that the two values are related by:

$$X_D = X_S - \frac{ap}{b}$$

where a and b are constants which are determined by the character of the parabola family and p is the semilatus rectum.

From the foregoing discussion, it follows that:

$$\text{for } X < X_D: \frac{dC}{dX} > 0; \frac{dC}{dD} < 0$$

and

$$\text{for } X > X_S: \frac{dC}{dX} < 0; \frac{dC}{dD} > 0$$

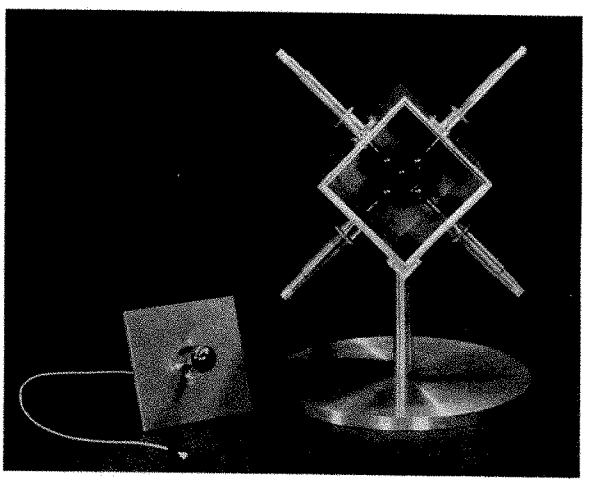

Fig. 1. Experimental unit constructed to permit wide range adjustment of the centre-to-centre sphere spacing. The spacing was varied by pulling out the spring-loaded sphere supporting rods through the mounting tubes outside the shielding cube, and inserting sets of 1/16-in. spacers

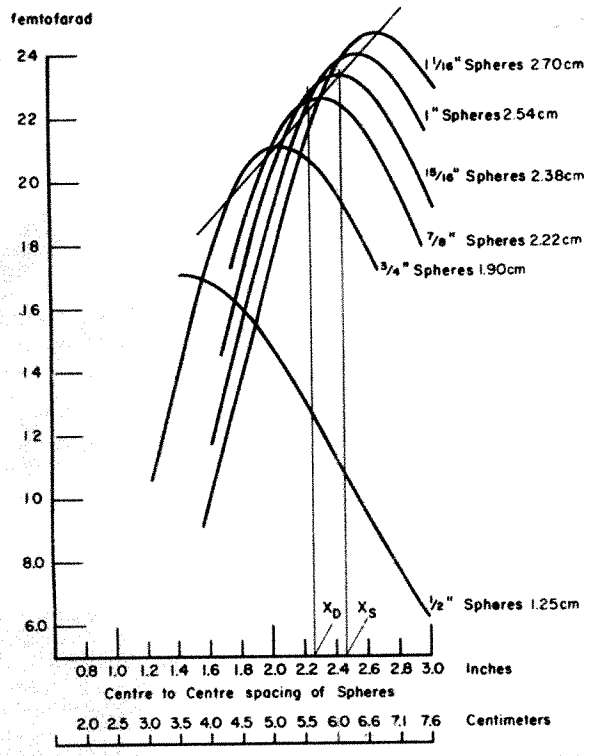

Fig. 2. Capacitance of the unit shown in Fig. 1, as a function of the centre-to-centre spacing of opposite spheres with sphere diameter as parameter

where C is the capacitance, X is the sphere spacing, and D is the sphere diameter.

Thus, for values of spacing smaller than X_D and slightly larger than X_S (the latter being preferred) effective temperature compensation can be achieved by the simple procedure of spacing adjustment. This has been confirmed by temperature tests where positive, negative and nearly zero temperature coefficients have been obtained, depending on the value of sphere spacing.

I believe that this capacitor could be reproduced with a precision in the order of ten parts per million. The spheres are available with a diameter and sphericity tolerance of two parts per million (commercial ball bearings), and the construction of the shield is not too critical. Subsequent adjustment to even closer tolerances could easily be accomplished with a screw penetrating through the shield and influencing the external field of the spheres, which represents a very small fraction of the internal field.

The promising characteristics of this capacitor suggest applications as a reference standard in the femtofarad range. If the value of capacitance could be computed from the dimensions, it would be worth while to consider the application of the capacitor for a primary standard.

Structure of the Cubic Phase of Lipid–Water Systems

IN the course of the structure analysis of the mesomorphic phases occurring in lipid–water systems[1–4] we have observed an optically isotropic phase, the X-ray reflexions of which can be indexed on a face-centred cubic lattice[2,3]. We assumed that its structure consists of spherical particles, packed in a face-centred cubic lattice. We further postulated that the spheres consist of micelles containing lipid[2,3]; but we pointed out that the alternative model, formed by water spheres embedded in a hydrocarbon matrix, could not be discarded solely on the basis of the X-ray data[5]. We intend to show in this communication that the latter structure is in fact more satisfactory, when other lines of evidence are taken into account.

The cubic phase is generally observed over a narrow range of concentration, between the lamellar (or neat) and the hexagonal (or middle) phases[3]. The essential properties of these two phases are summarized here as a basis for the discussion following[2,4]. The lamellar phase is formed by an alternating sequence of lipid and water leaflets; the hydrophilic groups of the lipid molecules are located on the interface. The hexagonal phase is a two-dimensional hexagonal array of rigid rods; in the case of soaps and detergents the rods contain the hydrocarbon chains, are covered by the hydrophilic groups of the lipid molecules and are separated from each other by water[2–4]. In all these structures (lamellar, cubic, hexagonal) the hydrocarbon chains take up a disordered, liquid-like conformation[2,4]. The lattice parameters are given by the X-ray experiments; when in addition the concentration and the specific volumes of lipid and water are known, various structural parameters can be determined, namely, the thickness of the lipid and of the water layers for the lamellar phase, the diameter of the cylinders for the hexagonal phase (assuming that the rods are circular cylinders) and the diameter of the spheres for the cubic phase. Furthermore, it is possible to calculate for all the phases the average area, S, available to one hydrophilic group on the lipid–water interface.

This type of analysis was recently extended by Clunie, Corkill and Goodman[6] to the system (*N*,*N*,*N*-trimethylamino dodecanoimide)–water. The phases found at room temperature, in the order of increasing concentration, are: hexagonal, cubic, lamellar (named by these authors, middle, viscous isotropic, neat). For each phase the various structure parameters were determined, assuming that the hexagonal phase is formed by circular cylinders, and that the cubic phase contains lipid spheres. Clunie *et al.* discuss these parameters, and point out that the area S in the cubic phase is larger than in both the lamellar and the hexagonal phases (compare S_I, S_H and S_L in Table 1). This anomaly was in fact present in our own data[3] (see Table 1), but we overlooked its significance at the time of our first report. We know now, in the light of the analysis of a large number of lipid–water systems[3,4,7], that such an erratic fluctuation is an exception to the rule that, as the lipid concentration increases, S decreases or remains constant, but never increases. In order to reconcile these conflicting results the structure of either the hexagonal or the cubic phase must be revised.

Clunie *et al.*[6] chose to reconsider the hexagonal phase. They put forward a structure formed by linear aggregates of identical spheres, arranged in a two-dimension hexagonal lattice. With this model in mind, and taking into account the various experimental results, they calculate the radius of the spheres and the area S : S, in this case, decreases linearly with increasing lipid concentration[6]. But there are two objections to this model. The first is based on symmetry considerations. There is ample

R_w radius of the water spheres, for cubic II.

evidence, resulting from the liquid-like conformation of the paraffin chains and from the polymorphism of the mesomorphic phases, that both the aqueous and the paraffinic structural elements are devoid of internal rigidity[3,4]. The shape of the structure elements must therefore be defined by the lattice interactions or, in other words, their symmetry must not be lower than the lattice symmetry. This rule appears to be obeyed by all the phases[3,4]: it is not clear why the hexagonal phase should be an exception. The second objection is founded on X-ray diffraction arguments. Clunie *et al.* explain the absence of non-equatorial reflexions by assuming that the strings of spheres are randomly displaced parallel to their neighbours. This hypothesis appears quite unrealistic in the light of the result that the distance between the rod axis becomes very close to the diameter of the spheres (at $c_g = 0{\cdot}63$ the diameter is 41·5 Å, the distance 41·6 Å, see Figs. 7 and 8 in Clunie *et al.*[6]).

Most of the difficulties are removed if the cylindrical shape of the rods in the hexagonal phase is preserved, and if the alternative structure of the cubic phase is taken into consideration, that is, if it is assumed that the spherical particles contain the water, and that the hydrocarbon chains fill the gap between the spheres. We call this structure cubic II; the previous one cubic I.

For the saturated potassium soaps, as well as for the detergent investigated by Clunie *et al.*[6], the area S in cubic II is intermediate between the lamellar and the hexagonal phases (compare S_{II}, S_L and S_H in Table 1): furthermore the sharp jump from S_L to S_I is smoothed out for cubic II.

The case of the cationic detergents (C_{12} TAB and C_{16} TAB) is somewhat anomalous, since S is either too large, for cubic I, or too small, for cubic II (compare S_I, S_{II}, S_L and S_H in Table 1). This anomaly could perhaps be explained by the symmetry of the model. Indeed the shape of the particles is bound to conform to the symmetry of the lattice, but need not be spherical, as was assumed in the calculation for S_I and S_{II}. Any departure from the spherical shape increases S, and, for cubic II, improves the agreement with the other phases; for cubic I the discordance is aggravated by increasing S_I (Table 1).

The very high viscosity of the cubic phase can be explained by the presence, in cubic II, of a paraffin matrix; this matrix is likely to determine the rheological properties of the whole structure. The highly viscous matrix also explains the frequent formation of fairly large crystals in the cubic phase, unlike the hexagonal and lamellar phases, in which such crystals are never observed. In these latter phases the probable cause of the lower viscosity is sliding in the water matrix.

Finally, it should be pointed out that another mesomorphic phase, namely, the hexagonal phase of phospholipid–water systems, contains water 'micelles' embedded in a hydrocarbon matrix[4,7].

CRYSTALLOGRAPHY

Order in Alkali Feldspars

IT has long been assumed that the degree of ordering between silicon and aluminium in the tetrahedral sites of feldspars is related to the conditions of formation of the minerals. A direct test of this idea has, up to the present, been hampered by the lack of an easy method of measuring the degree of order in a genetically related suite of feldspars. This communication describes a new method which, while applicable to all alkali feldspars, should be particularly useful for monoclinic potassium feldspars for which there is at present no generally accepted method of determining the degree of aluminium/silicon order short of a full-scale structural analysis.

Methods at present available for estimation of the degree of aluminium/silicon order are: (*a*) Measurement of the obliquity using 131 and $1\bar{3}1$ reflexions[1]. This is applicable only to geometrically triclinic varieties. (*b*) Measurement of $2V$ (refs. 2 and 3). Finney and Bailey express reservations as to the accuracy of this method because of the unknown effect of sodium content on $2V$. It is hoped to show in a later publication that $2V$ does provide a good measure of order provided suitable allowance is made for any sodium present in the feldspar under investigation. (*c*) Measurement of the partial birefringence ("b" $-\alpha$)[2,4]. This, so far as I am aware, has not so far been applied in practice. A correction for sodium content may be necessary, but the method should be much less sensitive to sodium than (*b*).

The present proposal is to use the ratio c^*/b^* as a direct measure of the degree of order of an alkali feldspar as defined by Mackenzie and Smith[8]. Fig. 1 shows this ratio plotted against the degree of order for all samples the structures of which have been published and Table 1 gives the data on which the figures are based.

It will be noticed that the curve is relatively insensitive to variation in sodium although there is a suggestion that the sodium feldspars may in fact lie on a curve which is slightly displaced from that of the potassium feldspars. No attempt has been made in the present curve to correct for the sodium content of mixed feldspars, although the amount of sodium present does vary slightly among the specimens used.

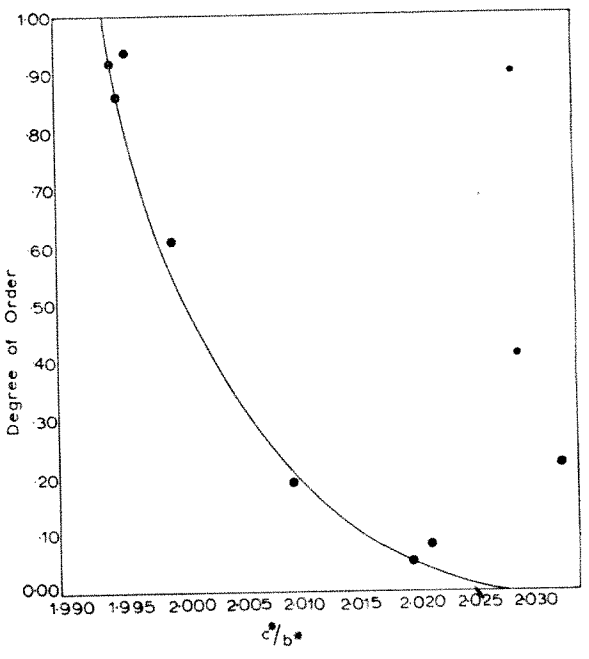

Fig. 1

Table 1

Specimen	Degree of order %	c^*/b^*	Reference
Pellotsalo	92	1·9948	Brown, B. E., and Bailey, S. W., *Acta Crystallog.*, **17**, 1391 (1964).
Pontiskalk	86	1·9952	Finney, J. J., and Bailey, S. W., *Zeit. für Kristallog.*, **119**, 413 (1963).
Spencer *U*	61	1·9999	Bailey, S. W., and Taylor, W. H., *Acta Crystallog.*, **8**, 621 (1955).
Spencer *C*	19	2·0104	Jones, J. B., and Taylor, W. H., *Acta Crystallog.*, **14**, 443 (1961).
Spencer *C* (sanidinized)	5	2·0205	Ribbe, P. H., *Acta Crystallog.*, **16**, 426 (1963).
Low albite	94	1·9962	Ribbe, P. H., Ferguson, R. B., and Taylor, W. H., *Norsk. Geol. Tidsskr.*, **42**, 152 (1962).
High albite	8	2·0219	Ferguson, R. B., Traill, R. J., and Taylor, W. H., *Acta Crystallog.*, **11**, 331 (1958).

Unpublished data on Spencer's specimen *B* (ref. 5) and on another adularia at present under study in this laboratory indicate that they also lie on the present curve. The degrees of order of the specimens investigated by Hewlett[4] and Spencer[6] deduced from the graph agree well with those deduced from measurement of $2V$ (after correction to $2V$ for sodium content has been applied).

The ratio c^*/b^* is amenable to routine measurement. The values used in Table 1 were obtained on single crystals, but for most monoclinic samples the ratio of $2 \times d_{040}/d_{002}$ may be obtained with sufficient accuracy from a diffractometer trace, preferably using an internal standard. In fact, the measurements of Hewlett[4] are of this type.

At $c^*/b^* \sim 2{\cdot}010$, the 002 and 040 peaks become unresolvable, but it is probable that the lines 003 and 060 (see the pattern for high albite[7]) can be used instead. A better procedure is to use all the low-angle lines to obtain accurate values of c^* and b^* with the aid of a computer.

It should be noted in particular that this curve provides an X-ray powder method for distinguishing orthoclase from sanidine. It is proposed that a value of $c^*/b^* = 2{\cdot}016$ (corresponding to $2V \sim 20°$ and degree of order $\sim 0{\cdot}1$) be used as the dividing line between orthoclase and sanidine.

Opal Genesis

EARLIER work on the structure of opal[1] has shown that precious opal, and probably most 'amorphous' opals with the notable exception of hyalites, are composed of silica spheres 1500–3000 Å in diameter. It was further suggested that the presence of these spheres may reflect a genetic difference from the majority of crystalline opals, which have a different gross structure.

Subsequent laboratory work has indicated one possible way in which spherical colloidal micelles of silica can form from natural minerals. Figs. 1 and 2 show aggregates of silica spheres which formed as a result of leaving flakes of biotite in cold, 10 per cent sulphuric acid for several months. The acid gradually dissolved all cations except silicon, leaving a white, fluffy residue which preserved the original flaky habit of the mica. However, in order to produce the spheres, extensive rearrangement on a submicroscopic scale has taken place. Some silica will have

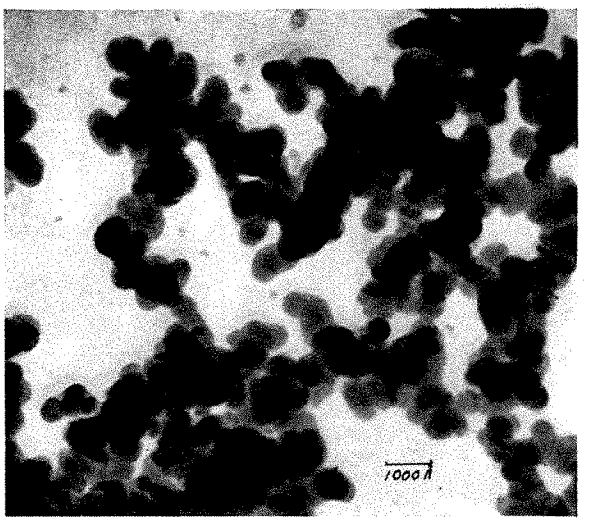

Fig. 1. Transmission electron micrograph of silica residue from the decomposition of biotite

Fig. 2. Electron micrograph of platinum-shadowed aggregate of the silica particles of Fig. 1

dissolved, at least to the extent of the solubility of amorphous silica (approximately 100 p.p.m.)[2], but it is evident that continuous re-precipitation and solution must have taken place between the silica released from the biotite and the solution. It is therefore probable that, as free silica is liberated from the mineral, it forms a supersaturated solution, which rapidly forms a sol. Silica micelles formed in this way normally assume a spherical shape[3]. The high concentration of electrolytes in the immediate neighbourhood of the biotite flakes could then cause the flocculation of the micelles into aggregates such as those of Figs 1 and 2. Under natural weathering conditions with water movement, such micelles could be transported as a sol and may form larger particles by surface growth[4] or aggregation[5].

Biotite is not the most likely source of secondary silica for the formation of most opal deposits. Other minerals (kaolinite, muscovite, montmorillonite, feldspar, chlorite, pyroxene) appeared to be stable when boiled for 2 h with strong acid, but have not yet been subjected to long-term attack by dilute acid. Silicates such as feldspars break down under hydrothermal or natural weathering conditions, and at least in some cases free amorphous or cristobalitic silica is formed, and may be found in the clay deposits so formed[6]. It is therefore possible that a process similar to this may play an important part over long periods of time in the formation of opal deposits. In view of these results, it is probable that silica will dissolve to supersaturation in some cases and will subse-

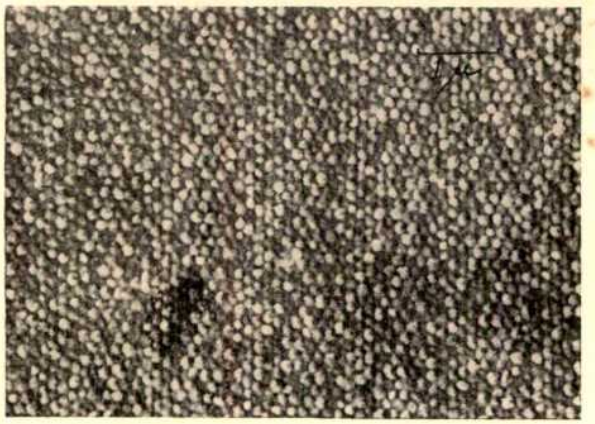

Fig. 3. Electron micrograph of lightly etched surface of a 'crystalline' precious opal from Tintenbar, New South Wales. Surface etched with hydrofluoric acid. (Carbon replica, chromium-shadowed)

quently form colloidal spheres capable of enlargement, flocculation, and deposition as opaline silica gel in the presence of a sufficient concentration of electrolytes.

Silicification of certain horizons is characteristic of many Australian lateritic profiles[7], and the major opal deposits are associated with such profiles. It is noteworthy, therefore, that abundant sulphates occur in the environment of opal deposition. Examples of this are the occurrence of gypsum at Andamooka, South Australia; gypsum and alunite at Coober Pedy, South Australia; gypsum and glauberite at White Cliffs, New South Wales; and alunite at Lightning Ridge, New South Wales.

These observations do not imply that all precious opals are formed by weathering processes. Precious opal from Tintenbar, New South Wales, occurs in amygdales in decomposed basaltic rocks, which may imply a hydrothermal or deuteric origin[8]. This material shows the characteristic regular particulate structure[1] (Fig. 3) of a precious opal, but is exceptional in that it is moderately crystalline (disordered tridymite-cristobalite). Other samples of precious opal associated with volcanic rocks, however (as at Rocky Bridge, New South Wales; Springsure, Queensland), yield only the customary near-amorphous type of diffraction pattern.

We thank Dr. M. J. Ridge for helpful suggestions and advice and Dr. R. Inman for assistance in the electron microscopy.

CHEMISTRY

Differential Thermal Analysis of Thallous Azide

IN their review of inorganic azides, Evans, Yoffe and Gray[1] note that the crystal structure of thallium azide is body-centred tetragonal and that the compound melts with decomposition at about 334° C. On differential thermal analysis, a solid-state transition is shown before

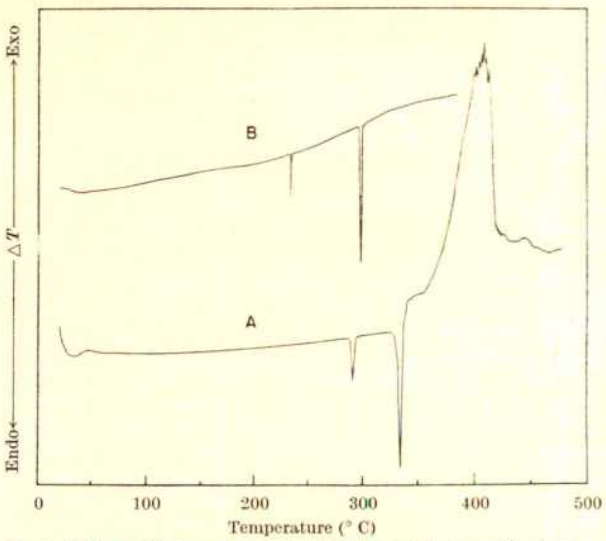

Fig. 1. Differential thermal analysis of thallium azide (*A*) and its decomposition product (*B*)

the fusion process. As shown in Fig. 1*A* this transition has a maximum peak temperature at 291° C. If the sample is allowed to undergo a cooling cycle before decomposition sets in, then the transition is seen to be reversible. Fig. 1*A*, however, takes the sample through the decomposition process. The exothermic peak is caused by oxidation of the azide group to molecular nitrogen. Thallium metal is the other product of the thermal decomposition and Fig. 1*B* shows the hexagonal–cubic transition near 234° C, previously reported by Mazières[2], followed by melting at 299° C.

The DuPont 900 differential thermal analyser, provided with an aluminium heating block and chromel alumel thermocouples, was used to obtain the thermogram. Approximately 3 mg of azide sample, contained in a glass capillary tube, was run in air against glass beads as a reference material. The heating rate was 20° C/min. The sample of thallous azide powder was prepared by precipitation from a mixture of ethanolic solutions of thallous acetate and sodium azide.

Radiolysis of Nitroalkanes

FEW investigations of the radiolysis of nitroalkanes have been reported[1] and, apart from the use of tetranitromethane as a scavenger in aqueous solutions[2], no systematic study of their radiation chemistry has been made. The liquids are highly polar and ionic reactions might be expected to play a significant part in the decomposition processes. In order to obtain information on this problem we have examined the radiation chemistry of nitromethane, nitroethane, 1- and 2-nitropropanes, the first in considerable detail. Some of the salient features of this investigation are reported here.

Nitromethane was prepared by the reaction of monochloroacetic acid and sodium nitrite and purified by fractional distillation. Nitroethane and the nitropropanes were purified by fractional distillation under reduced pressure after alkali and acid washing. The irradiations were carried out with γ-rays from a cobalt-60 source using dose rates between 0·5 and $2{\cdot}5 \times 10^4$ rads h^{-1}. Higher dose rates up

to 7.5×10^6 rads M^{-1} (mean values) were obtained by means of a linear accelerator at the Atomic Energy Research Establishment, Wantage. Degassed samples were irradiated in break-seal tubes. Gaseous products were separated at $-196°$, $-80°$ and in some cases also at $-120°$ C and analysed by gas chromatography and mass spectrometry. Liquid products were analysed by gas chromatography, infra-red and ultra-violet spectroscopy, and chemical methods (Table 1). The solid residue left after low-temperature distillation was analysed chemically and by ultra-violet absorption spectroscopy in solution.

The production of water in the case of nitromethane was shown by the Carl Fischer reagent and the solid residue was found to contain the *cis* dimer of nitrosomethane. It is possible that the *trans* form could have been carried over with substrate during distillation, but this was not substantiated.

Some of the products quoted were a result of reactions occurring a considerable time after the initial irradiation. The yield of gaseous products from irradiated nitromethane was drastically reduced if after a short irradiation, such as that obtained by using a linear accelerator, the samples were immediately quenched in liquid nitrogen until analysis. Under these conditions $G(N_2)$, 0·19; $G(CO)$, 0·27; $G(NO)$, 0·38; $G(CH_4)$, 0·08; $G(H_2)$, 0·21; $G(CO_2)$, 0·31; $G(N_2O)$, 0·35; $G(CH_3ONO)$, 1·58; $G(C_2H_6)$, 0·09; $G(HCHO)$, 0·32; $G(cis\text{-}(CH_2NO)_2)$, 0·43. It was noted that the decrease in gaseous products was accompanied by an increase in the yield of *cis*-nitrosomethane dimer. Allowing the sample to stand at room temperature for varying lengths of time increased the yields of nitrogen, carbon monoxide, carbon dioxide and nitrous oxide up to the limiting values quoted in Table 1. The post-irradiation reaction effects were complete after 5 h at room temperature.

The addition of iodine as a radical scavenger had no detectable effect on the amount of gaseous products. Nitrous oxide, a potential electron scavenger, slightly increased the nitrogen and carbon monoxide yields.

Table 1. PRODUCTS FOUND (APPROXIMATE VALUES)

(1) From nitromethane, $G(N_2)$, 0·86; $G(CO)$, 0·39; $G(NO)$, 0·34; $G(CH_4)$, 0·095; $G(H_2)$, 0·22; $G(CO_2)$, 0·68; $G(N_2O)$, 0·66; $G(CH_3ONO)$, 1·15; $G(HCHO)$, 0·26; $G(cis\text{-}(CH_2NO)_2)$, 0·22. Small amounts of dimethyl ether, methyl nitrite, formaldoxime, water and methanol were also detected.

(2) From nitroethane, $G(N_2)$, 0·50; $G(CO)$, 0·094; $G(NO)$, 0·08; $G(CH_4)$, 0·02; $G(H_2)$, 0·08; $G(CO_2)$, 0·12; $G(N_2O)$, 0·73; $G(C_2H_4)$, 0·78; $G(C_2H_6)$, 0·18. Ethyl nitrite and acetaldehyde were also detected.

(3) From 1-nitropropane, $G(N_2)$, 0·74; $G(CO)$, 0·08; $G(NO)$, 0·35; $G(CH_4)$, 0·02; $G(H_2)$, 0·02; $G(CO_2)$, 0·31; $G(N_2O)$, 0·71; $G(C_2H_6)$, 0·54; $G(C_2H_6)$, 0·08; $G(C_3H_4)$, 0·06. Propyl nitrite and propionaldehyde were also present.

(4) From 2-nitropropane, $G(N_2)$, 1·48; $G(CO)$, 0·04; $G(NO)$, 0·21; $G(CH_4)$, 0·03; $G(H_2)$, 0·15; $G(CO_2)$, 0·13; $G(N_2O)$, 0·07; $G(C_2H_6)$, 1·31; $G(C_3H_8)$, 0·10. Isopropyl nitrite and acetone were also present.

An examination of the decomposition of pure nitromethane was made by the technique of pulse radiolysis using the apparatus developed by Dr. J. P. Keene of the Christie Hospital and Holt Radium Institute, Manchester[3]. Two absorbing species were found, the spectra of which showed an absorption which increased from 6000 Å as the absorbing wave-length decreased. One of the species decayed by a second-order process, the other seemed to be relatively stable and increased with increasing dose rate and repeated pulsing. The identity of these species has not been definitely established, but it is tentatively suggested that the long-lived material is monomeric nitrosomethane and the shorter lived species is $CH_2NO^-_2$ which is removed by a bimolecular acid-base reaction. Owing to the acidic nature of the solvent, the lifetime of the analogue of the hydrated electron in an aqueous medium would be very short-lived.

No simple scheme is capable of explaining the observations and it is not possible to discuss adequately the mechanism here. The nature of the products can be explained in terms of a free radical scheme involving initial production of an alkyl radical and nitrogen dioxide such as that advanced for the photolysis of nitromethane[4]. This is certainly an oversimplification and it is significant that the proportions of products vary in the photochemical and radiation systems. For example, the low yields of paraffins suggest that primary processes other than homolytic fission are important. Ionic processes which occur in the mass spectrometer[5] are feasible in the radiolysis of nitromethane; in particular:

$$\begin{aligned} CH_3NO^+_2 &\rightarrow CH_3O + NO^+ \\ &\rightarrow CH^+_3 + NO_2 \\ &\rightarrow CH_3 + NO^+_2 \end{aligned}$$

Other reactions possible are:

$$\begin{aligned} CH_3NO^-_2 &\rightarrow CH_3 + NO^-_2 \\ &\rightarrow CH_3^- + NO_2 \\ &\rightarrow CH_3NO + O^- \\ &\rightarrow CH_3NO^- + O \end{aligned}$$

Certainly all the products found can be explained in terms of reactions involving these intermediates.

We thank Dr. J. P. Keene and Mr. K. Melhuish for assistance, the Atomic Energy Research Establishment, Wantage, for use of facilities, and the U.K.A.E.A. for support.

Improvements in Sensitivities with Flame Ionization Detectors

COMMUNICATIONS following our letter "Safety in Air Separation Plants—Determination of Atmospheric Pollutants by Gas Chromatography"[1] have indicated that some difficulty has been found in obtaining the quoted sensitivities. In order to obtain these detection levels, certain precautions are necessary which are not commonly adopted when using flame ionization detectors.

The use of oxygen in place of the more widely used air for combustion purposes provides about a five- to ten-fold increase in sensitivity, but of at least equal importance is the carrier and combustion gas purity. The carrier gas used throughout our experiments was helium, purified by the titanium–hopcalite–molecular sieve train described by Berry[2], but it should be noted that less expensive argon may be similarly purified. The combustion gases were passed through 12 ft. (× 0·25 in. o.d.) columns of Davison's silica gel, re-activated at regular intervals. The *in situ* generation of electrolytic hydrogen would be a preferred method[3]. Finally, the signal co-axial connecting cable between the detector and amplifier must be kept scrupulously clean, with all insulators having a resistance in excess of 100 M.ohm. In the present case it was found necessary to clean the signal cable thoroughly every 24 h.

We believe that a more rigorous purification of the combustion gases, in conjunction with improved precautions in order to maintain a high insulation, will improve sensitivity levels even further.

Oxidation of Gaseous Formaldehyde

IN a recent communication to *Nature* on this subject, J. M. Thomas and I[1] described some experimental results which showed that in a 'matured' quartz vessel at 320° C direct oxidation of formaldehyde by oxygen to hydrogen peroxide occurred to the very considerable extent of 70 per cent:

$$HCHO + O_2 = H_2O_2 + CO \quad (1)$$

In a reaction vessel newly treated with nitric acid or hydrofluoric acid, however, the production of hydrogen peroxide was minimal and not greater than 2 per cent, the main products being water and carbon monoxide:

$$HCHO + \tfrac{1}{2}O_2 = H_2O + CO \quad (2)$$

During a recent discussion in Moscow it was pointed out to me that very similar results had already been reported by Markewich and Filippova[2] and by Markewich and Pecherskaya[3] between 1957 and 1961, in which they showed that reaction (1) occurs to the extent of about 27 per cent in glass or quartz vessels "matured" after treatment with chromic acid, while with vessels treated with a 2 per cent solution of potassium borate ($K_2B_4O_7$), the reaction takes the second course represented by equation (2). Markewich and Pecherskaya[3] also proposed a chain reaction similar to the one which we proposed.

There cannot be the slightest doubt that full priority accrues to Markewich *et al.*, and I wish to express our regret to them for failing to acquaint ourselves with their work and, as a consequence, omitting reference to their publications.

Neutralization of Hydronium Ions in the Radiolysis of Water Vapour

WHEN water vapour is irradiated, the main primary positive ion is H_2O^+ and it may be assumed that the reaction:

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH \quad (1)$$

($k_1 = 1{\cdot}26 \times 10^{-9}$ cm^3 molecules^{-1} sec^{-1}) will result in the formation of hydronium ions[1]. It has been suggested[2,3] that neutralization of the hydronium ion by recombination with electrons can lead to the formation of two hydrogen atoms per ion:

$$H_3O^+ + e^- \rightarrow 2H + OH \quad (2)$$

but there has been no evidence available to decide between this process and the alternative:

$$H_3O^+ + e^- \rightarrow H + H_2O \quad (3)$$

giving one hydrogen atom per ion. In an investigation of the radiolysis of mixtures of deuterium oxide and propane, we have obtained results which have a bearing on this question.

Mixtures, prepared by distilling weighed, deaerated deuterium oxide (99·8 per cent) samples and known volumes of propane (Phillips Research Grade) into 'Pyrex' vessels (400 ml.), were irradiated with cobalt-60 γ-rays at 137°. The nitrous oxide dosimeter was used (assuming $G(N_2) = 12{\cdot}0$) and the dose-rates in deuterium oxide and propane calculated assuming stopping powers per molecule relative to nitrous oxide of 0·46 and 1·25, respectively.

Fig. 1 shows $G(HD)_t$ (molecules of deuterium hydride per 100 eV absorbed by the mixture of deuterium oxide and propane) as a function of the fraction of energy absorbed in deuterium oxide and in propane, for mixtures with propane concentrations from 2 to 98 mole per cent $G(HD)_w = 8{\cdot}0 \pm 0{\cdot}5$ and $G(HD)_p = 4{\cdot}6 \pm 0{\cdot}4$ (molecules per 100 eV absorbed in deuterium oxide and propane, respectively) are obtained by extrapolation to zero concentrations of propane and deuterium oxide. The results are consistent with the assumption that $G(HD)_w$ and $G(HD)_p$ are constant over the whole range of concentration (Fig. 1).

The observed $G(HD)_w = 8{\cdot}0 \pm 0{\cdot}5$ is in reasonable agreement with the hydrogen atom yield from water and deuterium oxide ($G_H = G_D = 7{\cdot}5 \pm 0{\cdot}7$) obtained by Baxendale and Gilbert[4,5] using methanol as scavenger. Hydrogen was also formed from mixtures of deuterium oxide and propane, $G(H_2)_p = 6{\cdot}0 \pm 0{\cdot}5$ being independent of the concentration of propane.

The observed $G(HD)_p$ cannot be explained by assuming that the exchange reaction:

$$H + D_2O \rightarrow D + HDO \quad (4)$$

occurs since the propane would compete with deuterium oxide for any hydrogen atoms formed from propane and this would be expected to result in a dependence of $G(HD)_p$ and of $G(H_2)_p$ on the concentration of propane. Charge-transfer, from the hydrocarbon positive ions to deuterium oxide, may also be excluded, on energetic grounds.

The observed $G(HD)_p$ may be interpreted in terms of proton-transfer from hydrocarbon positive ions to deuterium oxide:

$$RH^+ + D_2O \rightarrow R + HD_2O^+ \quad (5)$$

where RH^+ represents the positive ion or ions from propane which undergo proton-transfer. The main positive ions may be assumed to be $C_3H_8^+$ and $C_3H_7^+$, since ions of smaller mass can undergo hydride ion transfer with propane[6,7]. The proton transfer reaction (5), where $RH^+ = C_3H_8^+$, has been observed in the mass-spectrometer[1,8], and is reported to have a rate constant of about 2×10^{-9} cm^3 molecules^{-1} sec^{-1} (ref. 8). Proton transfer from $C_3H_7^+$ to deuterium oxide is exothermic if the proton affinity of deuterium oxide is similar to that of water ($\geqslant 154$ kcal/mole^{-1}) (ref. 9).

It may be assumed that equilibrium:

$$HD_2O^+ + D_2O \rightleftharpoons D_3O^+ + HDO \quad (6)$$

will be established rapidly and that the majority of positive ions undergoing neutralization will be the species D_3O^+. (There is evidence that the hydronium ions will be clustered at the pressures used, since at pressures as

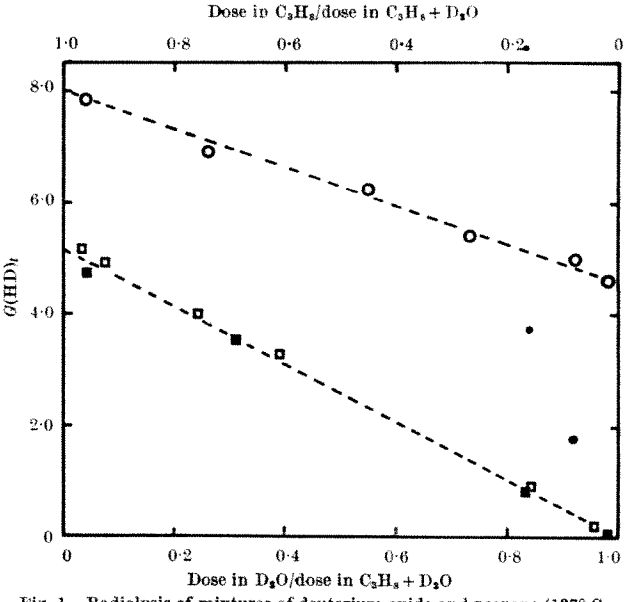

Fig. 1. Radiolysis of mixtures of deuterium oxide and propane (137° C, density 0·8–2·7 g l.). ○, $G(HD)_t$ (molecules per 100 eV absorbed in deuterium oxide and propane mixture); □, $G(HD)_t$ in presence of nitrous oxide (2·0 mole per cent); ■, $G(HD)_t$ in presence of sulphur hexafluoride (0·3 mole per cent)

low as 0·5 torr the ions in α-irradiated water vapour have been shown to be $H_3O^+(H_2O)_n$ where n is between 1 and 7 (ref. 10). For convenience, the hydronium ion is written here as D_3O^+.)

Deuterium atoms formed as a result of neutralization of D_3O^+ will be scavenged by propane according to:

$$D + C_3H_8 \rightarrow C_3H_7 + HD \quad (7)$$

and therefore measured as deuterium hydride.

The observed $G(HD)_p = 4{\cdot}6 \pm 0{\cdot}4$ is close to the total yield of positive ions from propane, $G(RH^+)_p = 4{\cdot}3$, calculated from $W(C_3H_8) = 23{\cdot}4$ eV (ref. 11). It seems reasonable to conclude, from the present data, that all the positive ions from $C_3H_n^+$ undergo the proton-transfer reaction (5) and that neutralization of D_3O^+ occurs according to:

$$D_3O^+ + e^- \rightarrow D + D_2O \quad (8)$$

These results suggest, therefore, that in the radiolysis of water vapour, neutralization of hydronium ions by electrons results in the formation of only one hydrogen atom per ion.

The results obtained when mixtures of deuterium oxide and propane were irradiated in the presence of nitrous oxide or sulphur hexafluoride show that, under these conditions, $G(HD)_w = 5{\cdot}0 \pm 0{\cdot}5$ and $G(HD)_p = 0$ (Fig. 1). At the concentrations used, nitrous oxide and sulphur hexafluoride cannot compete with reaction (7) for deuterium atoms. These scavengers have, however, been shown to be capable of reacting with electrons in irradiated gases to form negative ions[12], and their effect on the yields of deuterium hydride from deuterium oxide and propane may be attributed to a change in the process by which D_3O^+ is neutralized. It appears, therefore, that deuterium atoms are not formed in the neutralization process when D_3O^+ is neutralized by the negative ions from nitrous oxide or sulphur hexafluoride. It follows that $G(HD)_w = 5{\cdot}0 \pm 0{\cdot}5$, observed in the presence of electron scavengers, must be a result of the formation of deuterium atoms by processes other than D_3O^+ neutralization. The primary ionization process:

$$D_2O \rightsquigarrow OD^+ + D + e^- \quad (9)$$

which contributes about 18 per cent of the positive ions in the mass spectrum (see ref. 3) could give a $G(D)$ of about 0·6. The only other source of deuterium atoms envisaged is the decomposition of excited deuterium oxide molecules:

$$D_2O \rightsquigarrow D_2O^* \rightarrow D + OD \quad (10)$$

and the results suggest, therefore, that this process gives $G(D)$ between 4 and 5.

We thank Prof. J. J. Weiss for his interest and Dr. G. Scholes for helpful discussions. We also thank the Atomic Energy Research Establishment, Harwell, for financial support.

Chemical Group Separation in Radioactivation Analysis

The technique of detection and measurement of low concentrations of impurities by means of radioactivation analysis is now well established and the principles involved are well described in the literature[1,2]. For a large number of elements the technique is extremely sensitive and the sensitivity is limited only by the natural background radioactivity and the intensity of the neutron flux available. Some limitation on sensitivity is imposed by the neutron absorption characteristics of the material being analysed and the distance from the neutron source to the place of analysis. These limitations, however, are not generally serious. The work presented here describes the use of the foregoing analytical technique in conjunction with a chemical group separation. This procedure has been applied to the analysis of mineral specimens[3] and appeared suitable for application to the analysis of single crystal specimens of germanium, in order to obtain information about the concentration of several possible impurities in the samples.

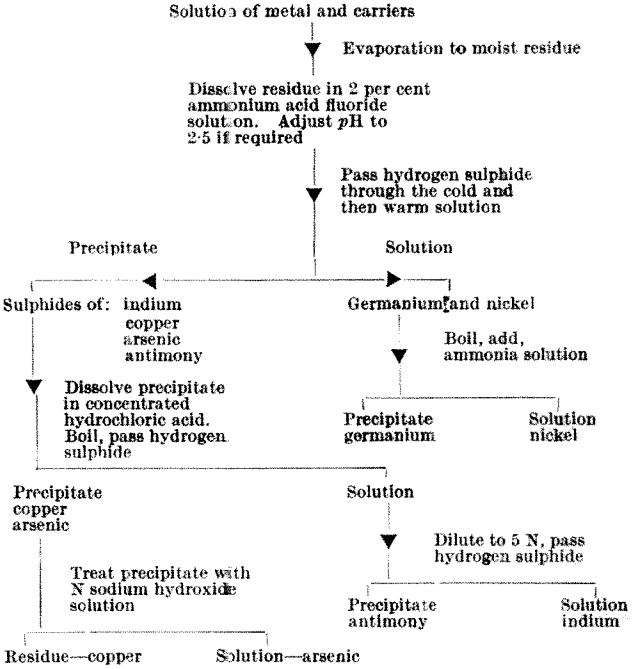

Fig. 1

The germanium samples, plus standard solutions of the impurities of interest, were irradiated together in a neutron flux of approximately 10^{12} n/cm²/sec. The period of irradiation was 6 days. On completion of the irradiation the germanium samples were rapidly dissolved in an equal volume mixture of 48 per cent hydrofluoric acid and fuming nitric acid, along with known weights of carriers for the impurities involved. The solution was then evaporated almost to dryness and the residue dissolved in 2 per cent ammonium acid fluoride solution. The group separation shown in Fig. 1 was applied and the carriers obtained as shown. The scheme depends for the separation of the major part of the germanium matrix on the fact that germanium is complexed in fluoride solution and is not readily precipitated as a sulphide under these conditions. The pH value used ensures the precipitation of the indium as a sulphide.

The separation and further purification of each carrier were performed in order of increasing length of half-life. Samples of the standards were also prepared in the same order. The activity of the carriers was then compared with the activity of known amounts of the standards, using a 1-in. end window Geiger–Müller tube and associ-

Table 1

Specimen	Elements determined	Concentration (w/w)
1	Indium	$1{\cdot}0 \times 10^{-8}$
	Copper	$< 1{\cdot}15 \times 10^{-7}$
2	Indium	$3{\cdot}5 \times 10^{-7}$
	Copper	$< 7{\cdot}5 \times 10^{-8}$
3	Indium	$8{\cdot}2 \times 10^{-9}$
	Copper	$< 3{\cdot}9 \times 10^{-6}$
4	Indium	$2{\cdot}6 \times 10^{-8}$
	Copper	$< 1{\cdot}0 \times 10^{-7}$
	Antimony	$< 3{\cdot}49 \times 10^{-8}$
5	Indium	$9{\cdot}3 \times 10^{-8}$
	Copper	$< 5{\cdot}2 \times 10^{-8}$
	Antimony	$< 3{\cdot}1 \times 10^{-8}$

ated counting equipment. From this comparison the impurity concentration was obtained. The presence of the correct isotope was confirmed by half-life measurements. The analysis of germanium samples for indium, copper and antimony was carried out, and some results are given in Table 1.

It is concluded that the application of a suitable chemical group separation in conjunction with radioactivation analysis can provide useful information about the extent of several impurities in a given specimen and increases the versatility of this method of analysis.

BIOCHEMISTRY

Volatile Constituents of Coffee-V

PREVIOUSLY[1–4], we described the isolation of an 'aroma complex' from roasted coffee and the methods used for the separation and identification of some of its constituents.

Interest in the chemistry of coffee has now considerably increased[5], and this suggests that progress in this field might perhaps be favoured by the publication of an additional list of volatile compounds the presence of which in roasted coffee has been conclusively established in this laboratory.

Table 1. SOME VOLATILE CONSTITUENTS OF COFFEE

Formula	Name of compound	Formula	Name of compound
H_2S	Hydrogen sulphide	C_4H_5N	Pyrrole
		$C_4H_6O_2$	Diacetyl
CH_2O	Formaldehyde	$C_4H_6O_2$	Butyrolactone
		$C_4H_6O_2$	Crotonic acid
CH_2O_2	Formic acid		
		C_4H_8O	i-Butanal
CH_4O	Methanol	C_4H_8O	Butanone
CH_4S	Methyl mercaptan	$C_4H_8O_2$	i-Butyric acid
		$C_4H_8O_2$	Acetoin
C_2H_4O	Acetaldehyde	$C_4H_8O_2$	Ethyl acetate
$C_2H_4O_2$	Acetic acid	$C_5H_4O_2$	Furfural
$C_2H_4O_2$	Methyl formate		
		C_5H_5N	Pyridine
C_2H_6O	Ethanol		
		C_5H_5NO	2-Pyrrolaldehyde
C_2H_6S	Dimethyl sulphide		
		C_5H_6O	2-Methylfuran
C_3H_6O	Propanal		
C_3H_6O	Acetone	$C_5H_6O_2$	Furfuryl alcohol
$C_3H_6O_2$	Propionic acid	$C_5H_6N_2$	2-Methylpyrazine
$C_3H_6O_2$	Acetol		
$C_3H_6O_2$	Methyl acetate	C_5H_7N	*N*-Methylpyrrole
C_4H_4O	Furan	C_5H_8	Isoprene
		C_5H_8O	*cyclo*Pentanone
C_4H_4S	Thiophene		
		$C_5H_8O_2$	Pentane-2,3-dione
$C_4H_4O_2$	Crotonolactone	$C_5H_8O_2$	2-Methyltetrahydrofuran-3-one
$C_4H_4N_2$	Pyrazine	$C_5H_8O_2$	Senecioic acid

Table 1 (*continued*). SOME VOLATILE CONSTITUENTS OF COFFEE

Formula	Name of compound	Formula	Name of compound
$C_5H_8O_3$	Acetol acetate	$C_7H_7NO_2$	Methyl nicotinate
$C_5H_{10}O$	2-Methylbutanal	C_7H_8	Toluene
$C_5H_{10}O_2$	2-Hydroxy-3-pentanone	C_7H_8O	*m*-Creosol
$C_5H_{10}O_2$	3-Hydroxy-2-pentanone		
$C_5H_{10}O_2$	i-Valeric acid	$C_7H_8O_2$	Guaiacol
$C_5H_{10}O_2$	2-Methylbutyric acid	$C_7H_8O_2$	5-Methyl-2-acetylfuran

Tea as a Source of Urinary Ethylamine

ETHYLAMINE is a normal constituent of human urine[1,2], but it is not found in rat urine. This suggested that urinary ethylamine might be a product of metabolism of a component of food or beverages.

In 1950, Sakato[3] isolated an amino-acid, L-theanine, from Japanese tea leaves and identified it as *N*-ethyl-γ-glutamine:

The presence of theanine in other varieties of tea was confirmed by Cartwright *et al.*[4].

A concentrated extract was prepared by shaking 10 g of tea leaves with 50 ml. of boiling water. Four albino rats (Wistar, 200–260 g; Oxoid diet) were placed in metabolic cages and 24 h urine was collected before and after oral administration of 5 ml. of tea-extract. Samples of urine, containing 1 mg creatinine, were taken and

dinitrophenyl derivatives of amines (DNP-amines) were isolated as described before, except that the preliminary step for the removal of ammonia was omitted[5]. DNP-amines were extracted with *cyclo*hexane and, after evaporation of the *cyclo*hexane, the residue in each case was dissolved in a small volume of ethanol. Amounts, equivalent to 400 μg creatinine, were analysed by reversed-phase chromatography on paraffin-treated paper[1]. Fig. 1 shows the result of the experiment on one of the rats. Identical results were found with the remaining three rats. It is seen that ethylamine appears in rat urine after oral administration of tea-extract. (Tea-extract was processed in the same way as the urine specimens and it was confirmed that ethylamine was not produced during the analytical procedure.)

Experiments, carried out in this laboratory, showed that ingestion of neomycin by human subjects did not result in marked variation in the level of ethylamine in urine. This finding suggested that the formation of ethylamine was not dependent on bacterial action in the intestine. However, the breakdown of theanine in the digestive tract by other processes, not dependent on bacteria, could not be excluded.

In order to ascertain whether hydrolysis of theanine took place in tissues, four albino rats were placed in metabolic cages and 24 h urine was collected before and after subcutaneous injections of 3 ml. of tea-extract, prepared in physiological saline. DNP-amines were isolated and analysed as mentioned before. Results were similar to those obtained when tea-extract was given orally (Fig. 1). Thus, ethylamine resulted from hydrolysis of theanine, presumably as a result of the amino-acid–amidase activity of tissues[6].

In another experiment, 24 h urine was collected from a normal human subject. After abstaining from tea for 72 h, urine was collected during the next 24 h. Finally, after the usual intake of tea in the course of the next 72 h, 24 h urine was again collected. DNP-amines were isolated from samples of urine containing 4·5 mg creatinine.

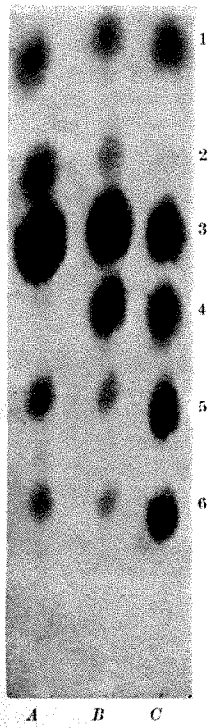

Fig. 1. Reversed-phase chromatography of DNP-amines isolated from rat urine: *A*, from basal urine; *B*, from urine after tea-extract, given orally; *C*, mixture of authentic DNP-amines. Numbers represent DNP-derivatives of: 1, ammonia; 2, methylamine; 3, dimethylamine; 4, ethylamine; 5, pyrrolidine; 6, piperidine. DNP-ethylamine is absent from *A* but is present in *B*. DNP-ethylamine and the corresponding spot in *B* show similar reddish-brown fluorescence in ultra-violet light

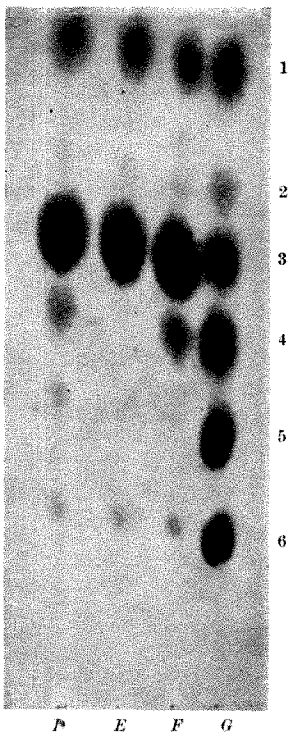

Fig. 2. Reversed-phase chromatography of DNP-amines isolated from human urine: *D*, from basal urine (tea taken); *E*, from urine, after 72 h without tea; *F*, from urine, 72 h after usual intake of tea; *G*, mixture of DNP-amines. Numbers represent DNP-derivatives of: 1, ammonia; 2, methylamine; 3, dimethylamine; 4, ethylamine; 5, pyrrolidine; 6, piperidine. Ethylamine disappears from urine (*E*) when tea is excluded

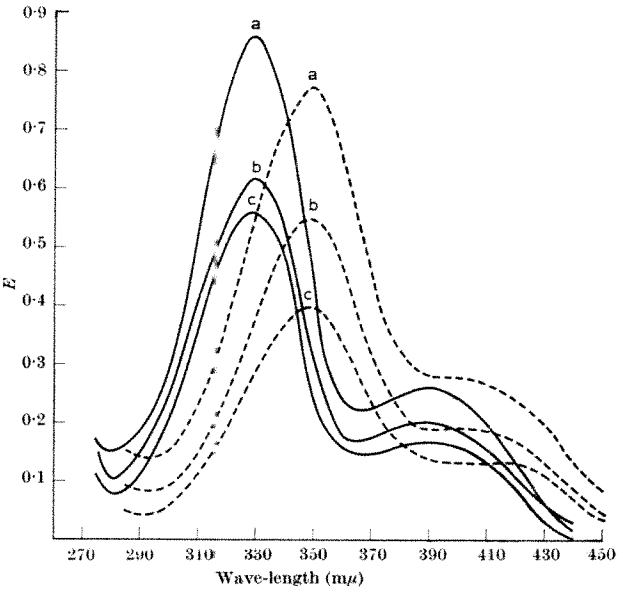

Fig. 3. Absorption spectra of: *a*, DNP-amine isolated from hydrolysate of tea-extract; *b*, authentic DNP-ethylamine; *c*, DNP-amine from rat urine, after giving tea-extract. ——, In *cyclo*hexane; - - - -, in monochlorobenzene

Portions of the final extract of DNP-amines in ethanol, equivalent to 1·6 mg creatinine, were chromatographed on paraffin-treated paper. Results shown in Fig. 2 demonstrate that ethylamine is found in urine only if tea is taken.

A small volume of tea-extract was refluxed with 5 N hydrochloric acid for 2 h and the hydrolysate was then brought to *p*H 7. The DNP-amine isolated from the mixture was chromatographically identical with authentic DNP-ethylamine and showed the same characteristic fluorescence. The DNP-amine from the hydrolysate,

authentic DNP-ethylamine and the spot that appeared in rat urine, after giving tea-extract (Fig. 1), were cut out from the chromatograms and were eluted with acetone. After evaporation of the acetone, the residue in each case was dissolved in *cyclo*hexane and the absorption spectra were determined. Finally, the *cyclo*hexane was evaporated and, using monochlorobenzene as the solvent, absorption spectra were noted again. As shown in Fig. 3, the three derivatives have similar absorption spectra in the two solvents, with a shift in the wave-length of maximum absorption from 330 mμ to 350 mμ.

It is concluded from these experiments that ethylamine found in human urine originates from tea.

A Sensitive Bioassay for Gibberellins based on Retardation of Leaf Senescence in *Rumex obtusifolius* (L.)

THE senescence and yellowing of detached leaves and leaf disks of many plants are retarded by low concentrations of kinetin. Gibberellic acid (GA) and indolyl-3-acetic acid (IAA) may also induce a similar response, depending on the age of the leaf and the species. Thus, mature leaves of dandelion (*Taraxacum officinale*) respond to low concentrations of kinetin and GA, but scarcely at all to IAA; whereas in banana (*Musa cavendishii* Lamb.) all three types of hormone are effective in retarding leaf senescence. Leaves of the broad-leaved dock (*Rumex obtusifolius*) are unusual in responding only to gibberellin, and this has been made the basis of the bioassay technique described in this report.

Leaves are taken from clonally propagated dock plants grown in pots in a glasshouse. The oldest leaves still retaining a uniform colour are used. After detachment from the plant the leaves are left with their petioles in water for 24 h in the dark at room temperature before use. 7 mm diameter disks are cut from the leaves, avoiding the main veins, and these are placed, abaxial surface downwards, on 2·5 cm diameter disks of filter paper moistened with 0·3 ml. of test solution in small glass dishes. Four leaf disks, each from a separate leaf, are placed on each filter paper disk, and each treatment is normally replicated four times. The small glass dishes containing the disks are placed in Petri dishes lined with moist filter paper and incubated at 25° C in darkness. When the chlorophyll has almost disappeared from the control disks—normally after 4 or 5 days—the four leaf disks from each replicate are placed overnight in 6 ml. of methanol or acetone, to extract the chlorophyll, and the optical density of the solution at 665 mμ (chlorophyll *a*) is measured on a spectrophotometer. The chlorophyll content is expressed as a percentage of that of the control.

Table 1

$A_3 = 100$	$A_2 = 0{\cdot}63$
$A_1 = 12$	$A_6 = 0{\cdot}32$
$A_7 = 4$	$A_9 = 0{\cdot}10$
$A_4 = 1{\cdot}5$	$A_8 = 0{\cdot}04$
$A_5 = 1{\cdot}5$	$A_{10} = 0{\cdot}04$
	$A_{12} = 0{\cdot}02$

The great sensitivity of the *Rumex* leaf senescence test to gibberellic acid is shown in Fig. 1, in which the dosage/response curve is compared with those of two other standard bioassay methods, the oat mesocotyl test and the lettuce hypocotyl test. The lower limit of the *Rumex* test is of the order of 0·00001 μg GA per ml., which is about the same as that of the barley endosperm test[1], and the useful upper limit about 0·1 μg per ml. The test has been successfully used for the detection and measurement of naturally occurring gibberellins in extracts of apple seeds after chromatography. Kinetin and IAA at concentrations of up to 6 μg per ml. produce no response in this test. Glucose and fructose up to 5 per cent, potassium nitrate and potassium chloride up to M/8, and adenine at 100 μg per ml. are also inactive.

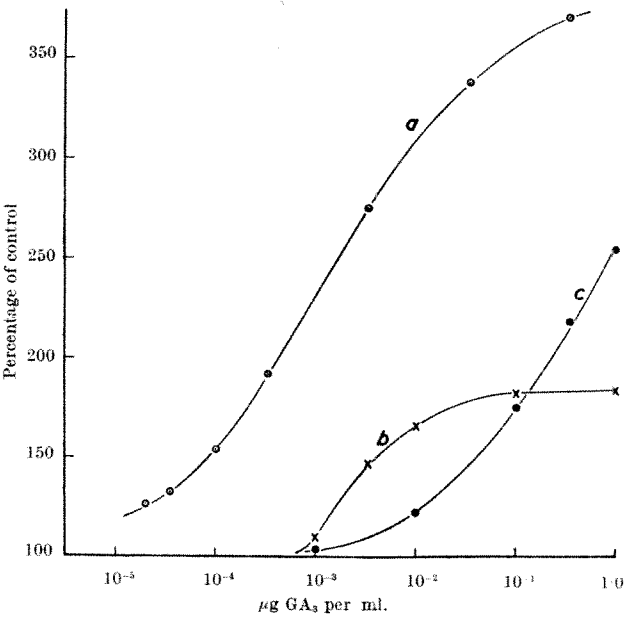

Fig. 1. Relationship between concentration of gibberellic acid and response, measured as per cent of control, in (*a*) *Rumex* leaf senescence test, (*b*) oat mesocotyl test (var. 'Brighton'), and (*c*) lettuce hypocotyl test (var. 'Grand Rapids')

The activities of other gibberellins in this test are considerably lower than that of gibberellic acid, but most are sufficiently active to make the test of value for routine detection and bioassay work. Table 1 shows the relative activities of different gibberellins (kindly supplied by Dr. J. MacMillan, Dr. D. Broadbent, Mr. J. B. Blundell and Dr. G. A. D. Jackson), based on the concentrations required to produce a 200 per cent response.

Flavoprotein in the Egg of the Silkworm *Bombyx mori*

THE eggs of a developing silkworm of Nippon 124 × China 124 strain were crushed at regular intervals directly on to Whatman No. 1 paper and chromatographed in one or two dimensions. The solvents used were 2,4-lutidine–*n*-butanol–water (4 : 1 : 5), *n*-butanol–acetic acid–water (4 : 1 : 5), 5 per cent sodium citrate and *n*-propanol–1 per cent ammonia (2 : 1). From the results it was demonstrated that riboflavin and a large quantity of flavin mononucleotide (FMN) were contained in the eggs throughout their development, but flavin adenine dinucleotide (FAD) was detected only in the egg on the day before hatching and in the newly hatched larva.

To investigate more closely the changes in flavin during development, further investigations of the quantitative differences of the flavoprotein have been carried out to

determine the protein and flavin content of each fraction by centrifugation. The eggs of silkworms of three strains, Daizo, China 108 and Nippon 124 × China 124, were used, either in the diapause stage or in the late postdiapause stage (1 day before hatching). All fractions of eggs were prepared at 4° C. The eggs were weighed and crushed with a mortar in 0·3 M sucrose solution, containing 10^{-3} M EDTA and 10^{-3} M phosphate buffer at *p*H 7·3. After removal of the chorion membrane by filtration through a layer of gauze, the brei was homogenized with a 'Teflon' homogenizer in 10 volumes of 0·3 M sucrose solution and centrifuged at 800*g* for 10 min to remove nuclei and cell debris. The precipitant was again homogenized and centrifuged. The supernatant obtained was added to the original and the combined supernatant was then centrifuged at 10,000*g* for 15 min. A fluff-layer containing Chino's 'lipid-rich granules'[1] was carefully gathered from the surface of the supernatant solution and washed with 0·3 M sucrose solution. This constituted the fluff fraction. The supernatant was again centrifuged at 10,000*g* for 20 min and the pellet was added to the previously centrifuged pellet. The combined pellet was washed with 0·3 M sucrose solution. These pellets contained mitochondria and pigment granules and constituted the mitochondrial fraction. Microsomes were sedimented from the mitochondrial supernatant by centrifugation at 105,000*g* for 30 min. Both pellets were combined and washed with 0·3 M sucrose solution. These pellets comprised the microsomal fraction. The microsomal supernatant fluid was brought to 80 per cent saturation with solid ammonium sulphate. After being stirred and allowed to stand for 15 min, proteins were sedimented by a 20-min centrifugation at 0° C and 10,000*g*. The supernatant was used as supernatant for the non-protein fraction. The sedimented proteins were dissolved in a small amount of water and re-precipitated with ammonium sulphate. This made up the supernatant of the protein-fraction. The pellet of each fraction was dissolved in water or suspended in it by homogenization.

The protein content in each fraction was determined by Lowley's method[2]. The intensity of the blue pigment resulting from addition of phenol reagent was determined by colorimetry using a 500-mμ filter. Bovine serum albumin was used as a standard protein.

The quantitative estimation of flavin was carried out as follows: 2 ml. of water suspension or solution of each fraction was boiled at 80° C for 15 min, cooled to room temperature, and filtered. The precipitant on the filter-paper was washed with 1 ml. of water at 80° C. 1 ml. of 2 per cent acetic acid was added to the filtrate and it was extracted three times with 3 ml. of water-saturated chloroform. To 2 ml. of the aqueous solution, 1 ml. of 1 N sodium hydroxide was added, and the mixture was exposed under ultra-violet light at 20° C for 30 min. The solution was acidified with 0·25 ml. of glacial acetic acid, treated with potassium permanganate and later with hydrogen peroxide. Thereafter it was extracted with 5 ml. of water-saturated chloroform by shaking vigorously for 3 min. The chloroform extract was determined by fluorometry and estimated in terms of riboflavin values.

The results are summarized in Table 1. No significant differences were found between the three strains. 'Content recovered' was calculated by adding the values of protein or flavin content of the fraction containing nuclei and cell debris to the sum of the values of the other fractions. The total flavin content of a silkworm egg was 7·5 μg/g egg in diapause and 6·0 μg/g egg in late postdiapause. This shows that total flavin content tends to become slightly reduced when hatched and would seem to correspond to the results of Bodine *et al.*[3] that flavin content tends to decrease during the embryonic development of grasshopper eggs. As shown in the non-protein fraction supernatant, the silkworm egg had a rather low free flavin content, which was probably to be regarded as a riboflavin content. The values of 'protein content' of this fraction seemed to represent the values of free aromatic substances in egg such as tyrosine and dihydroxyphenylalanine. The flavin content of the other fractions, except for the non-protein supernatant fraction, probably indicated the content of protein-bound flavin. The flavin content and the protein content of the protein fraction supernatant showed the highest values of the five fractions, but before hatching it was found that its flavin content decreased markedly. This flavin was analysed by paper chromatography and identified as FMN. The FMN detected qualitatively in silkworm eggs seems to be derived, in large part, from the flavoprotein of this fraction. Before hatching, on the other hand, the flavin contents of both the mitochondrial and the microsomal fractions approximately doubled. A marked quantitative increase of protein was also observed, especially in the late postdiapause mitochondrial fraction. In view of the evidence it may be suggested that proteins are plentifully synthesized in this stage in order to form the normal respiratory system in the larval stage. In fluff fraction there were almost no quantitative changes in protein and flavin from the diapause to the late postdiapause stage.

Table 1. DISTRIBUTION OF PROTEIN AND FLAVIN CONTENT IN SUBCELLULAR FRACTIONS OF SILKWORM EGGS IN DIAPAUSE AND IN LATE POSTDIAPAUSE (1 DAY BEFORE HATCHING)

Strain	Subcellular fraction	Protein				Flavin			
		Diapause egg		Late postdiapause egg		Diapause egg		Late postdiapause egg	
		Total protein (μg/g)	Fraction of total protein (%)	Total protein (μg/g)	Fraction of total protein (%)	Total flavin (μg/g)	Fraction of total flavin (%)	Total flavin (μg/g)	Fraction of total flavin (%)

The fact that the soluble fraction in the diapause silkworm egg contained large amounts of FMN-containing flavoprotein is of interest in view of Chino's report[1] that, during embryonal diapause in the silkworm, cytochrome *c* becomes undetectable, while the soluble fraction shows high NADH- and NADPH-cytochrome *c* reductase activity. It has recently been demonstrated that NADH-cytochrome *c* reductase in mammalian mitochondria is a degradation product of the NADH dehydrogenase of the respiratory chain, the prosthetic group of which is also FMN[4]. In silkworm eggs it is known that the catalase activity, which is indispensable to flavin-respiration, increases during diapause[5].

It may therefore be assumed that the flavoprotein which we have detected in the supernatant fraction plays an important part in respiration during diapause. The occurrence of FAD when the eggs hatch suggests the possibility of the formation and arrangement of a normal respiratory system containing cytochrome *c*, which takes the place of this flavin-respiration during diapause.

I thank Prof. S. Fukuda of Nagoya University, and Prof. H. Aruga of the University of Tokyo, for their kindness in supplying the silkworm eggs.

Inhibition of Pollen Respiration by Oligomycin

EARLIER experiments showed that respiration of germinating pollen was characterized by an initial high rate prior to pollen tube initiation, a subsequent lower rate during which tube growth began, and a second high rate associated with extensive tube growth[1]. DNP (2,4-dinitrophenol) stimulated oxygen uptake during each of these three phases of respiration. It was postulated that respiration was dependent on oxidative phosphorylation and that the observed respiratory pattern reflected various rates of utilization and resynthesis of energy-rich phosphate compounds[1].

This report presents additional evidence that respiration of germinating pollen is regulated by phosphorylative processes. Oligomycin inhibited pollen respiration, and the inhibition was reversed with DNP.

Oligomycin inhibits oxidative phosphorylation in isolated mitochondria with an accompanying inhibition of respiration[2-6]. Electron transport is not blocked directly because the respiratory inhibition is abolished by uncoupling agents such as DNP[5,6]. Hence, oligomycin acts between the DNP-sensitive step and the terminal reaction in which ATP is formed. In animal mitochondria it seems to prevent the formation of an energy-rich phosphorylated intermediate[2]. However, in plant mitochondria, oligomycin may allow formation of a phosphorylated intermediate but prevent transfer of phosphate to a phosphate-collecting enzyme which forms ATP[4]. In either instance oligomycin can be used to determine whether electron transport is tightly coupled to ATP synthesis.

Several workers have studied the effect of oligomycin on respiration of intact cells. Oligomycin inhibited endogenous respiration 80 per cent in Yoshida ascites cells, preventing the respiratory stimulation observed on adding glucose to uninhibited cells[7]. Oligomycin blocked ATP synthesis since glucose is rapidly phosphorylated by ascites cells, and respiration is stimulated by the ADP produced[8]. Oligomycin also inhibited respiration 22 to 25 per cent in slices of rat liver[9], brain[10] and kidney[11]. Aerobic glycolysis of kidney slices was stimulated to a rate similar to that of anaerobic glycolysis[11]. Oligomycin is reported to inhibit ion uptake by plant roots without affecting respiration[12].

The present investigation was undertaken using procedures similar to those described previously[1]. Oxygen uptake was measured manometrically, and pollen was incubated in a culture medium containing 0·29 M sucrose, 1·27 mM calcium nitrate, 0·16 mM H_3BO_3, 0·99 mM potassium nitrate, 3·0 mM KH_2PO_4 and 10 μg/ml. tetracycline, *p*H 5·2. Pollen tube initiation began after about 30 min of incubation, and 90 per cent germination was reached after about 2 h. The control flasks exhibited the same respiratory pattern reported earlier[1], and DNP stimulated oxygen uptake (Fig. 1). Oligomycin caused 54 per cent inhibition of the initial high rate of respiration, and the inhibition was maintained until DNP was added after 41 min of incubation. Several concentrations of oligomycin (0·5, 1·0 and 2·0 μg/flask) caused the same degree of inhibition. DNP reversed the inhibition; respiration increased 3·2-fold to a rate similar to that obtained by adding DNP to pollen in the absence of oligomycin (Fig. 1). It is of interest that this stimulation is greater than those reported (1·8–2·4-fold) when DNP was added to isolated plant mitochondria inhibited by oligomycin[5,6]. Oligomycin also inhibited respiration of growing pollen tubes, but the DNP stimulation was not as great (Fig. 2). Respiration was inhibited immediately after tipping in oligomycin.

These results could indicate (1) inhibition of reactions utilizing ATP or (2) inhibition of ATP synthesis within the mitochondria. In the former possibility oligomycin would not necessarily penetrate the cell since active transport might be inhibited at the cell membrane just as ion uptake by roots seems to be inhibited[12]. Respiration would be inhibited by accumulation of ATP and depletion of ADP. In the second case ATP would probably decrease, the effect actually observed in rat kidney slices[11].

DNP is thought to stimulate glycolysis in plant tissue by lowering the ATP/ADP ratio[13,14]. This causes an increased respiratory quotient (R.Q.) because pyruvate accumulates and is partly decarboxylated to acetaldehyde and ethanol[13,14]. An increased R.Q. would also be expected if oligomycin inhibited ATP synthesis in germinating pollen. Accordingly, pollen was incubated with oligomycin

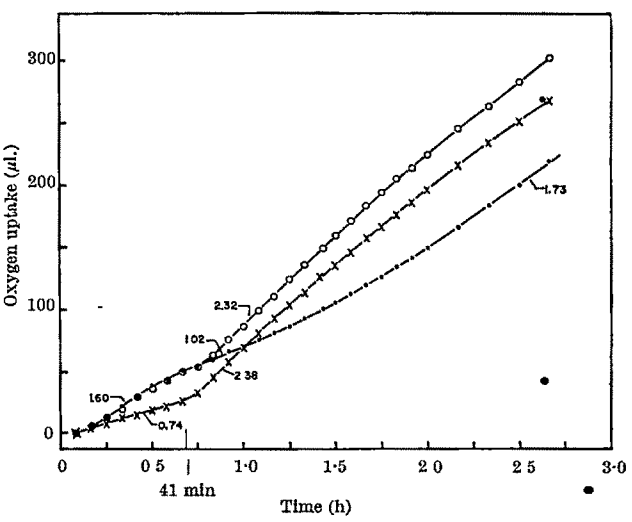

Fig. 1. Inhibition of pollen respiration by oligomycin and reversal of inhibition with DNP. Each point is the average oxygen uptake at 30° C of duplicate Warburg flasks. The numbers on the graph represent rates of oxygen uptake in μl./min. The main compartment of each control flask contained 1·4 ml. culture medium plus 7·0 mg pollen, and 0·3 ml. culture medium was placed in the side arm. Other flasks had the same contents plus the following additives. DNP treatment: sufficient DNP in the side arms to give 10 μM after tipping. Oligomycin treatment: 0·5 μg oligomycin in the main compartment, and sufficient DNP in the side arm to give 10 μM. Contents of all side arms were tipped after 41 min of incubation. ●, Control; ○, 10 μM DNP added at 41 min; ×, 0·5 μg oligomycin added at 0 min +10 μM DNP added at 41 min

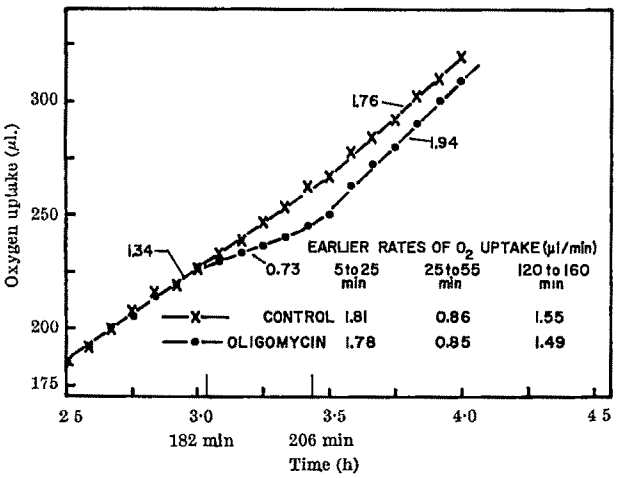

Fig. 2. Effect of oligomycin on respiration of growing pollen tubes. Conditions were as given in Fig. 1 with the following differences Double side arm flasks were used. The main compartments of all flasks contained 1·1 ml. culture medium plus 7·0 mg pollen, and all side arms contained 0·3 ml. culture medium. In the oligomycin treatment the first side arms contained 0·5 μg oligomycin. The second side arms of all flasks contained sufficient DNP to give 10 μM after tipping. First side arms were tipped at 182 min; second side arms were tipped at 206 min

or DNP, and the R.Q. was determined according to Gregory and Winter[15]. Oligomycin inhibited oxygen uptake but stimulated carbon dioxide output to give a 3·3-fold increase in R.Q. (Table 1). These results support the hypothesis that oxidative phosphorylation was blocked and that ATP utilization continued, causing decreased ATP and increased ADP.

Table 1. RESPIRATORY QUOTIENTS OF POLLEN TREATED WITH OLIGOMYCIN AND DNP

Treatment	O_2 (μl.)	CO_2 (μl.)	R.Q.
Control	35·4	38·3	1·08
Oligomycin, 0·36 μg/ml.	15·6	55·4	3·57
DNP, 10 μM	63·8	76·8	1·20

Conditions were as given in Fig. 1 except that the main compartment of each flask contained 10 mg pollen and 1·4 ml. culture medium which lacked KH_2PO_4. Oligomycin and DNP were present initially. CO_2 and O_2 refer to μl. absorbed or evolved during the period from 10 to 30 min after beginning the experiment.

Thus, oligomycin shows promise for use with intact plant cells to determine whether mitochondrial electron transport is tightly coupled to phosphorylative processes. This method may prove especially useful when the nature of the plant tissue causes difficulty in isolating tightly coupled mitochondria. An example is the acid tissue of fruits[16]. Oligomycin may be useful in studies of senescence to determine whether mitochondria remain tightly coupled in ageing cells.

I thank Dr. T. K. Hodges for advice and Miss M. Joan Misch for technical assistance. This work was supported by a grant from the U.S. National Science Foundation.

Conversion of Carbon-14-labelled Orotic Acid into Pyrimidine Nucleotides by Chloroplasts

SINCE it gives rise to 5′phospho oritidine which is rapidly transformed into pyrimidine nucleotides[1], orotic acid is useful in the investigation of nucleic acid biosynthesis. It seems to accumulate temporarily in plants before it is utilized as a precursor of the nucleotides[2].

In the present work, we have attempted to follow the transformations of ^{14}C-labelled orotic acid (specific activity, 5·2 mc./m.mole) in various chloroplast fractions obtained from young leaves of *Bryophyllum daigremontianum* Berger.

The chloroplasts were isolated either in aqueous or in organic media. The isolation technique in the aqueous medium consisted in a series of centrifugations alternately at 1,000*g* (5 min) and at 50*g* (20 sec) in 0·05 M triethanolamine, 0·3 M saccharose buffer. The *p*H of this buffer was 10·1 for the grinding of the leaves, which contain large quantities of organic acids, and for the first centrifugation. Later centrifugations were carried out at *p*H 7·6.

The separation technique in organic medium (mixtures of hexane and carbon tetrachloride) and the nucleic acid extraction and assay procedure were described earlier[3]. Labelled products (free nucleotides extracted in 5 per cent trichloroacetic acid at 0° C, and RNA nucleotides) were analysed by spectrophotometry, electrophoresis (*p*H 3·6 formate buffer, 1 h 30 min, 26 V/cm) or by paper chromatography (isopropanol–hydrochloric acid–water, 680:176:144).

Chloroplasts isolated in the aqueous medium slowly incorporate orotic acid into free nucleotides or into RNA. Taking as an index of RNA-synthetic activity the difference between the free-nucleotide content of chloroplasts heated to 100° C and those not so heated, it is seen (Fig. 1) that this activity is higher (by 40 per cent) in chloroplastic fractions isolated in organic media than in aqueous media. This difference cannot be explained by the activity of thermostable hydrolases. This is shown in Fig. 2, where the smaller differences are found in the fractions containing RNase-rich nuclear and cytoplasmic contaminants. In the course of the fractionation in the aqueous medium an important part of the intermediary or polymerization enzymes was lost in the supernatant through solubilization. The same is true for the free nucleotides as is shown in Fig. 1.

The ^{14}C-labelled orotic acid incorporation experiments in chloroplasts isolated in organic medium were carried

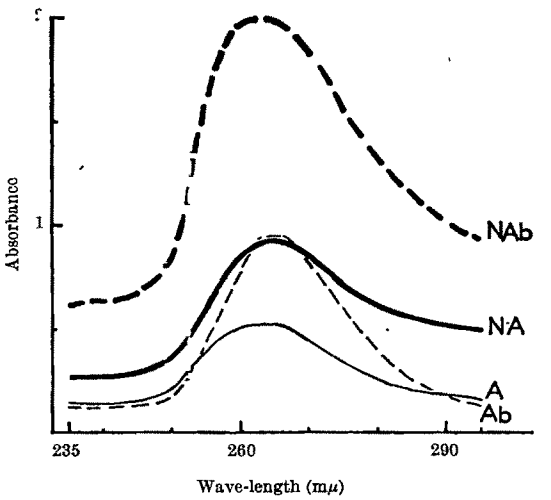

Fig. 1. Absorption spectrum of the free nucleotides of the chloroplast fraction. Each fraction containing the same amount of chlorophyll and incubated under identical conditions is extracted at 0° C by 5 per cent trichloroacetic acid. *NA*, Chloroplasts isolated in organic medium; *NAb*, chloroplasts isolated in organic medium and boiled for 5 min prior to incubation; *A*, chloroplasts isolated in aqueous medium; *Ab*, chloroplasts isolated in aqueous medium and boiled for 5 min prior to incubation

out on the fractions described in Table 1. From 100 to 200 mg of dry matter was used in each experiment. As shown in Table 2, incorporation into the soluble nucleotides is more marked in the various contaminated fractions than in our purest fraction (C_4).

Table 1. PROPERTIES OF THE VARIOUS CELLULAR FRACTIONS ISOLATED FROM LEAVES OF *Bryophyllum daigremontianum*

Fraction	Density (d)	Chlorophyll / Protein nitrogen	Appearance under light and electron microscopes
C_1	$d > 1{\cdot}46$	0 40	Chloroplasts contaminated by unbroken cells, starch grains and nuclei
C_2	$1{\cdot}46 > d > 1{\cdot}44$	0·45	Chloroplasts contaminated by cell walls, cytoplasmic material and a few nuclei
C_3	$1{\cdot}44 > d > 1{\cdot}42$	0 58	Chloroplasts contaminated by nuclei and nuclei fragments
C_4	$1{\cdot}42 > d > 1{\cdot}40$	0 65	Chloroplasts apparently without any impurity

Table 2 RADIOACTIVITY OF THE SOLUBLE NUCLEOTIDES AND OF RNA IN THE VARIOUS CELLULAR FRACTIONS

(C.p.m./g dry matter)

	C_1	C_2	C_3	C_4
Nucleotides	22,000	31,000	40,000	24,000
RNA	1,000	830	1,600	36,000

Each flask contained the following reaction mixture (4 ml) : 2 μM magnesium chloride, 0·2 mM (*p*H 7·5) triethanolamine buffer, 1·2 mM saccharose, 1 0 μM orotic acid (5 μc.), 0 6 μM phospho-ribosylpyrophosphate, 1 2 μM ATP; incubation at 25° C during 45 min at 22,000 lux; C_1, C_2, C_3 and C_4 are the cellular fractions as described in Table 1.

Table 3. RADIOACTIVITY OF PYRIMIDINE NUCLEOTIDES IN THE VARIOUS CELLULAR FRACTIONS

Fraction	Nucleotides C p m./mg dry matter Uridylic acid	Cytidylic acid
C_1	19,000	2,300
C_2	29,000	2,300
C_3	27,000	12,700
C_4	22,000	2,200

C_1, C_2, C_3 and C_4 are the cellular fractions described in Table 1.

Uridylic acid is about ten times more labelled than cytidylic acid in fractions C_1, C_2 and C_4 (Table 3). The relatively high labelling of cytidylic acid in fraction C_3, heavily contaminated by nuclear material, could be due to a higher activity of UTP-aminase catalysing the reaction: UTP→CTP.

In the C_4 fraction more than 50 per cent of the total radioactivity is found in RNA (Table 2) showing the presence in chloroplasts of a very active RNA-polymerase (Fig. 3). Uridylic acid isolated from the hydrolysate of this RNA is twice as labelled as cytidylic acid.

In the C_1, C_2 and C_3 fractions, the RNases may have hydrolysed the newly formed RNA[4], thus liberating the pyrimidine nucleotides found in large amounts in the trichloroacetic acid extract of the contaminated fractions. Although the reaction mixture contains only one tri-

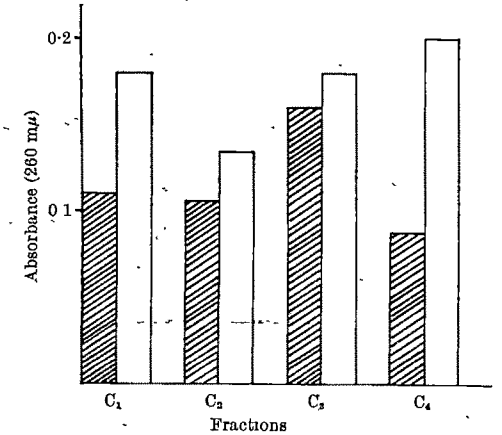

Fig 2 Absorption at $\lambda = 260$ mμ of the free nucleotides contained in mg of dry matter of each fraction isolated in organic medium after incubation under identical conditions (Table 2) Hatched areas, chloroplasts, non-hatched areas, chloroplasts boiled for 5 min prior to incubation. C_1, C_2, C_3 and C_4 are the cellular fractions described in Table 1

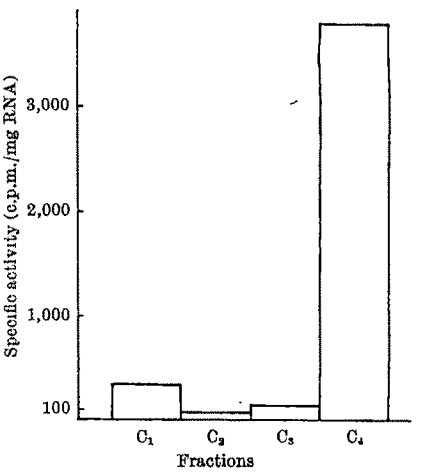

Fig. 3. Radiospecific activity of RNA in the various cellular fractions. C_1, C_2, C_3 and C_4 as described in Table 1

phosphonucleotide (ATP), the absence of one or several factors required for synthetic activity—that is, DNA and the four triphosphonucleotides—does not explain the low polymerization activity of the C_1, C_2 and C_3 fractions.

These fractions have been shown[3] indeed to have a high DNA content and the separation technique used to obtain them ensures the preservation of the nucleotides in the fractionation sediments.

These nucleotides are very largely lost when the chloroplasts are isolated in aqueous media, and it is for this reason that it is necessary to add them back to the reaction mixture[5–7].

The high RNA-synthesis activity in the chloroplast fraction may be another argument for the presence of DNA in plasts. It is probable that this DNA was used by the RNA-polymerase as a 'primer' in the chloroplastic fraction (C_4).

Effect of Quinidine and Related Compounds on Uptake and Release of Serotonin by Blood Platelets

BLOOD platelets have the ability both *in vivo*[1] and *in vitro*[2] to take up serotonin. It has been shown that *in vitro* this phenomenon may be depressed by certain drugs, such as imipramine[3], chlorpromazine[4], reserpine[5,6] and the cardiac glycosides[7].

In this communication we describe the results of experiments to test the effect of quinidine and related compounds on the *in vitro* uptake of serotonin by human platelets as contained in platelet-rich plasma.

Blood was taken from normal healthy donors, using 3·1 per cent sodium citrate as anticoagulant, and platelet-rich plasma was obtained by centrifugation, using an International refrigerated centrifuge (Model *PR*-2), at 225*g* for 15 min. The platelet count in this plasma varied between 400 and 450,000 per cm; ^{14}C-labelled serotonin

was used in these investigations and was made up in saline to a final concentration of 50 μg/ml. The quinidine solutions used were freshly prepared saline solutions of pure quinidine sulphate. The experimental system consisted of 1·6 ml. platelet-rich plasma and 0·2 m of quinidine or control solution (saline) and 0·2 ml. of radioactive serotonin (containing 10 μg serotonin). This mixture was incubated at 37° C for varying periods of time (15–150 min). At the end of the period of incubation, the tubes were immersed in iced water for 10 min and then the platelet button was obtained by centrifugation for 60 min at 2,000*g*. The platelet button was washed once with saline, then 2 ml. of distilled water was added. By rapidly freezing and thawing the mixture four times, the platelets were disrupted and the platelet debris deposited by centrifugation. Then 1·5 ml. of the supernatant was placed in an aluminium planchet, dried and counted in a gas flow counter (Model 821*B* flow counter, Baird Atomic, Inc., Cambridge, Mass.). The amount of radioactivity in the sample which was incubated for 120 min with saline was taken at 100 per cent and the other values expressed as a percentage of this.

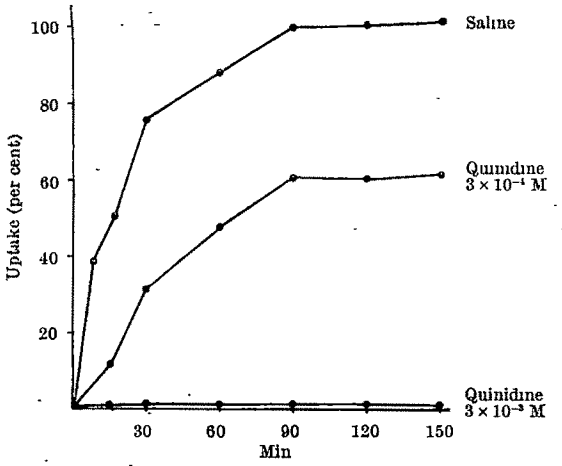

Fig. 1. The *in vitro* uptake of ^{14}C-labelled serotonin by normal human platelets was depressed by the presence of quinidine in the suspending medium

Fig. 1 shows the uptake of serotonin by platelet-rich plasma when incubated with saline and 2 concentrations of quinidine. The uptake of serotonin by platelets as measured by the present experimental model reached a maximum at 90–150 min, and incubation for periods up to 480 min did not result in an appreciable increment in uptake. The inhibiting effect of quinidine used at a concentration of 3×10^{-3} M was immediate and an effect could be seen after 5 min. With a concentration of less than 3×10^{-4} M the degree of inhibition was lessened and if used at concentrations of less than 3×10^{-5} M no significant inhibition occurred.

The addition of the solutions of quinidine did not alter the *p*H of the test mixture which lay in the range of 7·2 to 7·4. Using this experimental model the inhibiting effect of digitonin on the serotonin uptake by platelets was confirmed[7], and it was also shown that quinine, mepacrine and chloraquine, like quinidine, caused severe impairment of serotonin uptake by platelets. These results are set out in Table 1.

Table 1

	Saline	Digitonin 1×10^{-4} M	Quinine 3×10^{-3} M	Mepacrine 4×10^{-3} M	Chloraquine 3×10^{-3} M	Quinidine 3×10^{-3} M
Percentage of amount of serotonin taken up by control after 120 min incubation	100	39	4·5	1	6	3

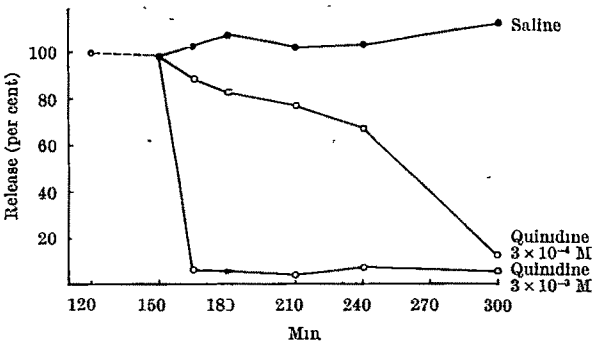

Fig. 2. The addition of quinidine to human blood platelets previously incubated with ^{14}C-labelled serotonin accelerated the release of serotonin from the platelets

Fig. 2 illustrates the result of an experiment in which quinidine and saline were added to platelets which had been previously incubated with radioactive serotonin for 150 min. It shows that following the addition of quinidine in concentrations capable of inhibiting the serotonin uptake, there was an immediate and marked release of serotonin from the platelets.

These experiments therefore, show that quinidine not only inhibits the ability of platelets to take up serotonin but that it also impairs their ability to retain it. The exact mechanism by which platelets take up serotonin and bind it is not clear. Born, Ingram and Stacey[8] showed that in normal platelets the amount of serotonin was related to their content of adenosine triphosphate. Weissbach *et al.*[7] studied the uptake of serotonin by platelets at ranging levels of *p*H. They showed that in systems in which the *p*H was 8·0 diffusion mechanism predominated, whereas at *p*H 5·7 an active transport mechanism was responsible for the uptake. This active transport mechanism functioned when platelets were suspended in saline but was enhanced by the addition of phosphate or potassium. The inhibiting effect of cardiac glycosides and reserpine was maximal in systems in which the active transport mechanism was predominant.

In the present work, in which platelets were suspended in plasma and the *p*H was between 7·2 and 7·4, the uptake of the serotonin by the platelets reached a maximum after 90–150 min, and the pattern of uptake suggested that, in the system used, the uptake was due mainly to an active transport process[7].

The mode of action of quinidine and related compounds, while likely to be similar to that of the cardiac glycosides, that is, depressing mostly the active transport of serotonin by the platelets, has not yet been completely elucidated.

Metabolism of Alpha-carotene

In the course of an earlier investigation into the utilization of carotene by the rat as a source of vitamin A, it was noted that there was a consistent difference between the absorption spectra of the liver non-saponifiable fractions from those rats fed vitamin A and those fed a mixture of 90 per cent beta- and 10 per cent alpha-carotene[1]. This difference was in the magnitude of the absorbance at 311 mμ as compared with that at 326 mμ. The alpha-ionone analogue of vitamin A was afterwards synthesized[2] and the absorption maxima were found to be at 311 mμ ($E^{1\%}_{1cm}$, 1,650) and 325 mμ ($E^{1\%}_{1cm}$, 1,500). This alpha-vitamin A was found to be biologically inactive but was found to be stored in the liver in the same way as vitamin A (ref. 3).

The purpose of the investigation reported here was to ascertain whether the abnormalities in the absorption spectra noted with rats fed a mixture of alpha- and beta-carotene could be the result of the deposition of alpha-vitamin A in the liver.

Female Sprague–Dawley rats with nursing litters were placed on a purified diet when the young were about 10 days old. Their dietary materials were so chosen that the basic ration was nutritionally complete except for the essential fatty acids and the fat-soluble vitamins. The fat-soluble vitamins were given dropwise by mouth, one drop twice each week. The weekly supplement contained 50 U.S.P. units of vitamin A, 100 U.S.P. units of vitamin D and 3·0 mg of alpha-tocopherol. This level of vitamin A intake allowed normal growth but did not result in any measurable liver storage of the vitamin. Half the animals were allowed to become depleted in the essential fatty acids, while cottonseed oil was added to the basal diet of the remainder of the animals in sufficient quantity to satisfy the requirement for the essential fatty acids. Each group was divided into three parts and the diets were supplemented with either vitamin A, beta-carotene or alpha-carotene when deficiency symptoms appeared in the animals depleted in essential fatty acids. After a 10-day supplementation period, during which the animals received 100 g of alpha- or beta-carotene, or 250 U.S.P. units of vitamin A per day, the animals were killed. The livers were removed, and the non-saponifiable extracts were dissolved in *cyclo*hexane. The absorption spectrum was determined for each solution, and a sample was then exposed to ultra-violet light for a period sufficiently long to effect the complete destruction of any photosensitive material. This was presumed to include both vitamin A and alpha-vitamin A. A second absorption spectrum was obtained over the same spectral range. The difference between the two curves obtained was thought to give a truer picture of the vitamin A content of the extracts, since the non-specific absorption is not uniform over the spectral range investigated.

The alpha- and beta-carotene were examined spectrophotometrically to make certain that they were not mixtures of the alpha and beta forms.

A comparison of typical absorption spectra of the photosensitive materials stored in the livers, and extracted with the non-saponifiable fraction, is shown in Fig. 1. These three animals were females fed on diet I. As can be seen in the figure, the absorption spectra show no significant difference when the animals are fed vitamin A or beta-carotene. There was no reason to expect that there would be any difference. However, when the same comparison is made with the extracts from animals fed vitamin A or alpha-carotene, the results are manifestly

Table 1

Diet I	Sucrose	75 parts
	Casein (vitamin-test)	20
	Salts (U.S.P. XIV)	1
	Vitamin mixture (water soluble)	1
	Hydrogenated cottonseed oil	3
Diet II	Diet I plus 1 part of Wesson oil	
Sample supplement		
	α-tocopherol	1 mg
	β-carotene	100 g
	Diet I	1 g

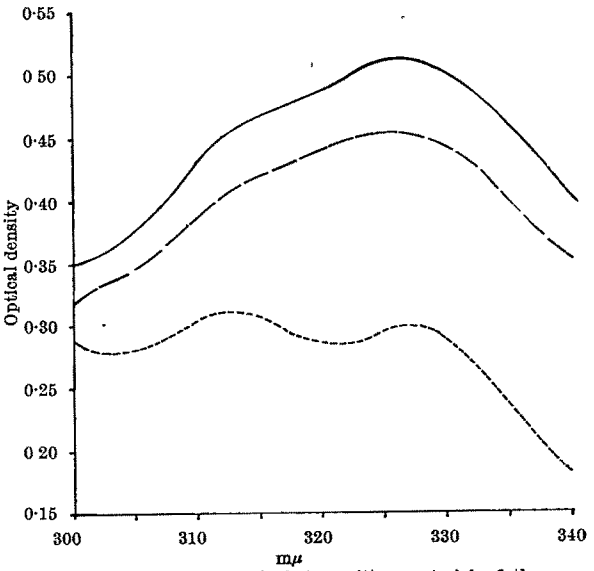

Fig. 1. Absorption spectra of photosensitive material of the non-saponifiable liver extract. (*a*) Vitamin A-fed; ———. (*b*) β-carotene fed; — — —. (*c*) α-carotene; - - -.

different. It is true that the material deposited in the liver with alpha-carotene feeding is not all alpha-vitamin A. The ratio E_{311}/E_{326} found for the pure compound was 1·10 (ref. 2), while for the curve shown in Fig. 1 the ratio is 1·02. It is obvious that the liver extract from the animal fed alpha-carotene contained more alpha-vitamin A than true vitamin A since the corresponding ratio for the vitamin A fed animal is 0·86, and this same value was found for the natural vitamin A concentrate used as a supplement.

When the quantities of vitamin A and alpha-vitamin A are calculated from the data shown in the figure using the $E^{1\%}_{1cm}$ values at 311 mμ and 326 mμ for the pure compounds, it is found that the liver contained 29 g of vitamin A and 67 g of alpha-vitamin A. Since the animal gained weight during the supplementation period, it seems safe to assume that some vitamin A was utilized for growth. If this allowance is made, the quantity of alpha-vitamin A is approximately equal to the quantity of vitamin A which must have been produced.

The feeding of alpha-carotene resulted, then, in the formation of a different end-product than did the feeding of either vitamin A or beta-carotene.

The results of this investigation do not unequivocally support either the theory of oxidation or hydrolysis at the central double bond of the carotene molecule[4,5] or the proposed mechanism of an oxidative process beginning at one end of the molecule[6]. What is demonstrated is that whatever the mechanism it very probably results in the formation of two products—vitamin A and alpha-vitamin A—and the storage of both in the liver of the test animal.

Urea Cycle Enzyme Activities of Liver of the African Lion

In the course of a continuous survey[1,2] on the occurrence and levels of activity of ornithine–urea cycle[3] enzymes, an unexpected opportunity was afforded for quantitative measurement of these activities in the instance of the African lion, *Felis leo*. At the Vilas Park Zoo in Madison (Wisconsin) the director, Mr. Dan Watson, decided that an infirm male lion about twelve years old had to be destroyed. The lion exhibited progressive difficulty in its ability to leap to a platform some 2 m high in the cage; this created a feeding problem and difficulty in moving the animal to an outside exercise yard.

The lion was killed and, after about 15 min, portions of liver and kidney cortex were removed from the animal, placed on ice, and taken to the laboratory for enzymatic assays. The preparation of the homogenate of liver with the aid of cetyltrimethylammonium bromide and the relevant assay procedures were essentially the same as reported elsewhere[4]. Arginase, however, was determined on a diluted (liver) as well as on an undiluted (kidney cortex) aliquot of 10 per cent (w/v) whole (that is, uncentrifuged) homogenates. Final reactant concentrations for the arginase assay were: 0·085 M L-arginine; 0·0005 M Mn^{++}; final *p*H 9·5. All assays were conducted at 38° C.

Table 1. Urea Cycle Enzymes of *Felis leo* ♂ Liver

Enzyme + (synonym)	I.U.B.* No.	μmoles/ min/g liver wet wt.†	μmoles/ min/mg protein†
Carbamate kinase (= carbamoylphosphate synthetase)	2.7.2.5	10·5 ± 0·6	0·130 ± 0·007
Ornithine carbamoyltransferase (= ornithine transcarbamylase)	2.1.3.3	248	3·07
Argininosuccinate synthetase (= condensing enzyme)	6.3.4.5	1·75‡	0·0240‡
Argininosuccinate lysase (= argininosuccinase; cleavage enzyme)	4.3.2.1		
Arginase	3.5.3.1	658 ± 31	5·13 ± 0·24

Assays performed at 38° C.
* International Union of Biochemistry Enzyme Commission Numbers (1964)
† Including mean deviation of individual assays where applicable.
‡ Reflects activity of the two enzymes in unison ('arginine synthetase'—see text).

The results of the assays are given in Table 1. The enzymes of the cycle were present in liver, and the levels found were of the same general magnitude as previously observed with liver of numerous other mammals[1,2]. The synthesis and cleavage of argininosuccinate are evidenced by the assay for 'arginine synthetase'[4,5] which exhibited an activity of 1·75 μmoles of product (arginine, measured as urea) per min per g liver wet weight. This activity probably reflects the rate by which argininosuccinic acid is synthesized by the enzyme, argininosuccinate synthetase (originally—condensing enzyme).

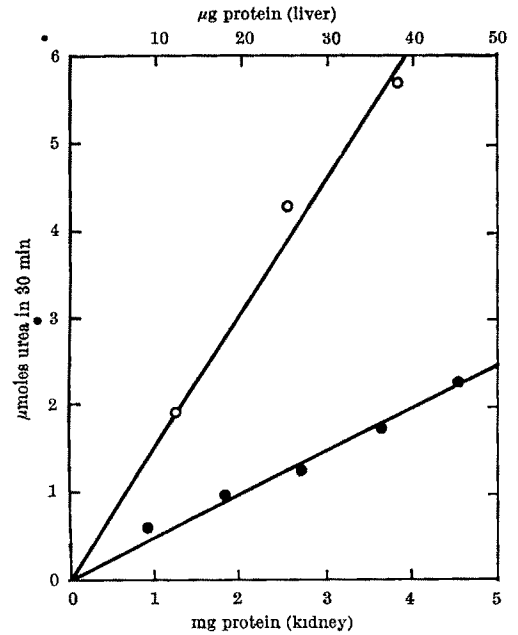

Fig. 1. Arginase of lion liver and kidney cortex. Urea production versus protein concentration. Conditions as in text. ○, Liver; ●, kidney

In addition to the liver assays, arginase was determined on the piece of kidney cortex tissue taken at the same time as the liver. A plot of activity versus protein concentration for arginase of the two tissues is shown in Fig. 1. A value (mean, and mean deviation) of 1·56 ± 0·15 μmoles per min per g wet weight was observed with kidney cortex in contrast to a much higher value of 658 ± 31 for liver. The lower value found for arginase of kidney is in keeping with previous observations[6–9] on the relative levels of this enzyme in these organs in other mammals.

The author is pleased to acknowledge support for this investigation through a grant from the National Science Foundation. Identification of the Stimulatory Factors in Citrus Molasses for Carotenogenesis in *Blakeslea trispora*

Citrus molasses and other citrus by-products stimulate carotenogenesis by mated cultures of *Blakeslea trispora*[1]. However, the substances in citrus by-products that stimulate carotene production in the fermentation process remain unknown. We attempted to determine the nature of the enhancing agent present in one of these by-products, citrus molasses.

Because organic acids are known to stimulate carotenogenesis by micro-organisms, we precipitated these compounds from citrus molasses by addition of an 8 per cent (w/v) aqueous solution of lead acetate[2]. The lead salts were treated with hydrogen sulphide to convert them into water-soluble free organic acids. Insoluble lead sulphide was removed by filtration and the aqueous acid solution evaporated to dryness at 55° C in a flash evaporator. The dry residue was redissolved in distilled water and used for fermentation experiments. Methods for conducting the fermentation have been described[1]. After separation of organic acids, the residual citrus molasses were treated with hydrogen sulphide to precipitate excess lead ions. Lead sulphide was removed by filtration, the residual solution evaporated to dryness *in vacuo*, and the residue redissolved in water to give the previous volume of citrus molasses.

Paper chromatography of the acid fraction (*n*-butanol–formic acid–water; 4 : 1·5 : 1) revealed the presence of citric acid as the major component plus a small amount of malic acid and a trace of a third unknown acid having a R_F similar to that of gluconic or 2-ketogluconic acid. Estimation of the total acidity of the organic acid fraction from citrus molasses (titration with 0·1 *N* sodium hydroxide) showed that 5 ml. of molasses contained 0·074 g of organic acids calculated as anhydrous citric acid.

Both citric and malic acid were added to fermentations to determine if these acids stimulated carotenogenesis. In addition, the residue of the molasses after precipitation of acids and also the carbohydrate components of the residue were tested. Approximately 43 per cent carbohydrate remained in the citrus molasses residue after organic acid separation. The carbohydrates were about 50 per cent sucrose and 50 per cent reducing sugars.

Table 1 shows that the combination of organic acid fraction or citric acid with the molasses residue or sucrose resulted in yields approximating that given by unfractionated citrus molasses. Either glucose or fructose at a concentration of 1·5 per cent could substitute for sucrose, but at higher concentrations this resulted in inhibition of carotenogenesis. Malic, gluconic, and 2-ketogluconic acid could not replace citric acid and gave only slight stimulation.

Table 1. STIMULATION OF CAROTENOGENESIS BY CITRUS MOLASSES AND VARIOUS FRACTIONS

Adjuvant* Type	Amount (per cent)	Dry mycelium g/100 ml.	Carotene yield In solids mg/g	Per volume mg/100 ml.

* In addition to the adjuvant, the fermentation medium contained cotton-seed embryo meal, 5 per cent; corn, 2·5 per cent; cotton-seed oil, 5 per cent, deodorized kerosene, 5 per cent; non-ionic detergent, 0·12 per cent, thiamine hydrochloride, 0 2 mg per cent; tap water; *p*H not adjusted

† One ml. of the organic acid fraction was equivalent to 2 5 ml of citrus molasses

‡ Residue is the aqueous fraction remaining after separation of organic acids from citrus molasses; 1 ml residue was equivalent to 1 ml citrus molasses.

Inhibition of metabolic processes by glucose is well documented[3,4] and has become known as the "glucose effect". Neidhart and Magasanik[5,6] formulated the concept that the glucose effect represented catabolite repression; that is, "Catabolites formed rapidly from glucose accumulate in the cell and repress the formation of enzymes whose activity would augment the already large intracellular pools of these compounds". However, glucose inhibition of carotenogenesis does not appear to be the result of catabolic inhibition as defined by Neidhart and Magasanik since carotene biosynthesis is an anabolic process.

Two hypotheses may be advanced to explain the present data. (*a*) Part of the biosynthetic pathway of carotene synthesis may be under repressor control[7]. If a potential internal inducer is used in biosynthetic processes that also involve catabolic products produced from a readily metabolized substrate such as glucose, then insufficient internal inducer is available to act on the repressed carotene pathway. When the carbon source is a less readily metabolized compound such as sucrose, the metabolite pool decreases and the internal inducer becomes available to de-repress carotenoid synthesis. (*b*) The second hypothesis assumes that the biosynthetic pathway of carotene synthesis is under continuous influence of an internal inducer but that in the presence of a readily metabolizable carbon source such as glucose, sufficient carbon is available to produce an "internal inducer-destroying enzyme" and the system becomes repressed. If sucrose were a less readily available carbon source because of slower uptake, or because of lower turnover number or concentration of invertase or sucrose phosphorylase, insufficient carbon would be available for synthesis of the enzyme. These hypotheses will be investigated.

The function of citric acid in enhancing yields is probably non-specific and would appear to be that of a precursor to early metabolites in the carotene biosynthetic sequence.

'Endogenous' Alcohol in Body Fluids

THE question as to whether or not ethanol is a normal constituent of body fluids has attracted the attention of many workers, and their findings have been ably reviewed by Harger and Forney[1] and Ward Smith[2].

Many methods used have been of doubtful accuracy and/or specificity at the levels of ethanol found, and the method of Curry, Walker and Simpson[3] has been modified to study the problem.

A Pye 104 gas–liquid chromatograph, fitted with a flame ionization detector and a *PEG* 400 on 'Celite' column, is used with an amplifier alternation setting of 20. 10 μl. of a 1 + 5 dilution of the sample (blood or urine) with a 0·25 mg per cent solution of *n*-propanol in water is injected.

Due to baseline instability, an integrator is not used as in the unmodified method, and quantitation is achieved by the ratios of the peak heights of the ethanol and *n*-propanol peaks: this means that each individual operator must establish his own factor.

The peak height ratios are linear against ethanol concentrations over the range 0·05–1·0 mg per cent, and it is possible to detect with certainty the presence of 0·03 mg per cent of ethanol. The accuracy found varies from ±5 per cent at the 1 mg per cent level to ±25 per cent at the 0·05 mg per cent level.

Preliminary results of a survey of the occurrence of ethanol in the blood and urine of normal persons who have not taken alcohol indicate that the amounts present are less than 0·1 mg per cent.

BIOLOGY

Genetical Homogeneity and the Stability of the Mating-type Factors of 'Fairy Rings' of *Marasmius oreades*

EXAMINATIONS have been made of the distribution of multiple-allelomorphic mating-type factors (m.t.f.) carried by basidiospores and produced by adjacent carpophores of higher fungi. The spatial distribution patterns found have been interpreted to provide evidence concerning the disposition of the mycelium giving rise to the sporophores and its genetical homogeneity or heterogeneity[1].

Many fungi give rise to a 'fairy ring' type of growth. It is generally assumed that such a mycelium has a central

Table 1. NUMBER OF CARPOPHORES INVESTIGATED AND THE DISTRIBUTION OF THE RINGS GIVING RISE TO THEM, THEIR SIZE, MATING-TYPE FACTORS AND ESTIMATES OF THEIR AGES

Group	Ring No.	No. of carpophores	M.t.f. No.	M.t.f. Designation	Radius of ring (m)	Estimated age (nearest whole year) min.	mean	max

	1	8	2	*A3A4*	3·5052	71	155	461
B	5	7	2	*A3A6*	2·2733	46	101	299
	9	12	2	*A3A6*	3·8700	77	169	501
C	7	7	2	*A1A2*	2·0955	42	93	276

origin and shows outward, radial marginal growth associated with the presumed death of the central older region[2].

We have used these techniques to study the genetical condition of the mycelium of rings of *Marasmius oreades*. Presumptive evidence concerning the stability of mating-type factors, in a natural environment, has also been obtained.

Many single-basidiospore isolations were made from carpophores disposed around eight rings at Embleton Golf Course (*NU* 245225) just north of Dunstanburgh Castle, Northumberland. Their mating types were determined; data are recorded in Table 1. Group *A* is in the centre of the area, group *B* at the southern end, and group *C* at the northern end (about 1 km from group *B*). No measurements could be made of the rates of growth of the rings because of inevitable interference with the golf course, but estimates have been based on previous studies with this species in England[3]. The mean rate was 22·6 cm/year; the highest and lowest annual rates ever recorded were 49·5 (ref. 4) and 7·6 cm respectively. These values have been used to estimate the minimum, mean and maximum ages of each ring.

The results show that *M. oreades* has a bipolar mating system and that no ring has more than 2 mating-type factors. This is good presumptive evidence that the mycelium of each ring is genetically homogeneous and, therefore, that each originated from a single dicaryotic mycelium. Had their origins been genetically heterogeneous, sectors giving rise to carpophores of different mating-type factor constitution might have been expected in the rings.

Such a situation might also be expected to arise (*a*) if a mating-type factor had undergone mutation either to a new effective allelomorph or to one lacking mating-type specificity; (*b*) if a suppressor or modifier mutation affecting the action of a mating-type factor had arisen; (*c*) if a new mating-type factor had arisen as a result of somatic recombination in hyphae of the perennial mycelium. Mutations of types (*a*) and (*b*) have been recorded from *Coprinus lagopus* and *Schizophyllum commune*[5] and recombinational events of type (*c*) have been recorded for the latter fungus[6]; both are diaphoromictic but tetrapolar, not bipolar, in their mating systems.

The absence of sectors of different mating-type factor constitution provides presumptive evidence for genetical stability of the mating-type factors of *M. oreades* for at least 30 years (the youngest estimated age) or even for about 500 years although the most likely estimates are of the order of 100–150 years (Table 1).

The inability of new effective mating-type factors, or more recently the sub-units of which some are composed[5], to arise spontaneously or to be induced, in the laboratory, has been known to be a characteristic feature of diaphoromictic forms since such mating systems were discovered nearly 50 years ago. However, evidence for mutation or stability in natural conditions has been lacking and this is true also for somatic recombination which, so far, is a laboratory phenomenon. It might have been supposed that a bulky perennial mycelium, such as that of *M. oreades*, would have provided an ideal situation in which mutation and/or recombination would have occurred and been detectable. The apparent absence of their effects suggests either that fungal mating-type factors are remarkably stable over long periods and somatic recombination involving them exceedingly rare, or else that, in nature at least, selection against the consequences of such events is very high. This seems improbable in view of the large numbers of mating-type factors found and estimated to occur in many higher basidiomycetes[7]. Experimental evidence also suggests that the occurrence of genetically heterogeneous, single mycelia is perfectly possible[1] so that the possibility of selection against such mycelia formed naturally seems to have no obvious basis. The mode of origin of new mating-type factors in higher fungi continues to be a most perplexing problem.

Wheat Root Exudate and Early Stages of Infection by *Helminthosporium sativum* Pamm., King and Bakke

THE observations of Flentje *et al.*[1,2] on *Corticium solani* led them to the hypothesis that the morphology of hyphal infection structures at the host surface may depend on a chemical stimulus contained specifically in host root exudate and not only on the physical stimulus of contact[3]. Evidence produced recently by de Silva and Wood[4] refutes this hypothesis. Working again with *C. solani* and the closely allied *C. praticola* they report that infection structures can be induced both with and without root exudate in a non-specific manner. Clearly this topic needs further examination, especially with other fungal genera. One recent report of another source of chemical stimulus supports Flentje's hypothesis. Guttation fluid, according to Endo *et al.*[5,6], stimulates the formation of infection structures of *Helminthosporium sorkinianum* on plastic slides, these structures being rare or absent in tap water and distilled water controls.

During work in progress at Leeds on the effect of various factors of the root environment on the germination of fungi causing diseases of cereals, an opportunity was taken to make detailed microscopical investigations of the effect of sterile root exudate obtained from wheat plants, on the early stages of infection by spores of *Helminthosporium sativum* Pamm., King and Bakke. Using wheat, variety Nord Desprez, root exudate was obtained by means of the Buxton[7] technique, concentrated to one-tenth of its original volume in vacuum and stored at −10° C. The characteristic feature of the germinating spores of this fungus on the intact wheat coleoptile is the profuse branching seen before penetration (Fig. 1*a*). Spores germinate readily in distilled water but afterwards show only one or two branches after 12 h compared with twenty or more usually seen after a similar time on the host surface. To examine the relationship of root exudate to this characteristic profuse branching, spores were germinated by placing them, dry, on the surface of small pieces of boiled and washed 'Cellophane' placed on top of exudate in small glass cylinders (5 mm in diameter) and enclosing the cylinder in a Petri dish with a piece of moist filter paper. Control cylinders contained distilled water. The microscopical examination of the 'Cellophane' over root exudate after 12 h and later showed profusely branched structures virtually indistinguishable from those obtained on the intact host (Fig. 1*b*). Branching of hyphae was infrequent on the 'Cellophane' over distilled water (Fig. 1*c*).

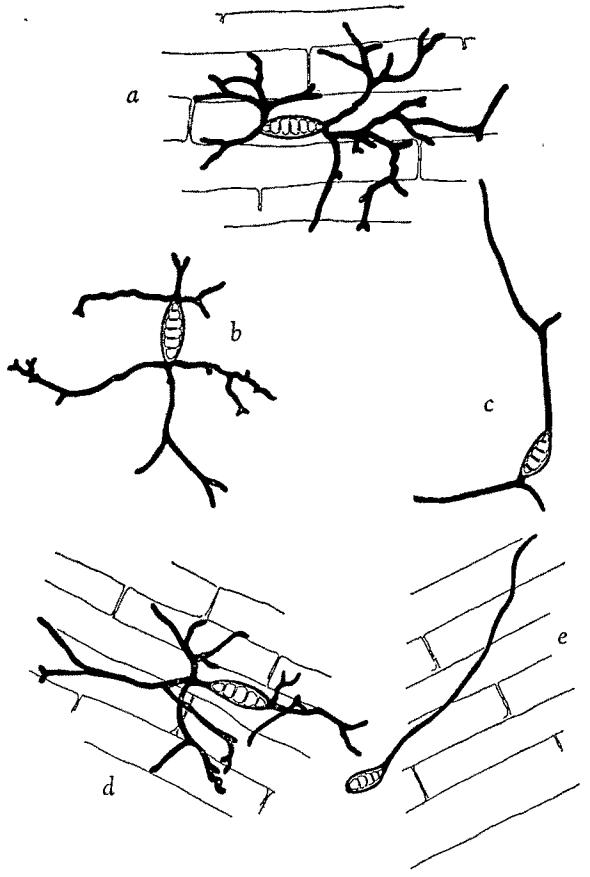

Fig. 1 Growth from a conidium of *H. sativum* after 12 h at 22° C. (*a*) On living wheat coleoptile; (*b*) on 'Cellophane', over exudate, (*c*) same over water; (*d*) on killed epidermis over exudate; (*e*) same over water. (× 172)

These experiments were then repeated using epidermal strips[8] killed by fixation in ethyl alcohol. These pieces of epidermal strips again gave branched hyphal structures (Fig. 1*d*) on the root exudate cylinders similar to those seen on the living host and on 'Cellophane' in contact with exudate. Branching was a rare occurrence on the epidermal strips over distilled water (Fig. 1*e*).

These results are reported here because this is a record of the formation of an essential pre-penetration structure induced by root exudate, and also the technique used here may not only be of value in examining the pathogenicity of similar fungi but could also be used to illuminate our picture of the mechanism of hyphal branching[9] in fungi.

Primordial Germ Cells and Fecundity

THE origin of the definitive germ cells of vertebrates from the primordial germ cells of the embryonic period is now widely accepted and has been supported in the case of a few species[1–4] by quantitative observations, which make it unnecessary to postulate the neo-formation of germ cells from the somatic elements of the so-called 'germinal epithelium'. In the lamprey, the history of the germ line has been followed from the first appearance of the primordial germ cells in the yolky endoderm[5], through their migration to the genital ridge and subsequent proliferation in the indifferent gonad, to the period of sex differentiation. At this time, in the female ammocoete larva, the stock of definitive oocytes is established[4,6]. These oocytes, or such of them as survive, are finally matured and deposited as eggs several years later, in the single short spawning season that immediately precedes the end of adult life.

Among the various species of lampreys there are wide differences in fecundity, ranging from the non-parasitic brook lampreys which produce 1,000–3,000 eggs to the large anadromous, parasitic sea lampreys which may contain up to 260,000 eggs[7–9]. These wide differences in fecundity offer an opportunity to test the possibility that species differences in primordial germ cell numbers might show some correlation with the differences in the numbers of definitive germ cells characteristic of the parasitic and non-parasitic forms. This possibility is suggested by the observations of Mintz[10] and Mintz and Russell[11] on a sterile strain of mutant mice, in which complete sterility or greatly reduced fecundity was associated with either the complete absence of or a marked reduction in the numbers of primordial germ cells. On the other hand, Bounoure *et al.*[12] and Blackler and Fischberg[13] have found some evidence for regulation in the germ line, whereby after the experimental destruction of germinal material, those germ cells that survive may show an increased tendency towards proliferation.

In comparing the fecundity of the various species of lampreys it is important to distinguish between the actual fecundity of the adult female and the potential fecundity of the ammocoete larva, as represented by its oocyte stock. Particularly in the brook lamprey, but also to a lesser extent in the landlocked form of the sea lamprey, the oocyte potential of the larval ovary is considerably higher than that of the adult female and a large proportion of these oocytes either undergo atresia during metamorphosis or fail to develop in the later stages of oocyte growth that precede sexual maturity. In contrast, it is believed that in the river lamprey, *Lampetra fluviatilis*, losses of oocytes through these causes are relatively unimportant and that the oocyte stock of the larval gonad is little inferior to that of the adult ovary[7,8,14]. A further factor that must be taken into account is the extent of germ cell degeneration before and during sex differentiation. In the ammocoete of the landlocked sea lamprey it has been estimated that after proliferation, during the first 2 or 3 years of the larval period, up to 500,000 germ cells may be present, but that up to 70 per cent of these may undergo degeneration, mainly in the course of the meiotic prophase[4]. In the undifferentiated gonads of *L. planeri*, it is thought that there may be up to 30,000 germ cells and that a similar proportion are lost by degeneration. The enormous differences in the fecundity of these two species (Table 1) have therefore been attributed to differences in the proliferation of the germ cells, rather than to differences in the proportion which degenerate.

Counts have been made of the total numbers of primordial germ cells in *L. planeri*, *L. fluviatilis* and the landlocked *Petromyzon marinus* at the pro-ammocoete stage, after the yolk had been completely absorbed from the gut. At this stage, migration of germ cells to the genital anlage had generally been completed and, although ectopic germ cells have been reported[5,6], the proportion which fail to reach the gonad site is probably quite small. Mitotic germ cells have never been observed at this stage and division is thought not to occur until some months later. In common with other vertebrate species, a wide range of variability was encountered in germ cell numbers, and this was more pronounced in the case of *L. planeri*. The

Table 1. FECUNDITY AND PRIMORDIAL GERM CELL NUMBERS IN THREE SPECIES OF LAMPREYS

Species	Fecundity: Adult egg numbers	Fecundity: Larval oocyte numbers	Fecundity: Estimated total germ cell numbers	Counts of primordial germ cells: Number of animals	Counts of primordial germ cells: Mean and S.E.	Counts of primordial germ cells: Range
L. planeri	1,000–3,000	5,000–10,000	30,000	44	51·4 ± 3·3	10–94
L. fluviatilis	11,000–26,000	7,000–42,000	—	13	26·5 ± 4·2	7–49
P. marinus (landlocked form)	21,000–107,000	114,000–165,000	500,000	7	54·1 ± 5·6	27–69

mean germ cell number for this species (51) was rather higher than the figures given by Beard[15] and Okkelberg[5] for the primordial germ cells of brook lampreys. In spite of its greater fecundity, the river lamprey, *L. fluviatilis*, gave significantly lower counts than *L. planeri* (Table 1) and a similar trend was also observed in some preliminary observations made during the preceding year. Counts on the larvae of *P. marinus* showed no significant differences compared to either of the other two species. There are, therefore, no grounds for believing that the number of primordial germ cells bears any direct relationship to the number of definitive germ cells characteristic of the three species, although the possibility cannot be excluded that within a particular species the wide range of observed germ cell numbers might have some influence on the fecundity of individual animals.

Dwarf Eggs and the Timing of Ovulation in the Domestic Fowl

THE production of eggs considerably smaller than the normal has been reported in various birds[1] and has been well documented for the domestic fowl[2]. Such eggs have been described as "witch eggs", "cock eggs", "dwarf eggs" and "wind eggs"—the latter term also being applied to infertile eggs[3]. It was known as early as the seventeenth century[3] that the yolks of such eggs were frequently absent, but that there was a central nucleus around which albumin was secreted. In an investigation of 236 dwarf eggs, Pearl and Curtis[2] reported that 35 per cent of all dwarf eggs were without a yolk, 55 per cent contained free yolk and 15 per cent had a complete yolk.

During recent observations on the time of oviposition in a group of hens, five were observed to lay dwarf eggs. The degree of calcification varied from a soft-shelled to a normal-shelled egg. On opening, the eggs were free from yolk but possessed a nucleus of solid material around which albumin had collected. No eggs weighed more then 25 g.

The eggs were not laid at any particular point in the clutch, and on examination of the time of lay it was found that this time was very close to that expected for the laying of an egg following a normal oviposition. This is illustrated by the data in Tables 1 and 2. In Table 1 is given the actual time of oviposition of all eggs including the dwarf eggs in each clutch, and in Table 2 is given the period of "lag"[4] found and expected between the laying of the dwarf eggs and the preceding and succeeding oviposition. The time of "expected lag" was calculated on the basis of a normal ovulation occurring. It will be seen that the production of the dwarf egg in no way altered the timing of the subsequent ovulation.

The normally low incidence of dwarf eggs, less than 0·1 per cent[2], has not in the past permitted many investigations to be made as to their cause. Pearl and Curtis[2], from an examination of autopsied hens, concluded that the eggs were probably formed as a result of an ovulation occurring at the normal time but depositing the yolk in the body cavity with debris entering the oviduct. This would appear to be a reasonable explanation both for their production and for their oviposition at the expected time.

Table 1. TIME OF OVIPOSITION OF DWARF EGGS IN CLUTCHES LAID BY FIVE HENS

Bird No.	Time of oviposition of follicle (h): C_1	C_2	C_3	C_4	C_5	C_6	C_7
1	—	11·15	13·15	14·00	[17·30]		
2	—	—	11·30	12·00	13·15	[14·00]	16·45
3	—	[09·00]	11·30	16·00	16·30	—	—
4_1*	08·00	[09·30]	11·00	12·15	16·00		
4_2*	08·00	09·15	[10·30]	12·30			
5	10·30	[13·30]					

The nomenclature C_1, C_2, etc., is that used by Fraps (ref. 4) and designates the first, second, etc., ovum in the clutch. A dash indicates a missing time. Dwarf eggs are enclosed in a panel.
* This bird laid a dwarf egg in two successive clutches recorded here as 4_1 and 4_2.

Table 2. CALCULATED AND OBSERVED LAG IN THE PRODUCTION OF DWARF EGGS

Bird No.	Lag between dwarf egg and previous egg: Found	Lag between dwarf egg and previous egg: Expected	Lag between dwarf egg and succeeding egg: Found	Lag between dwarf egg and succeeding egg: Expected
1	27·5	26·25		
2	26·25	25·0	26·75	25·75
3			25·5	25·5
4_1	25·5	25·5	26·5	25·75
4_2	25·25	25·25	28·0	27·75
5			27·5	27·5

The term "lag" is used as described by Fraps (ref. 4) and denotes the time in hours between one oviposition and the next.

Present theories for the control of ovulation in the fowl[5] place varying emphasis on the role of the oviducal egg, which has been ascribed a major[6] and a minor[5] role in controlling the time of ovulation. If dwarf eggs are produced without an accompanying ovulation, their appearance at the expected point in the clutch might be taken as support for the hypothesis ascribing a major role to the oviducal egg. On the other hand, if they are accompanied by an ovulation into the body cavity no major significance can be attached to their appearance.

A search of the literature has not revealed any further data on the precise time of production of dwarf eggs, and it is hoped that this communication will encourage the collection and publication of further data relating to the time of oviposition and the origin of these relatively rare curiosities.

Haemoglobin in a Marine Nematode

ALTHOUGH haemoglobin is present in numerous parasitic nematodes, it has never been recorded from a free-living form[1]. Even the recent demonstration of its presence in the free-living egg-laying female of *Mermis subnigrescens*[2] scarcely affects the generalization, for *Mermis* is parasitic in insects for most of its life-history. However, we have now found that it is present in abundance in the purely marine form *Enoplus brevis* and, to a lesser extent, in *E. communis*.

The haemoglobin of *Mermis* was present in the so-called "chromotrope". Since haemoglobin had not hitherto been implicated as a sensory pigment, the finding, in our view, cast doubt on the function hitherto attributed to this organ[3]. In addition to experimentation with *Mermis* itself, it seemed worthwhile to examine the pigments found in the eye-spots which are a not uncommon feature of certain marine nematodes. In all the examples examined, mostly Enoploidea, the eye-spot pigments have been found to be other than haemoglobin. However, during the course of our searches, we found specimens of a haemoglobin containing enoplid in the estuarine mud of Budle Bay, Northumberland; we are now satisfied that these are specimens of *Enoplus brevis* Bastian. As shown by spectroscopic and histochemical test, the haemoglobin is present in the pharynx of both male and female, and in the "copulatory muscles" of the male (Fig. 1); it is also present, in smaller quantity, in hypodermal chord material along the length of the animal.

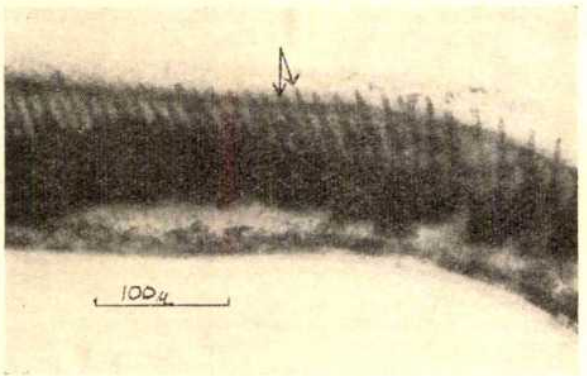

Fig. 1. Benzidine test on posterior end of male *E. brevis*. Haemoglobin is present in the series of "copulatory muscles" (arrows) which show heavy black

E. brevis has frequently been recorded from various localities[4] and it is, at first, puzzling that the presence of haemoglobin in such quantity should have gone undetected. Presumably, most other workers have only examined fixed material. We have confirmed that *E. brevis*, taken from two local habitats from which it has previously been recorded, have haemoglobin, distributed in the same way.

The haemoglobin in *E. communis* is present in much smaller quantity and, in this form, it occurs solely at intervals along the length of the hypodermal chords. Since it is present in this position also in *E. brevis*, and the tissue in which it is found in *Mermis* is hypodermal chordal in nature[5], the pigment may prove to be much more widely distributed in free-living forms.

ENTOMOLOGY

Chemosterilization of *Aedes aegypti* (L.) by Pupal Treatment

THE concept of insect control through the liberation of sterile males[1] proved successful in the eradication of the screw-worm fly (*Cochliomyia hominivorax*) from the south-eastern United States[2]. Following this success, in which sterility was induced by γ-irradiation, interest was taken in the possibility of inducing sexual sterility by chemical means[3]. Screening of chemicals yielded several substances with a prospective sterilizing capacity[4,5], notably alkylating agents incorporating the aziridine moiety. In general they are less injurious to insects than radiation[6,7], and treatment of insects with chemicals is in certain respects more convenient than the procedures of irradiation.

In the first of the experiments carried out on chemosterilization of mosquitoes[8], the fertility of *Aedes aegypti* and *Anopheles quadrimaculatus* was reduced by feeding adults on the alkylating agents 'Tepa', aphomide or apholate dissolved in honey; other workers successfully sterilized both sexes by tarsal contact[9,10]. Sterilization of several mosquito species has also been obtained by immersion of larvae in solutions of the order of 10 p.p.m. of various aziridine compounds[11–13].

For practical applications of chemosterilization against natural mosquito populations, it seems logical to focus attention on sterilization of the mosquitoes in the aquatic stages. This is due to the fact that the principle of sterilization as a control method depends on sterilization of male insects and adult male mosquitoes cannot be readily found in nature, only females of troublesome or disease-carrying species being common as they come to feed, or at rest in the precincts of their hosts. By treatment of aquatic stages in their natural breeding sites, both sexes would be exposed to sterilization and the sterile males at emergence immediately available to produce sterile inseminations in females of other broods which had not been exposed. An alternative, and more acceptable, approach is to avoid dispersal of these mutagenic chemicals in the natural environment by treating the male insects in the laboratory and later releasing them at selected points in the area to be controlled so that they may disperse into the wild population to mate with normal wild females.

Although treatments of male insects for their subsequent release have been made by larval exposure, little attention has been given to the effectiveness of treatment of mosquitoes at the pupal stage, and this communication directs attention to certain advantages which pupal treatment appears to offer.

The toxic and sterilizing dosages of alkylating agents for mosquito larvae do not differ greatly, so that the dose required to ensure induction of complete sterility in the resultant adults also incurs mortality[9,12,14]. Investigations carried out in this laboratory on the sterilization of *Aedes aegypti* with the chemosterilant 'Thiotepa' (*tris* (1-aziridinyl) phosphine sulphide) show that this difficulty is avoided when the pupal stage is treated. Preliminary tests using aqueous solutions of this alkylating agent indicated that, although fertility was unaffected in adults which emerged from pupae subjected to doses of the same order as those which sterilized but also caused partial mortality of larvae, pupal mortality was negligible. Further experiments were conducted to determine what dosage pupae would tolerate and if sterility could be obtained with sub-lethal treatments. Immersion of pupae in 'Thiotepa' solutions as strong as 500 p.p.m. or more for 24 h proved highly satisfactory in inducing complete and permanent sterility in both sexes. It was also repeatedly found that this was far below the toxic dose for pupae, which could tolerate immersion in concentrations as high as 2,000 p.p.m. for 24 h. Adults

obtained following this treatment also survive well, there being no increase above control mortality at emergence nor during the first 2 weeks of adult life. In further tests pupal treatment at as low a concentration as 100 p.p.m. for 24 h rendered more than 90 per cent of 200 males completely infertile, with an average of only 6·5 per cent of eggs hatching in the ovipositions of normal females with which the incompletely sterilized males were mated; total sterility was obtained in all resultant males after pupal immersion for 28 h. The same pupal treatment was less efficient in reducing the fertility of twenty emergent females, an average of 50·6 per cent of eggs laid being viable following crossing with normal males. This comparative tolerance by the females may well be simply a function of their greater size. However, a heavier dosage to female pupae, immersion in 'Thiotepa' at 500 p.p.m. for 24 h, gave better results, causing considerable inhibition of ovarian development. This was yet more pronounced at still higher concentrations, immersion of female pupae for 24 h in 1,000 p.p.m., that is a 0·001 per cent solution, suppressing ovarian development in the emergent female at a point earlier than the usual resting stage characteristic of the unfed, newly emerged, normal mosquito. Before these treated females could oviposit, three blood meals were necessary and, even then, the few eggs obtained were spherical and failed to hatch, while others did not tan.

In tests of pupae at different ages, using a dosage of 2 h in 'Thiotepa' at 200 p.p.m. as inadequate for complete sterilization and therefore suitable to compare the responses of pupal batches of different ages, no major differences in their susceptibility with age were observed, other than extreme sensitivity within 1 h of either ecdysis.

In ten tests of the ability of males, treated as pupae, to compete with normal males for copulation with normal females, equal numbers of untreated males and of sterilized males exposed as pupae to the highly sterilizing doses of 100 p.p.m. or 200 p.p.m. for 24 h (none of the males being more than 10 days old) were allowed to compete for copulation with half their combined number of virgin females. At least half the females which were inseminated consistently proved infertile. When treated and normal males were only 2–4 days old, the totals of sterile : fertile matings were 62 : 35, while in experiments comparing 14–16-day-old sterilized males in competition with normal males of the same age totals of sterile : fertile matings were 18 : 38. Thus, treated males appear to be more competitive when young.

Throughout all experiments with pupal-treated females no change occurred in the initial level of sterility during the course of sequential ovarian cycles and, more important, the pupal-treated males showed no recovery of fertility with time as tested in repeated crosses with normal female mates. This is to be expected as sterilization in the pupal stage precedes full differentiation of the gonads, making recovery of fertility in relation to differential sensitivity of stages in gametogenesis highly improbable.

In conclusion, administration of sterilizing alkylating agents such as 'Thiotepa' to mosquitoes at the pupal stage seems a particularly promising method of dosage, the pupae tolerating well immersions for 24 h in concentrations which ensure complete sterility of adults of both sexes. Emergent adults survive well for at least 2 weeks and the sexual vigour of young sterilized males is good, with evidence for some enhanced ability over normal young males in mating with females. Thus, pupal treatment may well be of value as a means of treating male mosquitoes under controlled laboratory conditions for subsequent mass release after emergence, but the possibility of dispersion of the treated pupae themselves into the natural environment, either in artificial containers or placed in natural breeding places, seems also to be a feasible approach to distributing sterile males in the environment of a wild population. Apart from efficacy and convenience, the distribution in this way of pupae after treatment eliminates problems of toxicity to man and wild life.

I thank Prof. D. S Bertram, director of this Department, for his supervision of this work and Lederle Laboratories, England, for supplies of 'Thiotepa'. The work was done during tenure of a Medical Research Council scholarship.

CYTOLOGY

A Penetrated Human Ovum studied by Electron Microscopy

UNTIL the present time, only two unequivocally penetrated human ova have been recovered and studied morphologically. Both of these were in the pronuclear stage. The first was recovered by Khvatov in 1959[1], and the second was recently described by Dickmann, Clewe, Bonney and Noyes[2]. These ova were studied by light and phase microscopy. A penetrated human ovum in the pronuclear stage has been recovered in our laboratory and studied by electron microscopy.

The ovum was obtained from a 33-year-old woman (D. E.), who had a vaginal hysterectomy for symptomatic pelvic relaxation. A bilateral salphingectomy was also performed. The patient had sexual intercourse approximately 26 h before the operation. The two oviducts were flushed with Krebs–Ringer phosphate solution from the utero-tubal junction to the fimbriated end. An ovum was collected and immediately fixed with cold 1 per cent buffered osmium tetroxide. The specimen was embedded in 'Epon' and serially sectioned. Thin sections were stained with lead hydroxide.

The ovum was surrounded by the zona pellucida from which it was separated by a 7-μ wide perivitelline space. A few corona radiata cells were still present around the zona pellucida. In addition, two spermatozoa were observed within the zona. Three polar bodies were present in the perivitelline space. Two of them, conceivably representing a divided first polar body, were located adjacent to each other. In addition to cytoplasmic organelles, they showed naked clumps of chromatin and microtubules of the meiotic spindle. The second polar body was located at a considerable distance from the first two, outside the opposite hemisphere of the ovum. It had recently separated from the egg, to which

it was still connected by a stretched cytoplasmic bridge. It contained a spherical mass of chromatin which was surrounded by a nuclear envelope.

Two large, spheroidal pronuclei (Fig. 1) were observed in the cortical region of the ovum close to the second polar body. They showed highly hydrated chromatin and dense prominent nucleoli. The pronuclei were completely surrounded by a double membrane envelope. The tail of the penetrated sperm was located very close to one of the two pronuclei (Fig. 2).

It would seem that the fine structural characteristics of the fertilized human ovum are markedly similar to those of the fertilized rabbit[3] and monkey ovum[4]. Further detailed investigations are in progress.

This work was supported by a grant from the Ford Foundation and, in part, by a U.S. Public Health Service

A Diploid *Gymnocarpium dryopteris* (L.) Newman in Alaska

THE fern species *Gymnocarpium dryopteris* (L.) Newman is widely distributed over the northern continents, being found in Europe, Asia, North America and Greenland. The taxonomic status of this species has been uncertain for a long time. It was first named *Polypodium dryopteris* by Linneus (1753). Bory (1824) included it in the genus *Lastrea*, and even Copeland, as late as 1947, preferred to keep it there[1]. Chromosome investigations carried out on the Pteridophyta during the past 15 years have shown, however, that the genus *Lastrea* Bory consists of many different basic chromosome numbers: $n = 30$ (*Lastrea phegopteris* e.g.); $n = 40$ (*Lastrea dryopteris* e.g.); $n = 27$, 30, 31, 34, 35 and 36 (*Lastrea thelypteris* group, and others)[2,3]. On this account the genus *Lastrea* Bory has recently been divided into many different genera, such as *Phegopteris* (Fée 1850), *Gymnocarpium* (Newman 1851), and *Thelypteris* (Schmidel 1762).

The chromosome number of *Gymnocarpium dryopteris* (L.) Newman (= *Dryopteris linnaeana* C.Chr. 1906) has been reported by many cytologists to be $n = 80$ (refs. 4–7).

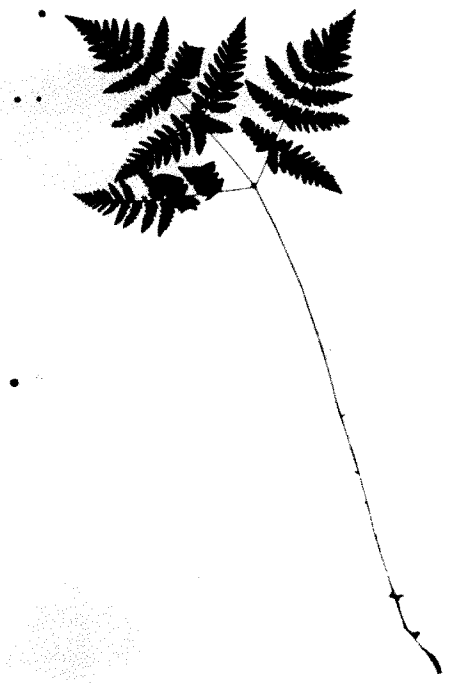

Fig. 1. Photocopy of the diploid *Gymnocarpium dryopteris* (L.) Newman found in Alaska (one-third natural size)

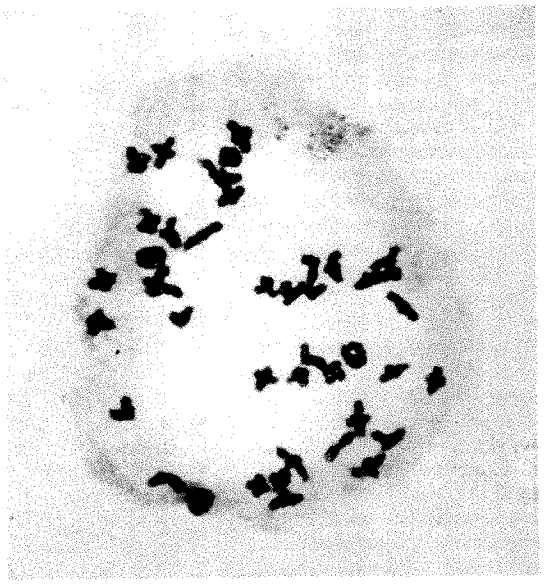

Fig. 2. Chromosomes of the diploid *Gymnocarpium dryopteris* (L.) Newman at diakinesis, $n = 40$. Acetic–iron–haematoxylin squash. (× *c.* 1,500)

The only information about the diploid *Gymnocarpium dryopteris* from Washington, United States, was reported, as a personal communication from Wagner, by Fabbri (1963) (ref. 3).

In June 1964 I had an opportunity to collect some plant material from Alaska for cytological investigations. The fern species *Gymnocarpium dryopteris* (L.) Newman was collected from coastal forest in the Auke region about 20 miles north-west of Juneau. Young sporangia were fixed in acetic alcohol (1 : 3) and stored for almost a year in the fixative in a refrigerator (−10° C) before the preparations were made. After squashing on slides, sporangia were stained for some minutes in acetic–iron–haematoxylin solution.

Forty bivalents were counted at diakinesis and the first meiotic metaphase. Three or four of them were regularly found to be ring bivalents. The chromosome number, $n = 40$, observed now is diploid compared with the tetraploid counts, $n = 80$, made previously. The diploid species of *Gymnocarpium dryopteris* (L.) Newman obviously has a north-western distribution in North America, as is also indicated by the diploid species found in Washington, United States, as mentioned earlier[3]. In the central and eastern parts of North America, as well as in Europe, only the tetraploid number, $n = 80$, was known before[2,3,7].

The interesting hybrid of *Gymnocarpium dryopteris* and *Gymnocarpium robertianum*, with 120 chromosomes, reported by Wagner[7] is possibly a hybrid between the diploid *G. dryopteris* and the tetraploid *G. robertianum*. *Gymnocarpium dryopteris* × *G. robertianum* hybrids were also found in Sweden, Finland and Russian Karelia[8], but they have not been investigated cytologically.

PHARMACOLOGY

Effect of Reserpine on the Reactivity of Atrial and Ventricular Pacemakers to Quinidine

AN antagonism of the cardiac actions of quinidine by exogenous catecholamines has been demonstrated[1–3]. It is likely, therefore, that cardiac catecholamines also antagonize the depressant action of quinidine. To test this possibility, the effect of reserpine pretreatment on the action of quinidine in isolated cat hearts with complete heart block was investigated.

Cats were rendered unconscious with electric shock. The heart was removed and perfused according to the method of Langendorff with Krebs–Henseleit[4] solution, bubbled with 95 per cent oxygen and 5 per cent carbon dioxide. The perfusion pressure was kept constant at 52 cm water; the temperature of the perfusion fluid was maintained at 37° C by appropriate thermoregulation of the water jacket. Complete heart block was produced by using a modification of the method described by Grumbach[5]. The right atrium was opened to visualize the bundle of His, and complete heart block was produced by ligating the bundle.

Quinidine was perfused in the concentrations of 2, 10 and 50 μg/ml. The quantities used are expressed in terms of the free base. Reserpine, 5 mg/kg, was administered intraperitoneally 24–30 h before the experiment.

Table 1. EFFECT OF RESERPINE ON QUINIDINE DEPRESSION OF ATRIAL AND VENTRICULAR PACEMAKERS

Quinidine concentration (μg/ml.)	Average maximum depression of rate (percentage of depression ± *S.E.*) Atrium		Ventricle	
	Non-reserpinized	Reserpinized	Non-reserpinized	Reserpinized
2	13 ± 5·8 (5)*	57 ± 10·8‡ (7)	9·4 ± 4·4 (5)	33·3 ± 11·8 (7)
10	73·9 ± 3·2 (10)	87·4 ± 4·9 (7)	8·4 ± 3·3 (10)	52·4 ± 7·3‡ (7)
50	53·0 ± 6·5† (7)	93·4 ± 6·4 (6)	80·3 ± 5·9 (7)	91·3 ± 8·2 (6)

* The numbers in parenthesis represent the number of experiments.
† It was not possible to observe further depression since five of seven preparations developed rhythm disturbance after this point.
‡ Significantly different from non-reserpinized group ($P < 0·05$).

After reserpine, the reactivity of the atrial and ventricular pacemakers to quinidine was increased. The results are summarized in Table 1. The average atrial and ventricular rates before quinidine was administered were, in non-reserpinized hearts, 113 ± *S.E.* 3·8 beats/min and 49 ± *S.E.* 2·4 beats/min respectively, and, in the reserpinized hearts, 119 ± *S.E.* 5·3 beats/min and 46 ± *S.E.* 1·6 beats/min respectively. In non-reserpinized preparations the decrease in atrial and ventricular rates produced by 2 μg/ml. and the decrease in the ventricular rate caused by 10 μg/ml. were not significantly different from that which occurs normally during the perfusion of Krebs–Henseleit solution ($P > 0·05$). Therefore, what appears to be a quinidine effect on rate at these concentrations actually represents the spontaneous decay of the preparation.

While it required the perfusion of 10 μg/ml. of quinidine to alter the rate of the atrial pacemaker in the non-reserpinized preparations, after reserpine pretreatment, 2 μg/ml. was sufficient to produce significant depression ($P < 0·05$). However, the effect of quinidine when it was perfused at 10 μg/ml. on the atrial pacemaker was similar in reserpinized and non-reserpinized hearts. It was not possible to observe the full effects of quinidine perfused in a concentration of 50 μg/ml., since rhythm disturbances developed in five of seven preparations within 30 min of perfusion. Consequently, the effect of reserpine on the reactivity of the atrium to quinidine perfused at this concentration could not be determined.

Whereas it required 50 μg/ml. of quinidine to depress the ventricular pacemaker in the non-reserpinized preparations, after reserpine it required only 10 μg/ml. to reduce significantly the ventricular rate ($P < 0·05$). It might appear that 2 μg/ml. of quinidine also reduced the ventricular rate in the reserpinized preparations, but the responses at this concentration were quite variable and were not significantly different from those produced in the non-reserpinized hearts ($0·10 > P > 0·05$). Reserpine pretreatment did not affect the depression of the ventricle produced by the perfusion of 50 μg/ml. of quinidine. Thus, the effect of reserpine pretreatment on the reactivity of the atrial and ventricular pacemakers to quinidine was evident only when lower concentrations of quinidine were perfused.

After reserpinization, the recovery of the atrial and ventricular pacemakers from quinidine depression was not so marked as in the non-reserpinized preparations (Table 2). After perfusion with 10 μg/ml. was terminated, it required about twice the time for the activity of the atrial pacemaker to recover to approximately the same degree as in the non-reserpinized preparations. Furthermore, the degree to which the atrial pacemaker recovered from 50 μg/ml. of quinidine was considerably less and the time to maximum recovery was almost doubled. While the recovery of the ventricular pacemaker from quinidine depression proceeded to almost the same extent as in the non-reserpinized preparations, after reserpine the time to maximum recovery was doubled.

Although reserpine decreased the incidence of rhythm disturbances occurring when quinidine was perfused at 50 μg/ml., the total incidence of atrial and ventricular rhythm disturbances caused by quinidine was not affected by reserpine pretreatment. Thus, atrial arrhythmias occurred in eight of twenty-two non-reserpinized hearts and in six of twenty reserpinized preparations (χ square test; $0·30 < P < 0·50$). Ventricular arrhythmias occurred in five of twenty-two non-reserpinized hearts, while they occurred in two of twenty reserpinized preparations (χ square test; $0·10 < P < 0·20$). These results confirm those previously reported by Roberts *et al.*[6], who showed that reduction in sympathetic activity in unanaesthetized dogs with complete heart block did not alter the arrhythmogenic effects of quinidine.

It is clear from the data that, after reserpine, the isolated heart became more sensitive to quinidine depression. The action of reserpine causing greater sensitivity of the heart to quinidine is probably related to its catecholamine-depleting effect. On acute denervation, it is unlikely that the heart loses all its catecholamines. It is possible, therefore, that the residual catecholamine activity is of sufficient magnitude to antagonize, at least in part,

Table 2. EFFECT OF RESERPINE ON RECOVERY OF ATRIAL AND VENTRICULAR PACEMAKERS FROM QUINIDINE DEPRESSION

Quinidine concentration (μg/ml.)	Non-reserpinized: No. of exp. 50	7	53	92	30	6	44	91	60

Recovery from quinidine depression was followed for 1 h after perfusion of the drug was terminated.

quinidine depression. Consequently, depletion of catecholamines by reserpine would permit quinidine depression to develop more readily. It may also be argued that reserpine, like quinidine, is a cardiac depressant[7] and that against a background of reserpine-induced depression, the effect of quinidine would be enhanced. However, a direct depressant action by reserpine seems unlikely since the rate and stability of isolated reserpinized hearts did not differ from those of non-reserpinized preparations[8]. Furthermore, unlike quinidine, reserpine pretreatment does not affect the rate of rise or the overshoot of atrial action potentials[9].

Tumour-inducing Effect of Hydrazine in Mice

AFTER the discovery of the experimental tumour-inducing effect of isonicotinic acid hydrazide[1] several later investigations verified that this compound showed carcinogenic effects in white mice of different inbred strains when administered intraperitoneally or orally over a long period[2–8]. According to Mori *et al.*[2], the carbamyl group is responsible for the cancerogenic effect of isonicotinic acid hydrazide. On the other hand, Biancifiori *et al.*[3] are of the opinion that the hydrazine radical[10] detached from the compound during the metabolic process plays a part in producing tumours. They found in their experiments that the frequency of tumours in mice of *BALB/c* strain caused by isonicotinic acid hydrazide or hydrazine sulphate was very high, while isonicotinic acid alone showed no carcinogenic effect.

In our own experiments we administered hydrazine to white mice having an average weight of 20 g. Hydrazine (NH_2–NH_2) is easily soluble in alcohol and water. It is a bivalent weak base; in a watery solution mono- or bivalent mono- or dihydrate develops. Each injection contained 0·5 mg hydrazine in a 0·5 ml. physiological saline solution. We treated thirty male and thirty female mice intraperitoneally, at the beginning of the experiment on each second day, and later on each third day. 16 injections were given in all over a period of 46 days. Altogether, 400 mg/kg body weight of hydrazine entered the organism of the experimental animals.

Treatment with hydrazine caused the development of focal liver necroses in some of the animals; twenty-six animals died as a result of severe liver damage in the first period of the experiment. The liver-damaging effect of drugs containing the hydrazine radical is a well-known clinical phenomenon[11–13]. Thirteen of the thirty-four mice surviving the treatment developed tumours and myeloid leukaemias between days 100 and 313 reckoned from the beginning of the experiment. The tumours appeared in the mediastinum and showed a local invasion, sometimes provoking metastases in the lungs, pleura and liver. Histologically the tumours proved to be reticular-cell sarcomata. In the cases of myeloid leukaemia, enlargement of the liver, spleen and lymph nodes was to be seen; histologically, there was infiltration of these organs as well as of the bone marrow by immature myeloid cells. As controls, we used sixty white mice of the same pedigree and age; there was only one case of spontaneous thymic lymphoma in them during a year's observation.

The hepatotoxic effect of hydrazine has been known for some time, but there were no communications on its cancerogenic effect. The investigations carried out with isonicotinic acid hydrazide directed attention to this property of hydrazine. The further examination of this compound, which has a very simple chemical structure, may reveal other valuable results. The question is of interest also from the point of view of human pathology, since many other drugs also contain hydrazine radicals, which may liberate hydrazine in the course of metabolism. Thus, a thorough investigation of hydrazine may also give us information about the important question of the cancerogenic effect of drugs.

Effects of 3,4-Dimethoxyphenylethylamine in Man

FOUR laboratories have reported finding 3,4-dimethoxyphenylethylamine (DMPEA) in the urine of schizophrenic patients[1–4]. Evidence for its occurrence in some patients with this disorder seems well established despite a single negative report[5]. As the compound is quite closely related chemically to mescaline, the latter possessing an additional methoxy-group in the 5-position, it is conceivable that DMPEA might have similar activity in humans.

In initial attempts to determine activity in man, conservative oral doses of the free amine were used, beginning with 50 mg and increasing to a dose of 600 mg, without any appreciable clinical effects being noted. Because of the possibility that the free amine might not be absorbed, a bitartrate salt was prepared, and administered in similar fashion with similar lack of effect at doses up to 800 mg. A similar testing procedure was followed with the hydrochloride salt and then a formal investigation was contrived to compare DMPEA with mescaline and placebo under blind controlled conditions.

Thirteen volunteer subjects were studied. Twelve were recovered psychiatric patients, seven with previous diagnoses of schizophrenic reaction, three with depressive reactions and two with psychoneuroses; the other volunteer had no history of emotional disorder. Three trials were conducted at weekly intervals. In the first trial, DMPEA was given on each occasion, nine of the subjects receiving doses of 500 mg, the last three receiving doses of 1,000 mg. Mescaline and placebo were administered in random order over the next two trials; the dose of mescaline was based on 6 mg/kg, the actual ranges being 405–

635 mg. Clinical effects were assessed by observation, by self-report of patients on the Clyde Mood Scale prior to treatment and at two, four and six hours after, and by completion of a symptom-sign check-list after the effects of drugs had worn off. A 24-h urine sample was collected from each subject after each treatment.

In each instance in which mescaline was administered, a rather typical clinical syndrome ensued, but neither DMPEA nor placebo produced any discernible effects. As judged by the symptom-sign check-list, mescaline evoked nausea, dizziness, blurred vision, tension, weakness, drowsiness, perceptual distortions, depersonalization, difficulty in thinking or expression, rapid flow of thoughts, poor memory, and a dream-like state. Only a few symptoms were reported from the DMPEA and placebo trials and these most commonly were weakness, drowsiness, and sadness, possibly attributable to the enforced inactivity of the testing situation. As reported on the Clyde Mood Scale, mescaline produced significant increases in friendliness, sleepiness, and dizziness, and a significant decrease in clear thinking, over several time-periods in each case. A sporadic significant increase in sleepiness was reported from DMPEA after four hours and an increase in aggressiveness from placebo at the same time. Due to the number of comparisons made, at least one significant change might have been expected to occur by chance from treatment. In addition, of the three treatments only mescaline produced pupillary dilation, increased deep tendon reflexes, unsteadiness and tremors, signs characteristic of increased sympathetic stimulation.

Table 1. RECOVERY OF METABOLITES FROM EIGHT OF THIRTEEN SUBJECTS ADMINISTERED DMPEA AND MESCALINE

	Mean percentage recovered per 24-h urine*		
	As DMPEA	As dimethoxyphenyl-acetic acid (DMPAA)	Total
After administration of DMPEA	0·37 (σ = 0·20)	77·1 (σ = 18·5)	77·5
	Percentage recovered as mescaline (TMPEA)	Percentage recovered as trimethoxyphenyl-acetic acid (TMPAA)	Total
After administration of mescaline	23·1 (σ = 8·4)	18·1 (σ = 13·2)	41·2

* Uncorrected for losses from the procedure. Approximate recovery of authentic material added to urine was: DMPEA 74 per cent, TMPEA 73 per cent, DMPAA 98 per cent, TMPAA 98 per cent.

It can be concluded that DMPEA administered orally in doses comparable to those used for mescaline exhibits none of the psychotomimetic effects of the latter drug. This is in contrast to findings from investigations carried out with lower mammals[6,7].

The difference in response of human subjects to mescaline and DMPEA may be related to the relatively complete conversion of DMPEA to its corresponding acid. Mescaline, in contrast, is, in significant amounts, excreted as the unmetabolized amine which is presumably the active form. This can be concluded from the data in Table 1. A detailed report of the metabolic aspect of this investigation is in preparation.

These investigations were supported by grants from the National Institutes of Health, U.S. Department of Health, Education and Welfare.

PATHOLOGY

Teratogenic and Carcinogenic Effects in the Offspring after Single Injection of Ethylnitrosourea to Pregnant Rats

ALKYLNITROSOUREAS give the corresponding alkylating diazoalkanes on heterolysis, and are potent carcinogens, selectively producing malignant tumours in the brain[1] and peripheral nerves[2] of rats. As might be expected, methylnitrosourea is also mutagenic as in *Saccharomyces cerevisiae*[3] and is teratogenic in rats[4]. In teratogenesis investigations the embryos are generally killed and examined immediately after Caesarean delivery. If, however, only slight teratogenic effects are produced to allow the offspring to survive, cancer may also develop later on.

Ethylnitrosourea (ENU; melting point, 103° C) has been used in our experiments on rats of our inbred strain *BD* IX (*CPAH*, agouti). Using intravenous injection, the *L.D.* 50 is 240 mg/kg. At the fifteenth day of pregnancy, three rats were injected with 80 mg ENU/kg bodyweight. Twenty-one young rats were born. All showed malformations of the paws, as shown in Fig. 1. Two of these three litters were lost after 5 days due to agalacty of the mother rats. Five rats of the remaining litter survived and matured under artificial feeding. At the age of 160 days, three of them died with the symptoms of intracranial pressure. Autopsy revealed extensive tumours of the trigeminal nerve (Fig. 2), histologically classified as malignant neurinomata. Additional tumours were observed in two of these rats; one was a polymorphic cell glioma in the right frontal lobe, and the other was a very malignant neurinoma of the left brachial plexus. This was sucessfully transplanted to young *BD* IX rats.

The fourth animal developed paralysis of the left foreleg and the right hind limb. At the age of 165 days it

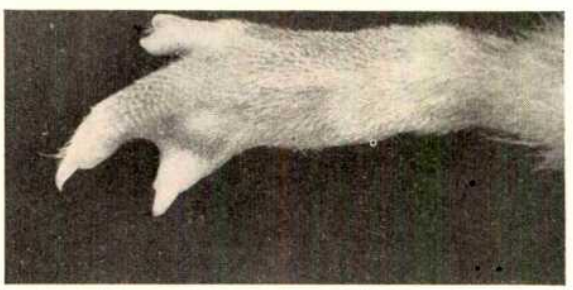

Fig. 1. Oligodactylia and syndactylia in a rat, induced by a single injection of 80 mg ethylnitrosourea per kg at the fifteenth day of pregnancy. (×2·5)

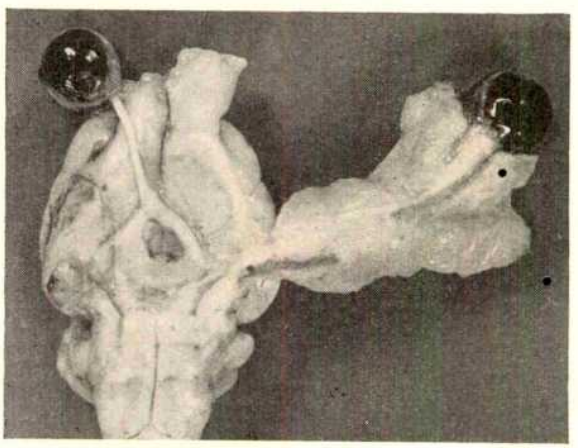

Fig. 2. Malignant neurinoma of the left trigeminal nerve with exophthalmia and rupture of the optic nerve. Ethylnitrosourea, 80 mg/kg, fifteenth day of pregnancy. (×2·5)

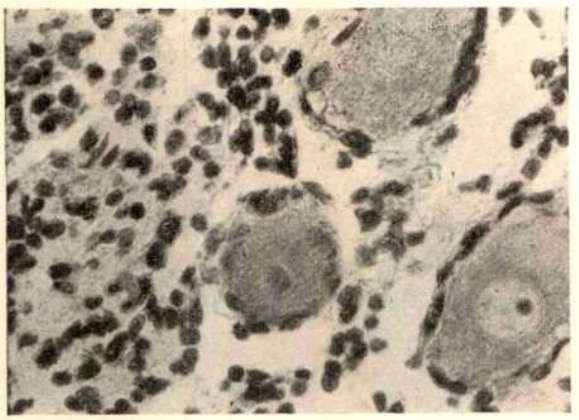

Fig. 3. Section of malignant neurinoma shown in Fig. 2. (×400)

died with neurinomata of the respective brachial and lumbosacral plexuses. The last rat also shows clear symptoms of intracranial tumour development.

Neither neurogenic tumour nor malformation of the paws occurred spontaneously in our strains of rats. The mother animals are still alive and show no sign of tumour formation, which we have found can only be expected after an induction period of more than 360 days[5].

The observations reported here are interesting in the following respects: (1) a single dose of a potent carcinogen given to a pregnant animal can produce teratogenic as well as carcinogenic effects in the offspring, (2) the organotropy of the carcinogen is unchanged, and (3) embryos are more susceptible than adults. The relatively short induction time observed may have some bearing on the important problem of cancer in childhood. Furthermore, it offers a rapid method for use in carcinogenicity tests.

Systematic investigations of these phenomena are under way. Detailed results will be published elsewhere. The work was supported by the Deutsche Forschungsgemeinschaft.

IMMUNOLOGY

Structural Heterogeneity of L Chains in Antibodies of Restricted Specificity

ZONE electrophoresis suggests that L chains of specific antibodies are less heterogeneous that L chains of whole γ-immunoglobulins (IgG)[1]. It would therefore be interesting to determine whether all L chains of an antibody directed against a single antigenic determinant (and therefore possessing a restricted specificity) have the same primary structure or not. If their primary structure is different, it may be wondered whether their degree of heterogeneity in this respect is the same in antibody as in whole IgG, and whether this heterogeneity is related to antibody specificity. The analysis of the N-terminal amino-acids is a useful preliminary approach to the study of this problem.

IgG were obtained from rabbit sera with allotypic markers, Aa3 Ab4. Sodium sulphate was used to bring about the precipitation (according to Kekwick[2]). IgG were purified by chromatography on DEAE cellulose columns using 0·0175 M sodium phosphate, *p*H 6·3. Reduction and alkylation were performed essentially according to Fleischman[3]. The final concentrations of mercaptoethanol and iodoacetamide were 0·75 M.

After dialysis for 15 h against 6 M urea and 0·05 M formic acid, fractionation was performed on 'Sephadex *G*-100' columns (3 cm × 105 cm) previously equilibrated with this solution. Harris and Knight[4] have shown that the presence or absence of the C-terminal threonines of tobacco mosaic virus (TMV) injected into rabbits determines the appearance of two different antibodies. A fraction of antibody molecules, here called anti-TMV thr$^+$, does not precipitate with TMV which has lost its C-terminal threonine by carboxypeptidase action. Another category of antibody does not precipitate with normal TMV but only with TMV treated with carboxypeptidase (antibody anti-TMV thr$^-$). This has been confirmed recently[5].

After complete absorption of the respective sera with TMV thr$^-$ and TMV thr$^+$, the remaining anti-TMV thr$^+$ and anti-TMV thr$^-$ antibodies were precipitated with the corresponding antigens. Antibodies were extracted by treatment of the immune precipitate at *p*H 1·8 (ref. 6). TMV was removed by ultracentrifugation at 28,000 r.p.m. for 45 min and the antibodies were lyophilized. Rabbits were injected with bovine DNP γ-globulin and the corresponding anti-DNP antibodies were purified by the method of Farah[7]. Dinitrophenylation of IgG and antibodies, hydrolysis and DNP amino-acid extraction were performed according to the method devised by Phillips[8]. DNP amino-acids were identified by two-dimensional thin-layer chromatography on kieselgel *G* according to Stahl's method[9].

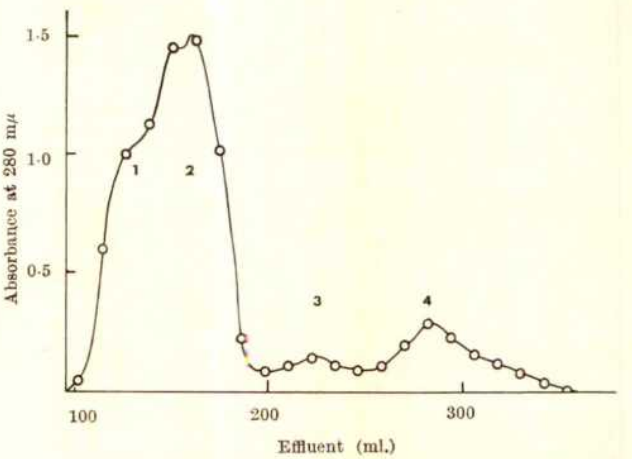

Fig. 1. Fractionation of reduced and alkylated IgG on 'Sephadex *G*-100' in 6 M urea–0·05 M formic acid

Filtration on 'Sephadex' of reduced and alkylated IgG always showed four peaks (Fig. 1). These different peaks were run again on 'Sephadex *G*-100' under the conditions already described. The content of peak 2 did not show detectable N-terminal amino-acids. This peak must therefore have contained almost exclusively H chains. Peak 4, containing the bulk of L chains, was characterized by the presence of alanine and aspartic acid, as previously shown by Fleischman[3]. Other amino-acids were detected and were present in lower but notable concentration (see Fig. 2): glutamic acid, serine, threonine, valine and leucine (or isoleucine). Peaks 1 and 3 had the same N-terminal amino-acids as L chains and, for this reason, would have been composed of incompletely separated L and H chains (peak 1) and aggregated L chains (peak 3).

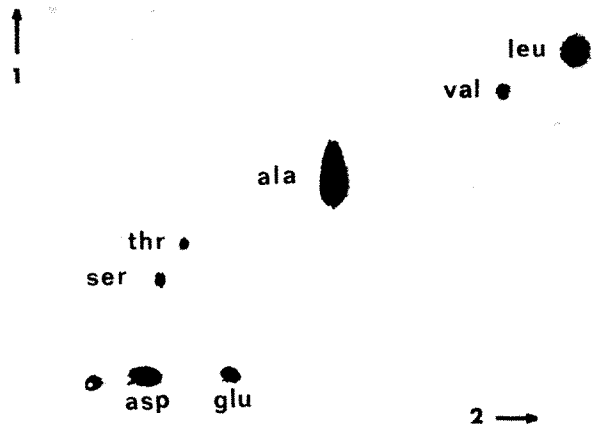

Fig. 2. Two-dimensional chromatogram of the DNP derivatives of the N-terminal amino-acids of IgG. Solvent 1 : toluene–pyridine–ethylene-chlorhydrin–0·8 N ammonia solution (100 + 30 + 60 + 60). Solvent 2: chloroform–benzyl alcohol–glacial acetic acid (70 + 30 + 3)

Total anti-TMV antibody from a single rabbit, homozygous for allotypic markers Aa3 Ab4, has the same seven N-terminal amino-acids in its L chains as whole IgG. The amounts of alanine and aspartic acid we have found per mole of IgG agree with the results of Fleischman[3]. Antibody anti-TMV thr$^+$ from the same rabbit also has seven detectable N-terminal amino-acids, like antibody anti-TMV thr$^-$ and anti-DNP-OH.

These findings concerning antibodies of restricted specificity indicate that the N-terminal amino-acid multiplicity found for whole IgG is not due to contamination, since this multiplicity is also found in that fraction of IgG molecules specifically precipitated by an antigen.

On the other hand, it seems improbable that these N-terminal amino-acids come from partial proteolytic hydrolysis, because H chains treated in the same way as L chains do not reveal detectable N-terminal amino-acids. A more quantitative comparison of the N-terminal amino-acids of antibodies anti-TMV thr$^+$ and anti-TMV thr$^-$ using 1 fluoro, 2-4-dinitrobenzene carbon-14 has been undertaken. The radioactivity of each N-terminal amino-acid of antibody anti-TMV thr$^+$, measured in a scintillation counter[10], is compared with the radioactivity of the corresponding N-terminal amino-acid of anti-TMVthr$^-$. Initial results seem to show that the N-terminal amino-acids are present in equal amounts in the two types of restricted specificity.

These results can be compared with those obtained with Bence-Jones proteins and L chains of myeloma proteins. Ten years ago, Putnam[11] and Vis and Crokaert[12] showed that Bence-Jones proteins synthesized by a single patient are homogeneous and characterized by a single N-terminal amino-acid—though they differ from one patient to another. The amino-acid composition of the N-terminal region of group I Bence-Jones proteins which have been studied differs considerably from one to another[13,14].

It can be concluded that: (1) There are at least as many different L chains in an antibody as N-terminal amino-acids detected. Thus one of the differences between a Bence-Jones protein and an antibody of restricted specificity is the multiplicity of L chains which are involved in antibody formation. (2) The L chains of antibodies of restricted specificity do not seem to be less heterogeneous than L chains of whole IgG with respect to their N-terminal amino-acids. (3) If specificity depends on the primary structure of the H chain involved[15], different L chains can be combined with that particular H chain.

This work was carried out under Euratom-ULB contract.

Note added in proof. The heterogeneity of the N-terminal amino-acids of IgG has since also been pointed out by Utsumi, S., and Karush, F. (*Biochemistry*, 4(9), 1766; 1965).

Transplantation and Function of a Histo-incompatible Tumour in Thymectomized Rats

NEONATAL thymectomy is known to diminish the ability of rats to react immunologically to some antigens[1–5]; the Jensen sarcoma has been shown to grow faster in thymectomized than in intact Sprague-Dawley rats[6]. In mice, a mammary adenocarcinoma has been transferred into a histo-incompatible host thymectomized before 48 h of age[7]. In the present investigation, thymectomy is shown to alter sufficiently the immunological capacity of the rat so that it will not only accept a histo-incompatible tumour, but the tumour–host relationship which results permits the tumour to produce hormones and the host to respond to these hormones.

The tumour used in the present investigation was chosen because previous attempts had shown that it would not grow in intact Wistar/Furth rats. The tumour is designated 'mammotropic tumour number 4 of Fisher/Furth rats' or *MtT/F4*; it originated in a Fisher/Furth (Fisher/Fu) rat implanted subcutaneously with diethylstilboestrol, and has been carried subcutaneously in this laboratory for over sixty transfer-generations[8]. It has a latent period of approximately three weeks and kills the host after eight to fifteen weeks of progressive local growth. Occasionally, metastases are found in the thorax and/or abdomen. The *MtT/F4* tumour consistently produces strong ACTH and prolactin effects in the host; the adrenal glands are stimulated to approximately ten times normal size and the mammary glands are greatly enlarged and frequently lactate. These effects begin just before, or soon after, the tumour becomes palpable.

The hosts in this investigation were male and female Wistar/Furth (Wistar/Fu) rats thymectomized within 48 h of birth. The *MtT/F4* was transferred when these thymectomized hosts were eight to eleven weeks of age using scissor-minced tumour diluted approximately 1 : 1 with a tissue-culture fluid containing penicillin and streptomycin. Approximately 0·1 c.c. of the tumour-diluent suspension was injected subcutaneously in the intra-scapular area, using a No. 18 needle. Groups receiving the tumour included: thymectomized Wistar/Fu; intact Wistar/Fu; thymectomized Fisher/Fu; and intact Fisher/Fu. Each group was further divided into males and females. In addition, non-tumour-injected controls were observed for each of these groups.

Unlike previous experience with the *MtT/F4*, most of the animals in which the tumour grew had some, and usually extensive, growth of tumour in the thorax; this included both the Wistar/Fu and Fisher/Fu rats. This unusual pattern of growth is probably due to a technical error whereby the tumour was inadvertently introduced directly into the thorax; a subsequent investigation in which the tumour was transplanted as a single small fragment by trocar into the subcutaneous tissues, has resulted in local subcutaneous growth only. For this reason it was not possible to make observations on the latent period or rate of growth in relation to thymectomy.

The tumour killed, or severely debilitated, most of the hosts by extensive intra-thoracic growth, seven to eight weeks after transfer. At this time, all the debilitated animals were killed and it was found that the tumour had taken in 2/5 female and 2/5 male thymectomized Wistar/Fu rats. Ten weeks after transfer of the tumour, five male and five female Wistar/Fu, intact littermates of the thymectomized rats, were killed and none was found to have growth of the tumour; seventeen weeks after the transfer, an additional four male and four female Wistar/Fu, intact littermates, were alive without detectable growth of tumour.

As expected, all five of the intact, and all four of the thymectomized, Fisher/Fu rats had successful growth of the tumour when they died or were killed, seven to eight weeks after the transfer. In all the rats in which the tumour grew, both Wistar/Fu and Fisher/Fu, the adrenals were approximately ten times normal size and the mammary glands were greatly enlarged.

I thank Drs. Jacob Furth, Jane Taylor and Erwin Vollmer for their critical assistance and Janice Williams for technical assistance. This work was supported in full by the National Cancer Institute, National Institutes of Health, Cancer Chemotherapy National Service Center.

Effect of *p*H on Human Complement Activity

WHILE investigating the effect of acetylsalicylic acid (aspirin) on complement (*C′*) activity, it was observed that incorporation of 40 mg per cent of the drug in a well-buffered reagent diluent, 0·15 M triethanolamine buffered salt (TBS) solution[1], significantly increased the haemolytic activity of human complement (Hu*C′*)[2]. Since it was also noted that the drug slightly reduced the *p*H of the reaction mixture, the studies were extended to investigate the effect of *p*H change on Hu*C′* activity.

Pooled human serum freshly collected and stored not longer than one month in a mechanically operated freezer (−60° C) provided the source of Hu*C′*. Assays of *C′* were carried out using a precise spectrophotometric method as previously described[3]. Haemolytic activity was expressed as 50 per cent haemolytic units per ml. ($C'H_{50}$/ml.) of serum. TBS, *p*H 7·2, containing magnesium and calcium ions in concentrations optimal for immune haemolysis, was used as the standard reagent diluent. For experiments in which it was desired to alter the *p*H of the system, required volumes of 0·1 N hydrochloric acid or 0·1 N sodium hydroxide were added to a stock concentration of TBS and then diluted so that a constant ionic strength was maintained. The influence of *p*H on the haemolytic activity of Hu*C′* was investigated over the *p*H range 5·55–8·20.

Table 1. EFFECT OF *p*H ON THE HAEMOLYTIC ACTIVITY OF Hu*C′*

*p*H	5·55	6·14	6·53	6·77	7·20	7·55	7·80	8·20
Hu*C′* titres* ($C'H_{50}$/ml.)	<30	88	226	279	239	197	186	166

* Arithmetic means of three independent determinations.

The results of this investigation are summarized in Table 1. Maximum haemolytic activity of Hu*C′* was observed at *p*H 6·77 and not at the *p*H level (7·2) usually used. Adjustment of *p*H to either the acid or alkaline side of *p*H 6·77 resulted in reduced Hu*C′* titres. These observations paralleled the findings of Ibe and Wardlaw[4] in which it was demonstrated that in the case of guinea-pig *C′* (Gp*C′*), maximum haemolytic activity was manifested at *p*H 6·8. Both studies corroborate and extend the observations of Kabat and Mayer[5], who noted that the haemolytic activity of Gp*C′* progressively increased as the *p*H of the system was reduced from 8·52 to 7·15. However, the latter investigators did not present data concerning the effects of lower *p*H values on immune haemolysis. In view of the present findings, consideration should be given to the potential value of conducting tests involving guinea-pig and human *C′* at *p*H 6·8 rather than using the more generally used *p*H 7·2.

Adenovirus 12 Virion-free 'T' Antigen from Infected Cells inhibited with Cytosine Arabinoside

RAPP *et al.*[1] described a method for producing *SV* 40 'T' antigen free of virion by using cytosine arabinoside (CA) to block the growth of virus in tissue cultures of cercopithecus kidney cells. We found that cytosine arabinoside could also be used to produce virus-free adenovirus 12 'T' antigen in human cell tissue cultures as follows: It was found that the *p*H of the media and the condition of the human cell lines (*HEK*, HeLa or *KB* monolayers) used to produce adenovirus 12 'T' antigens could be best controlled in test-tubes and that when this was done more uniform production of 'T' antigen was obtained. About three hundred test-tubes were used for each experiment. Evenly growing cell monolayers were drained of fluid and washed with Eagle's basal medium containing 4 mM glutamine plus antibiotics. Each culture was then inoculated with 0·2 c.c. virus mixture (virus diluted with Eagle's basal medium containing 4 mM glutamine plus antibiotics) at multiplicities between 1 and

Table 1. HARVEST OF CRUDE ADENOVIRUS-12-INDUCED NON-VIRION 'T' ANTIGENS FROM INFECTED CELLS INHIBITED BY CYTOSINE ARABINOSIDE

HEK cells, 72-h harvests:	Complement-fixed antigen titre: Human*	Broad-reacting hamster‡	Infectivity titre $TCID_{50}$
Cytosine arabinoside inhibited 40× concentrate	0†	32	$<10^{-0.5}$§
Control 40× concentrate	64	32	10^{-2}§

* Human adenovirus antisera, Laboratory for Infectious Diseases (LID) pool 26186, diluted 1–32 (for detecting virion antigen).

† Reciprocal of complement-fixed antigen titre (0 equals negative at a 1 : 2 dilution).

‡ Adenovirus 12 hamster tumour antisera, LID pool 13, diluted 1–20 (for detecting non-virion 'T' antigens (ref. 5)).

§ Twenty-one-day titration in *HEK*, five test-tubes per dilution, tenfold dilutions; undiluted through 10^{-5} with secondary passage of negative materials, undiluted observed for 21 days.

2 $TCID_{50}$ per cell. The cultures were incubated for 1 h at 34° C and then each was fed 1 c.c. of a mixture of Eagle's basal medium + 2 per cent A-γ calf serum + 2 mM glutamine + antibiotics + 10γ cytosine arabinoside. 72 h after infection, the media were drained and the cultures were washed with large quantities of Eagle's basal medium and overlaid with 0·2 c.c. Eagle's basal medium + antibiotics + 4 mM glutamine. The cells were frozen in the test-tubes on a slant, thawed quickly, pooled, homogenized and clarified at 2,000 r.p.m. for 10 min. The resulting material was concentrated forty to fifty times by Kohn's method[2], and three hundred test-tubes yielded 6 c.c. of crude 'T' antigen. A large number of replicate experiments using this method yielded results comparable with those presented in Table 1. Adenovirus 'T' antigen produced in *HEK* monolayers in the presence of cytosine arabinoside had an average complement-fixed antigen titre of 1 : 32, whereas, when produced in HeLa and *KB* cells, the average titre achieved was 1 : 8. In other experiments using cytosine arabinoside, a multiplicity of 10 $TCID_{50}$ adenovirus 12 per cell yielded about the same 'T' antigen titre, but virion antigen was not inhibited and 30-day infectivity titrations in *HEK* cells showed the presence of at least one log of virus.

et al.[1] and Melnick *et al.*[3], which showed that the progression to mature *SV* 40 infectious virion was delayed by IUDR. Rowe *et al.*[4] in their investigations of *E*46+ hybrid virus found that pretreatment of *HEK* cells with a $10^{-4.1}$ M concentration of 5-fluorouracil deoxyriboside (FUDR) did not affect the induction of adenovirus or *SV* 40 'T' antigens but did prevent formation of adenovirus 7 viral antigen. Gilead and Ginsberg[5] described the inhibition of adenovirus type 12 viral proteins and the production of 'T' antigen in *KB* cells treated with 10^{-6} M FUDR.

Because it was likely that the crude preparations of cytosine arabinoside-inhibited adenovirus 12 would contain at least a few infectious particles which could not be demonstrated by routine titration on *HEK* cultures, a further separation of the 'T' complex was carried out using 'Sephadex *G*-200' columns in a Beckman 'Spectrochrom Analyzer'. The 'T' preparations were run, under a constant *p*H of 7·6 and constant conductivity, over 'Sephadex' columns with phosphate-buffered saline. One hundred drops were collected in each of seventy-five test-tubes and the drops were monitored at 220, 260 and 280 mμ simultaneously. Eluents were concentrated and re-tested for infectivity. Eluents from two connected peaks (absorbance at 220 and 280 mμ) were negative for infectivity and again showed no complement-fixing reaction with human adenovirus antisera. These two components were labelled, for convenience, part No. 1 and part No. 2 of the adenovirus 'T' complex and were tested with broad- and narrow-reacting hamster antisera (Table 3). It can be seen in Table 3 that part No. 1 of the 'T' antigen complex[6,7] reacts primarily with broad-reacting antisera and that part No. 2 reacts with both narrow- and broad-reacting antisera. The sensitivity to heat of part No. 1 of the adenovirus 12 'T' complex is illustrated. Investigations of the molecular weights and chemical composition of these components are in progress.

In conclusion, cytosine arabinoside blocked adenovirus 12 virion antigen and permitted 'T' antigen to be produced. Previously described heat-labile and heat-stable

* Reciprocal of complement-fixed antigen titre (0 equals negative at a 1 : 2 dilution).

† With 250γ FU, all tubes negative for complement fixation.

A preliminary pilot study comparing three different DNA inhibitors was performed (Table 2). The antigen titres are not very high as only five *HEK* monolayer test-tubes were used for each time period and the final concentration of cells to fluid was five times more dilute than in the experiments already described. The twenty-seven sets of five test-tubes were each removed from the incubator after the times shown in Table 2, the supernate removed for separate testing, the cells thoroughly washed, drained, suspended in 1 c.c. of buffer, frozen and thawed three times, pooled and concentrated[2] for complement-fixation testing from 5 c.c. to 0·5 c.c. As can be seen in Table 2, cytosine arabinoside inhibited adenovirus type 12 virion antigen but not 'T' antigen. As fluorouracil (FU) was increased from 50γ to 100γ to 250γ, the complement-fixing titre of the virion antigen and the 'T' antigen were both reduced in a proportionate manner. In the 48-h period, the 10γ and 30γ iododeoxyuridine 5′-phosphate (IUDR-5′P) slowed the formation of the adenovirus antigens; this was analogous with the observations of Rapp

components of the adenovirus 12 'T' complex were shown to be present.

Significance of a Single-hit Event in the Initiation of Antibody Response

THE origin of the physico-chemical and immunochemical heterogeneity of immunoglobulin molecules has been a perplexing problem for many years. Recently, evidence has been accumulating which points to variability in the expression of antigen-stimulable progenitor cells as the cause of immunoglobulin heterogeneity. Whether or not this is the case—or whether, for example, the variability may result from non-uniformity of polypeptide chain construction by polysomes—can only be decided when methods are available for analysis of immunoglobulins at various times during response by the progeny of a single precursor cell. Before such clonal investigations can be attempted, it is obviously necessary to have some clear notion about the number and frequency of these precursor cells. This communication presents the results of experiments designed to enumerate such cells in spleen cell suspensions from non-primed and primed mice of two different hybrid strains of various age groups.

For our purposes it was desirable to investigate the production of antibodies in a system involving the quantitative transfer of mouse spleen cells. The system consisted of transfer and culture of inocula of dispersed spleen cells in genetically compatible (syngeneic) recipient mice; the latter had been rendered immunologically incompetent beforehand by X-irradiation[1]. In this manner, stimulation of spleen cell inocula with optimum doses of antigen resulted in antibody formation.

The amount of antibody formed in such a system is a linear function of the number of cells transferred[2]. This observation strongly suggests that there are independent immunocompetent 'units' which control antibody formation (a unit could be an 'antibody virus', or a multicellular aggregate involving one competent cell and phagocytes or nurse cells, but is presumably a single competent cell). The probabilities are such that only one unit would be necessary for the initiation of antibody synthesis. Co-operative events among immunocompetent units would lead to non-linear dependence on cell number of antibody formation. The statement that there are independent units that are essential for the initiation of antibody synthesis merely focuses attention on the limiting step, but does not deny the existence of other steps in the process.

If there are independent units that control the production of antibody, it should be possible to reduce the inoculum size so that there is a finite probability of the inoculum containing only one or none of the controlling units. Statistical methods based on the Poisson distribution would be applicable to such an experiment, and:

$$\ln p_0 = -n \qquad (1)$$

where p_0 is the probability of a null response and n is the number of immunological units. The probability of a null response would be 0·37, 0·14 and 0·09 for 1, 2 and 3 units respectively.

In any such experiment a crucial point is the sensitivity of the assay system and the question of the possibility of detecting the output of one unit. In Fig. 1 are shown the results of two experiments in which teased spleen cells were mixed with an optimum proportion of rat red blood cells and a small inoculum was injected into a series of mice. The observed frequencies of the different haemagglutinating antibody titres of sera obtained 7 days later are plotted. The distribution is bimodal and can be separated into a group of non-responders with background titres and a group of responders with titres significantly above background. Although the observed titres depend on the particular technique used (micro-titration versus standard tube titration), the bimodal distribution is a characteristic feature of the results obtained with small inocula.

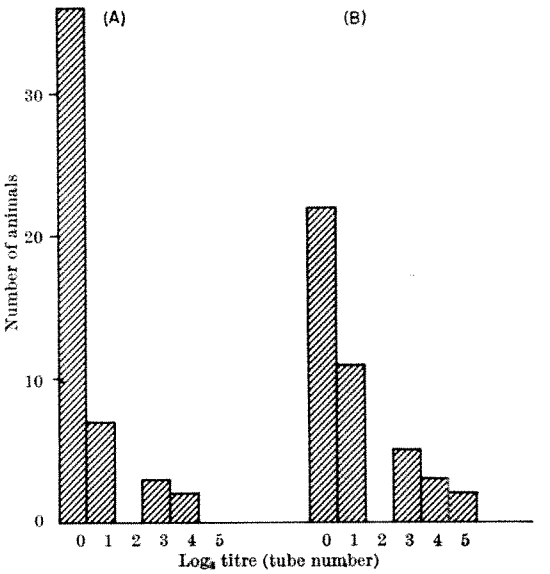

Fig. 1. Number of animals from which sera were obtained 7 days after antigenic stimulation gave haemagglutination titres of 1, 2, 4, etc. *A*, Secondary response by *C*3*H*.*F*1 spleen cells; *B*, primary response by *C*3*H*.*F*1 spleen cells

In a series of experiments using rat red blood cells as the antigen, the frequency of non-responders as a function of inoculum size was determined for several groups of animals. Spleen cells were obtained from non-primed and primed donors. In the latter case the mice were injected with 2×10^6 red blood cells 1–6 months before their spleen cells were collected. The number of units in the spleen cell inoculum has been calculated using the statistical method of Finney[3], and the results are presented in Table 1. The frequency of non-responders as a function of the number of immunological units is plotted in Fig. 2. For graphical simplicity, almost identical points from the experiments have been omitted. The straight line is the theoretical line calculated from equation 1. A comparison of frequencies predicted by equation 1 with observed frequencies gave a χ^2 (ref. 4) of 23·0 with 35 degrees of freedom. The probability of observing this good a fit or better by chance would be 0·05 and it can be concluded that equation (1) adequately represents the data. Because there is no suggestion of a shoulder in the experimental data, it is reasonable to conclude that there are independent units controlling the synthesis of haemagglutinating antibody, regardless of whether the response is primary or secondary. Although it is improbable, one must admit that the statistical evidence could be fortuitous and that the process may be more complicated.

Table 1. STATISTICAL ANALYSIS OF IMMUNOLOGICAL UNITS IN SPLEEN CELL SUSPENSIONS

Previous data have shown that antibody production is correlated with cellular replication[5–8] and that the mean generation time is 8–9 h[9]. Furthermore, there are about ten generations involved, or a thousand-fold increase in the number of functional cells[10]. Although it remains to be proved, it is very reasonable to assume that the independent immunocompetent unit is the progenitor cell for this replication cycle. It follows then that all the functional cells in this system initiated by a single progenitor cell constitute a functional clone, and according to the Poisson distribution, in the case where only twenty out of two hundred mice respond (10 per cent responders), nineteen of these twenty responders are due to functional cells derived from a single antigen-stimulated progenitor cell.

Recent investigations[11–14] have clearly demonstrated that most functional cells are committed to the exclusive production of one of a number of genetically possible globulin antibodies. However, it is not known when in the differentiation process of immunologically competent cells the decision is made; that is to say, does the decision precede or follow antigenic stimulation? This problem of decision-making at the genetic level, which is the essence of cytodifferentiation, can be directly resolved by assessing the capabilities of functional cells derived from one antigen-stimulated progenitor cell.

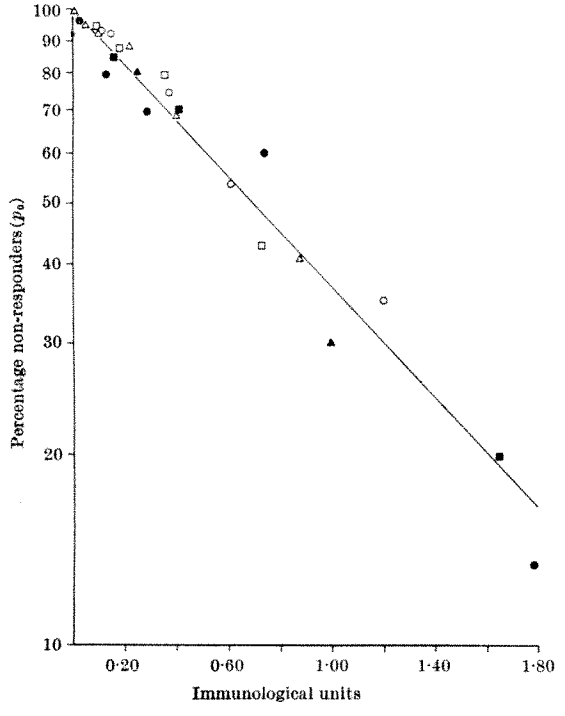

Fig. 2. Frequency of non-responders as a function of immunological units. See Table 1 for experiments: ○, experiment 1; △, experiment 2; □, experiment 3; ●, experiment 4; ▲, experiment 5; ■, experiment 6

Demonstration of Circulating Antibodies to *Plasmodium falciparum* by Gel-diffusion Techniques

As age advances, Africans resident in hyperendemic regions of The Gambia, West Africa, acquire a marked ability to limit malarial parasitaemia[1]. IgG (7 *S* gamma-globulin) prepared from the sera of adult Gambians exerts a profound anti-plasmodial effect about the time of schizogony when administered to young children experiencing heavy *Plasmodium falciparum* infection[2]. Recently, using antigen preparations of locally acquired *P. falciparum*, we have been able to demonstrate, by gel-diffusion techniques, the existence of precipitating antibody in the sera of Gambians believed to be immune to malaria.

Two antigen samples (*T*1 and *T*2) were prepared by Zuckerman's modification[3] of the technique of Spira and Zuckerman[4] from trophozoites recovered from the blood of heavily infected children. This modification included the preliminary removal of leucocytes by sedimentation of the blood in a solution of dextran. Two further samples, *P*1 and *P*5, have been prepared from asexual parasites of more advanced development (pre-schizonts and schizonts) recovered from densely infected placental blood. The *P*1 antigen was prepared by Zuckerman's modification, as already described. The *P*5 antigen was prepared as follows without attempting to separate the parasitic material from the cellular constituents of placental blood. After mincing, the mixture of blood and placental tissue was suspended in M/15 phosphate buffered saline, *p*H 7·2, and filtered. The filtrate was centrifuged for 15 min at 900*g* and the supernatant discarded. The cellular deposit was washed once with M/15 phosphate buffered saline and recentrifuged at 1,400*g* and the supernatant again discarded. The parasite-rich upper layer of the deposit, visible as a dark band, was removed and resuspended in its own volume of M/150 phosphate buffered saline, *p*H 7·2. This final suspension (containing $1{\cdot}045 \times 10^6$ large parasites/mm^3) was lyophilized and stored *in vacuo* at −20° C. Before it was used, the lyophilized material was reconstituted to half its original volume with distilled water and disintegrated in a Hughes press[5]. The disintegrated material was later centrifuged

at 28,000*g* for 20 min and the resulting supernatant taken as antigen.

A range of sera obtained from Gambian Africans has been tested against the various antigen preparations. One serum (J. S., fluorescent antibody titre (FAT)[6], 1 : 6,400) was concentrated threefold by the globulin precipitation technique developed by Thurston *et al.*[7], and to the same degree following lyophilization and reconstitution with distilled water. This serum and samples from six adults, selected to represent the blood groups A, B and O (T. S., FAT, 1 : 800; A. M., FAT, 1 : 3,200; A. S., FAT, 1 : 400; J. D., FAT, 1 : 3,200; M. S., FAT, 1 : 800; J. B., FAT, 1 : 3,200) from the donor of antigen *P*5 (V. B., FAT, 1 : 800) and from her infant (F. G., FAT, 1 : 25), have been studied (unconcentrated). Sera from non-immune expatriates (I. M., T. P., D. H., P. H. and L. J.), representing the blood groups A, B and O, and all possessing negative fluorescent antibody titres, acted as controls. The Ouchterlony double-diffusion technique[8], using 1·5 per cent special Difco 'Noble-Agar' in 0·3 M phosphate buffer (*p*H 8·0), was used to observe reactions between the various sera and antigen preparations.

Concentrated J. S. serum was tested against all the antigen preparations and against disintegrated erythrocyte stromata prepared from the blood of a non-malarious African (Fig. 1). It yielded three distinct precipitin lines with antigen *P*5, no definite lines with antigen *P*1 (although two of the lines evident against antigen *P*5 were apparently deviated towards the *P*1 region), a faint line with antigen *T*2, but no definite line with antigen *T*1.

Unconcentrated samples of the other immune sera yielded single precipitin lines when tested against schizont antigen *P*5. At a dilution of 1 : 10 only sera J. D. and T. S. were reactive. The following samples of non-immune sera were not reactive: globulin concentrate of I. M., unconcentrated L. J. and D. H., and a 1 : 10 dilution of L. J.

To obviate the possibility that the precipitin lines observed were due to blood group agglutinins of the A, B or O type, three non-immune and three immune sera from donors representing groups A, B and O were studied simultaneously in the same system against schizont antigen *P*5 (Fig. 2). A single line of precipitation was produced against two of the immune sera and two lines against the remaining one. All three non-immune sera failed to react.

As it was known that schizont antigen *P*5 contained disintegrated fragments of blood cells, certain absorption experiments were made. A sample of serum T. S. was absorbed with a third of its volume of erythrocytes obtained from the donor of the relevant placenta. A second sample was absorbed with leucocytes and thrombocytes from the same source. When these absorbed preparations were tested against schizont-antigen *P*5 (Fig. 3), a precipitin line was still produced in each case and fused in a reaction of complete identity with the line produced by the unabsorbed serum. Serum from the donor of the placenta (homologous serum) produced two lines, one of which fused in a reaction of complete identity with the single line that developed against the serum of her infant. The sera of mother and child were taken 6 weeks after delivery.

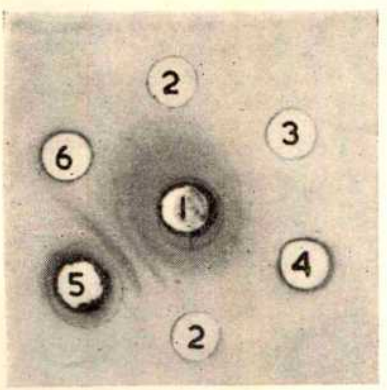

Fig. 1. Gel-diffusion analysis of J. S. serum concentrated by lyophilization and reconstitution (1), with trophozoite antigens *T*1 (3) and *T*2 (4), with schizont antigens *P*1 (6) and *P*5 (5) and with erythrocytic stromata obtained from non-parasitized blood (2). Reaction occurred only against *P*5 (three lines) and *T*2 (one line)

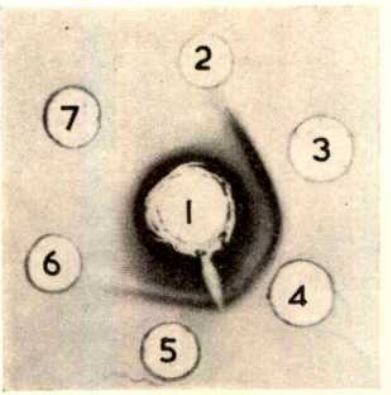

Fig. 2. Gel-diffusion analysis of schizont antigen *P*5 (1) showing the line of precipitate with each of the immune sera T. S. (3), J. S. (4), J. B. (5), representing blood groups A, B and O respectively. Three non-immune sera T. P. (2), P. H. (7) and D. H. (6), representing blood groups B, A and O, respectively, failed to react. (Schizont antigen was obtained from donor of blood group B)

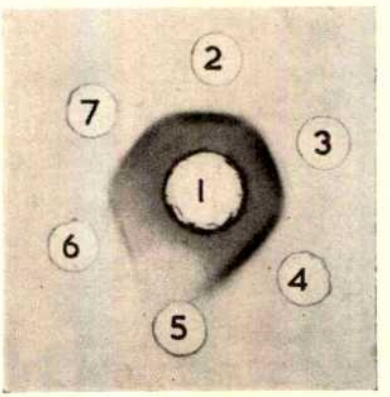

Fig. 3. Gel-diffusion analysis of placental schizont antigen *P*5 (1) showing precipitin lines with unabsorbed T. S. serum (2), the same serum absorbed with erythrocytes of the placental donor (3) and with erythrocytes and leucocytes from the same source (4), the homologous serum (from placental donor) (7), and the serum of her infant (6). No line developed against non-immune serum D. H. (5)

It would seem that the observations described here can be ascribed to the specific interaction of malarial antigen and malarial antibody, and preliminary observations have shown that the reactive material in immune serum migrates in the γ-globulin region. There was no evidence that the naturally occurring isoagglutinins of the serum donors influenced the results. It may be that some unidentified antigen, possibly a virus, reacted with its specific antibody, but this is unlikely as our reactant antigens did not derive from a single source and because the non-immune expatriates studied had encountered, in periods of Gambian residence ranging up to 17 years, many local infections but never malaria.

Several findings seem worthy of comment. First, the positive results obtained with adult sera and with serum from a 6-week-old infant, in whom no evidence of malarial infection could be found, suggested that both actively and passively acquired malarial antibodies can be demonstrated by gel-diffusion techniques. Secondly, the fact that our most reactive antigen derived from plasmodia at a late stage of their asexual development may lend support to the view that the antigenicity of the asexual

parasite may change quantitatively and/or qualitatively as it matures[9–11]. Finally, the apparent lack of correlation between the fluorescent antibody titres of the immune sera tested and their ability to produce lines of precipitation indicates that gel-diffusion and fluorescent techniques may not measure the same antibody.

HISTOLOGY

A New Method for the Decalcification of Adult Human Enamel

Certain stages of an investigation into the histopathology of adult human fluorosed enamel, which is at present being carried out in this department, have called for the decalcification of thin ground specimens used for light microscopy and microradiography. As none of the previously designed methods for the decalcification of enamel (including the most recently devised one[1]) has proved satisfactory for this purpose, a search was made for a new method.

In the investigations undertaken to obtain a satisfactory routine method for the decalcification of thin ground specimens of adult human enamel, the aim has been primarily to retain as completely as possible the organic matrix. A simultaneous tanning and decalcification of the specimens were thought to offer many advantages; results obtained with a simple watery solution of chromium sulphate have proved particularly promising. The enamel matrix recovered with chromium sulphate decalcification at *p*H 3·5 is well preserved throughout its thickness and shows no separation from underlying dentine. It further shows prismatic markings and cross-striations (Fig. 1) corresponding to the appearances of the non-decalcified section. In polarized light, the matrix is positively birefringent when immersed in water. In inhibition fluids with refractive index 1·48 and 1·62 the same matrix shows a weaker positive birefringence, whereas at refractive index 1·55 the birefringence is very weak. The thickness of the ground specimens used so far has been about 40 microns.

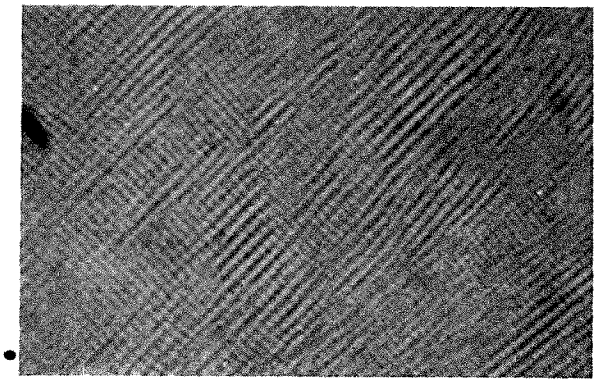

Fig. 1

Further investigation is needed to establish any more general validity of the decalcification procedure. Thus it is desirable to know to what extent the preserved matrix is chemically related to the total organic content of enamel and also to what extent its structure may have been altered as a result of the procedure.

An interesting observation, which might be of special importance, is that decalcification in a chromium sulphate solution of *p*H about 2·8 initially is slower than when a comparable section from the same tooth is decalcified in, for example, the solution suggested by Brain (*p*H about 3·5). Tanning of the matrix seems to have protected the crystals from solution by the acid. The role of the enamel matrix in carious destruction has recently received fresh attention[2], and any possible use of tanning agents as a means of preventing caries should be investigated.

A detailed account of the chromium sulphate procedure is being prepared. Further investigations of the properties of the matrix recovered with chromium sulphate decalcification are also being undertaken.

Reaction of Formaldehyde with Unsaturated Fatty Acids during Histological Fixation

Formaldehyde reacts with ethylenic double bonds in the presence of an acid catalyst to give 1 : 3 glycols and 1 : 3 dioxanes (the Prins reaction)[1]. This reaction is well documented[2,3] and the following sequence is generally accepted:

(*a*) Formation of electrophilic species:

$$CH_2{=}O \; + H^+ \rightarrow \; CH_2{=}O^+H \leftrightarrow \dot{C}H_2OH$$

(*b*) Reaction with double bond:

Though the Prins reaction is widely used in synthetic organic chemistry, little attention has been directed to the reaction of formaldehyde with lipids in biological materials. Wolman[4] suggested that formaldehyde may react at the sites of double bonds in fatty acids; he offered little evidence of this, and his suggestion that a side-chain carbonyl group is formed is obviously not in keeping with the accepted modes of reaction of formaldehyde. It is probable that the formaldehyde did react with the unsaturated acids during Wolman's experiments, but following the scheme outlined above.

As most material required for lipid histochemistry is 'fixed' in formaldehyde-containing solutions, it was considered desirable to investigate further the reaction of formaldehyde with lipids, particularly unsaturated fatty acids, both in the pure state and in tissues.

To characterize the products likely to be observed during fixation, unsaturated acids of more than 99 per cent purity were heated at 100° C with a solution of the following composition for up to 8 h:

40 per cent formaldehyde solution	85 parts v/v
Glacial acetic acid	10 parts v/v
Concentrated hydrochloric acid (35 per cent hydrogen chloride in water)	5 parts v/v

The *p*H of solution was 0·5.

New products were detected by gas chromatography of the methyl esters on polyethylene glycol adipate (PEGA) as stationary phase. The apparatus used was a Pye argon chromatograph.

With oleic acid, five new products totalling 34 per cent of the mixture were detected. Their retention times were considerably longer than that of methyl oleate. The retention time of one product was increased on hydrogenation. Table 1 gives representative results. More complex mixtures were obtained from linoleic and linolenic acids.

Table 1. EFFECT OF FORMALDEHYDE ON PURE OLEIC ACID*

Description	Carbon Nos. on PEGA 16·0	18·0	18·3 (oleic acid)	23·35	23·85	24·15	24·5	25·9

* Expressed as percentage of total.
† *H*, 40 per cent formaldehyde solution, 85 parts v/v; glacial acetic acid, 10 parts v/v; concentrated hydrochloric acid, 5 parts v/v (*p*H 0·5).

At room temperature, reaction was much slower. Acids were stirred with a 4 per cent solution of formaldehyde in 0·9 per cent sodium chloride (routine histological fixative, *p*H 4·05). Only two new products were obtained from oleic acid (see Table 1). The significance of these results is discussed later on.

In order to appraise the true significance of these reactions, the fatty acid patterns of the fractions[5] obtained from tissue lipids before and after fixation have been determined. Table 2 gives figures for the lipids of a sebaceous tumour, both before fixation[6] and after fixation for 3 years.

It was noted that with oleic acid 'fixed' in formal saline at room temperature a compound of carbon No. 24.5 appeared in the reaction products. This does not correspond to any compound appearing in the reaction mixture when oleic acid was heated with formaldehyde, but the reagent used in this case contained acetic acid and hydrochloric acid. The hydrochloric acid, in addition to supplying protons to catalyse the reaction of formaldehyde with the double bond, also catalysed the esterification of hydroxy-groups formed in the reaction.

The number of compounds formed from the 'hot' reaction can be attributed to isomers:

(*b*) (*a*)

Arrows indicate charge distribution due to inductive effect of the carboxyl group (*a*) and methyl group (*b*). Both these effects are very slight, owing to the saturated chains of methylene groups separating the functional groups. However, at room temperature preferential attack by the $^{+}CH_2OH$ electrophile will lead to addition at position 9. At higher temperatures the slight energy barrier to addition at position 10 is overcome. This leads to two slightly different glycols and two slightly different dioxanes.

Table 2 represents the effect of fixation on a biological mixture of lipids, and serves to demonstrate only that a change does occur during fixation. Many compounds were observed with high carbon numbers, but, due to the large number of acids originally present, it is impossible to correlate these with the original reactant. Instead, decrease in concentration of unsaturated acids must be taken as proof of reaction. Table 2 only presents a few of the acids observed, but it does indicate that, during fixation in tissues, the predominant reaction was between free fatty acids and formaldehyde, since the fatty acid composition of this fraction shows the greatest change. Esterified fatty acids do not seem to react so readily. This is not due to any intrinsic difference in reactivity, but to the physical nature of these compounds. Triglycerides and cholesterol esters are 'hydrophobic', and not permeable to aqueous formaldehyde solutions, whereas fatty acids possess a slight solubility in aqueous solutions. Formaldehyde-based fixatives hydrolyse ester linkages slowly; in the presence of phospholipid, which tends to emulsify triglycerides and cholesterol esters, the rate of hydrolysis is greater[7]. Under such conditions, formaldehyde should react more rapidly with these 'hydrophobic' fractions; this point is being investigated.

It is difficult to demonstrate lipids histologically in tissues which have been stored in formaldehyde for more than 4 or 5 years[8]. This is due partly to loss of lipid into

Table 2. EFFECTS OF FIXATION ON FATTY ACIDS OF A SEBACEOUS TUMOUR*

Description	Before / After fixation	Carbon Nos. on PEGA Less than 16·0	16·0	16·3 / 16·4	16·7† / 16·8	16·9 / 17·0	17·3 / 17·4	18·0	18·3 / 18·4	18·9 / 19·1	19·2 / 19·4	More than 19·4
Acid			16:0	16:1		17:0	17:1	18:0	18:1	18:2	18:3

	2	62·4	9·0	5·1	—	1·4	3·2	1·4	5·5	3·4	2·4	6·1

This table represents only acids with 16, 17 or 18 carbon atoms. Acids with carbon Nos. less than 12 are not detectable by this method.
* Expressed as percentage of total.
† This fatty acid did not occur before fixation.
‡ There were two free fatty acid fractions after fixation. Fraction 1 was least polar on thin-layer chromatography.

the fixative, and partly to destruction or modification of lipid so that staining by conventional methods is impossible; if fixation is sufficiently prolonged, many of the unsaturated fatty acids may be polymerized by formation of intermolecular bonds, and converted into a macromolecular network which ceases to behave, either chemically or histologically, as lipid.

These reactions are being investigated further; it is hoped to elucidate the structure of all products, and determine any practical use which the presence of these products in the tissues can be applied to.

PHYSIOLOGY

Thalamic Inhibitory Interneurone

SINCE the investigations of Renshaw[1] and Eccles *et al.*[2] on the central inhibitory action of antidromic impulses in motoneuronal axons, indirect evidence has accumulated which suggests that a similar mechanism occurs at higher levels of the neuraxis[3]. Physiological identification of neural units responsible for such effects has proved to be technically difficult. Andersen *et al.*[4] recently published records of presumed inhibitory interneurones from the ventrobasal complex of the thalamus.

This communication gives a brief account of neurone recordings during the course of a larger series of investigations on striothalamic pathways in the cat. Further investigation will be described in a later article. The specimen records shown were obtained with a 1-μ tip glass micropipette, filled with 2 M potassium citrate. The micro-electrode lead was fed through cathode followers to d.c.—and a.c.—coupled amplifiers. Photographs were taken of the amplified signals as they were displayed on a dual-beam oscilloscope.

In Fig. 1*A* two free sweeps are shown with two "spontaneously" discharging neurones labelled (*r*) and (*i*). Cell (*r*), of considerably larger amplitude, fired at an average of 50 impulses per sec, while cell (*i*) at times followed, or intermingled with, bursts of spike potentials from cell (*r*). This neurone (*i*) fired at 225 impulses per sec. The responses of these two cells to electrical stimulation were studied in the succeeding frames. *B* shows that cell (*r*) could be triggered at lower gain and sweep speed by a stimulus applied to the nucleus ruber. After this initial spike potential a silent period of 60 msec ensued in association with hyperpolarization of the cell membrane. Thereafter a burst of spike potentials followed riding on the peaks of depolarization. In *C*, a stimulus was applied to the internal capsule. Neither antidromic invasion nor synaptic activation of the cell was attained. The unit responded, however, with a short-latency hyperpolarizing potential terminating in a greater burst of late discharges but similar in temporal sequence to that evoked by rubral stimulation in *B*. Frame *D*, in conjunction with *B*, would appear to characterize unit (*r*) as a thalamo-cortical relay cell. Note that in this frame (*D*) a single shock of opposite

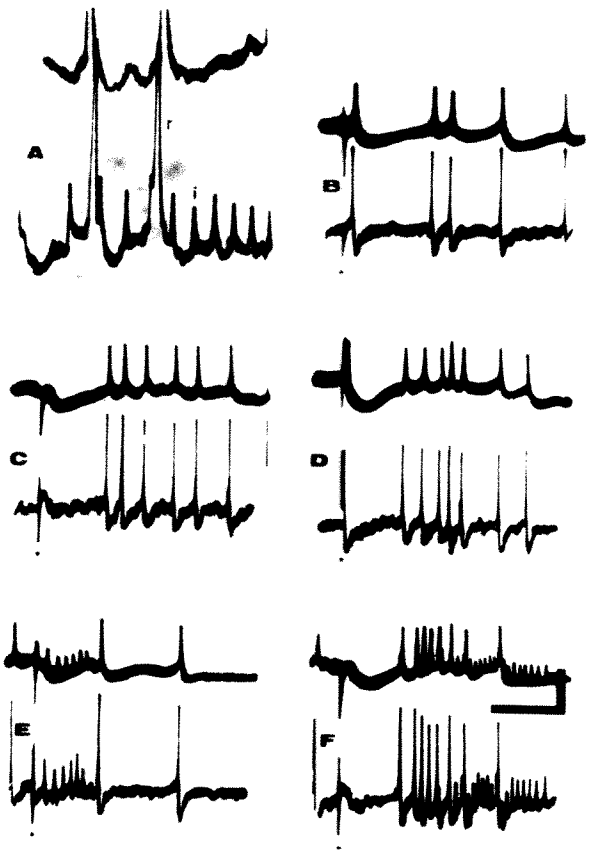

Fig. 1. Illustrating two cells in the nucleus ventralis lateralis of the thalamus firing spontaneously (*A*) and in response to orthodromic rubral (*B*) and antidromic capsular (*C*–*F*) electrical stimulation. Upper trace is d.c. and lower trace is a.c. recording for all frames except *A* in which both traces are d.c. records. Positive is represented as an upward deflexion. Stimulus (*B*–*F*) is marked by a dot. Frames are continuous. Time scale gives 15 msec for *A* and 60 msec for all other records. Potential scale gives 10 mV for all d.c. traces from *B* to *F*. Further description in text

polarity to the internal capsule succeeds in evoking an impulse discharge in less than 1 msec. In *E*, the same stimulus as in *C* failed again to evoke the short latency antidromic spike potential but produced a similar hyperpolarizing potential. In association with the latter, this time the stimulus succeeded in bringing into activity cell (*i*) which is represented in *A* at greater sweep speed and amplification. The hyperpolarizing potential of cell (*r*) and the burst of discharges of cell (*i*) coincided in time and duration. Compare the discharge rate during the following 100 msec in *E* with those of *B*, *C* and *D*. Cell (*i*) already fell within the recording field of the micro-electrode tip at *D*. Observe one single impulse discharge fused with the rising phase of the sixth spike of the relay cell. In *F*, a late high-frequency burst from the relay cell appears to be successfully arrested by a long-lasting (100 msec) barrage of neurone (*i*) discharges. The beginning of activity of cell (*i*) coincides with the slowing down of the relay cell. Toward the middle of the burst of cell (*i*), coinciding with the longest relay cell interspike interval, the rate of discharge was around 300 per sec. The correlation between the frequency of cell (*i*) spike discharges and build-up of the relay cell hyperpolarizing potential can also be observed in this record.

Cell (*i*) would appear to fulfil the criteria postulated in the literature for qualification as an inhibitory interneurone. These illustrations show spike potential characteristics of a thalamic inhibitory interneurone in interaction with a relay cell and its concomitant hyperpolarizing potentials. Judging from the positive polarity of the spike responses of the two cells, it is presumed that the micro-electrode tip was on, or very near, the relay

cell membrane and the interneuronal axon, possibly at the synaptic zone.

A Simple Catheter for Intermittent Intravenous Anaesthesia in Animal Surgery

RECENT allograft experiments on rabbits in our laboratories prompted the development of a simple and safe anaesthetic technique which could be administered by the surgeon to two animals simultaneously. Inhalation techniques require the almost constant attention of another assistant; parenteral barbiturate administration requires repeated and increasingly difficult intravenous injections for maintenance. The following intravenous catheter and continuous technique were therefore devised, based on the standard technique of pentothal induction of anaesthesia in human surgery.

Two No. 25 gauge needles (Yale hypodermic needle, sterile, disposable, No. 25*G*, 5/8, Becton-Dickinson and Co., Rutherford, New Jersey) and a 12-in. length of polyethylene catheter (Clay-Adams polyethylene tubing, No. *PE*20, New York) are used. The hub is pulled off and discarded from one needle, and the catheter is swedged on to it, allowing most of the needle to protrude. The other end of the catheter is swedged to the other whole needle, or is attached to an adapter (Clay-Adams plastic adapter, No. *A*-1025, size *A*). A 2·5-c.c. syringe containing a 5 per cent solution of thiamylal sodium (Surital sodium, Parke-Davis and Co., Detroit, Michigan) is attached.

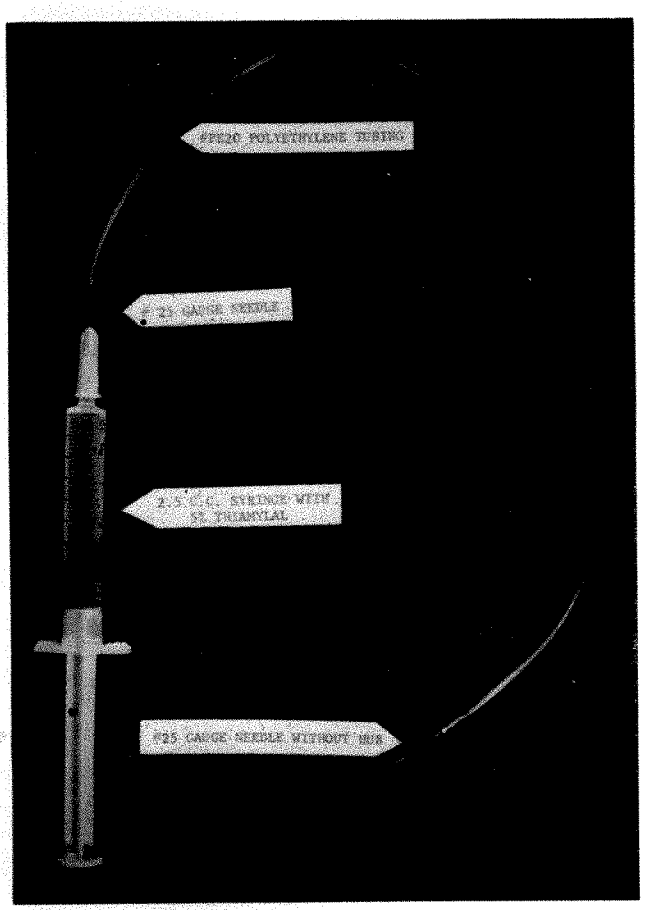

Fig. 1

The distal needle is introduced into an ear vein and taped in place while the rabbit is alert. To induce anaesthesia, 0·5–0·8 c.c. of barbiturate is injected over a period of 30 sec. For maintenance, repeated doses of 0·2 c.c. can be given, usually about every 5–10 min. The taped catheter allows the rabbit's head to move without dislodging the needle; the syringe allows the surgeon himself to maintain satisfactory anaesthetic levels. For sterile procedures, the syringe can be wrapped in a sterile towel or glove in the surgical field.

We have found this technique inexpensive and effective in more than 500 laparotomies and graft exchanges.

Blood Volume of the Nasal Salt Glands and other Glands and Organs of Sea Gulls

THE ability of an organ to function is dependent on its blood supply. The salt gland operates as a highly efficient sodium pump capable of secreting about 8 sodium/adenonine triphosphate[1,2] and its secretion has a concentration of sodium ranging from 400 to 1,200 m.equiv. sodium chloride/l. (ref. 3). The unique function of the avian salt gland and the lack of information on its blood volume prompted this investigation.

Six sea gulls (Laridae) captured along the northern California coast were used. The gulls were maintained in a screened flight cage and given canned dog food to eat and 3 per cent sodium chloride to drink. Their wing vein was cannulated with a short piece (about 8 in.) of 'Teflon' tubing, A.W.G. No. 22, and 5 ml. of blood withdrawn into a heparinized syringe. The blood was incubated with about 100 μc. of chromium-51-labelled sodium chromate at 25° C for 1 h. The labelled erythrocytes were packed by centrifugation and the supernate discarded. The cells were washed twice in physiological saline by alternately suspending and packing by centrifugation. The erythrocytes were finally resuspended in physiological saline to about their original concentration and injected into the cannulated wing vein. After 15 min a 1-ml. sample of blood was drawn, and the gull was killed by rapidly injecting 2 ml. of 6 per cent pentobarbital sodium. The organs were dissected and care was taken to minimize any contamination of their surfaces with blood or any squeezing of blood from the organ. The haematocrit and radioactivity of triplicate 0·1-ml. portions of blood were determined using a lead-shielded well-scintillation counter, and the radioactivity per unit volume of whole blood calculated. The whole organ or two representative portions were weighed to the nearest mg, the radioactivity measured with a scintillation counter, and the blood volume calculated.

Of the twelve glands and organs examined, the brain had the lowest blood volume per unit weight, while the lung had the greatest (Table 1). Both right and left salt glands had a blood volume of about 25 μl./g, which was comparable with that of the thyroid, adenohypophysis, Harderian gland, pancreas and the pectoralis muscle. However, both the cranial and caudal lobes of the kidney had a blood volume about 4·5 times greater than that of the salt glands. One noticeable reason for this marked

difference in blood volume between these two important excretory organs of the gull was the larger venous pool of blood present in the veins of both kidney lobes. The liver with its large venous channels and sinusoids had the second largest blood volume per unit weight. Many of the blood volumes reported here for the sea gull are comparable with values reported for similar organs in various mammals and fowl[4]. Therefore, the data of the gulls appear to be valid, even though there are gross errors resulting from surface contamination, oozing of blood, and the tendency for venous pooling due to death from a barbiturate.

Table 1. BLOOD VOLUME OF THE NASAL SALT GLANDS AND OTHER GLANDS AND ORGANS FROM SEA GULLS

Organ	μl./g organ ± S.E.
Brain	9·1 ± 1·3
Nasal salt gland, right	25·6 ± 4·6
left	26·5 ± 4·9
Thyroid	28·1 ± 1·7
Adenohypophysis	29·5 ± 1·3
Harderian gland	35·9 ± 5·2
Pancreas	38·2 ± 7·1
Pectoralis muscle	38·5 ± 6·9
Adrenal	62·5 ± 13·6
Lacrimal gland	80·3 ± 15·8
Kidney, cranial lobe	113·1 ± 23·8
caudal lobe	112·0 ± 18·1
Liver	159·9 ± 32·7
Lung	573·6 ± 105·4

Although this report has presented data on the static blood volume of the nasal salt gland, there are no reports dealing with the circulatory rate of this gland. This is mainly because of the difficulty in approaching the blood vessels supplying the gland. Sufficient information, however, is available to estimate the circulatory rate of these glands.

A recent enzymatic study[5] of the salt gland has indicated that the energy yield for the gland is about 148 μmoles adenosine triphosphate/g/min, of which one-third would be required to support a secretory rate of 400 μmoles sodium/g/min. Avian blood contains about 8·3 μmoles glucose/ml., and each μmole glucose yields 38 μmoles adenosine triphosphate. Assuming that 10–25 per cent of the blood glucose is removed by the gland, a blood flow of 1·9–4·7 ml./min/g would be required to supply the total energy for the gland. This estimated flow for the nasal salt gland is comparable with the 4 ml./min/g flow in human and dog kidneys[6]. With a static blood volume of 25 μl./g the blood of the salt gland would be replaced 80–200 times a minute—essentially a total replacement with each cardiac output.

Potential and Resistance Measurements of Rat Liver Cells *in situ*

ALTHOUGH information is available[1–4] concerning the potentials of liver cells *in situ*, no systematic investigations of the electrophysiological properties of these cells have yet been reported.

In a series of experiments on this topic, we measured the potential by means of intracellular micro-electrodes, drawn by hand, of 'Supremax' glass, and filled with 3 M potassium chloride. The rats weighed 150 g and were anaesthetized with urethane. The abdomen was then opened and the liver immobilized. A plastic ring, 8 mm in diameter, was placed on the liver surface and filled with medium through which the penetrations were made[4]. The reference electrode was situated in the abdomen and a check was made that the resistance between medium and reference electrode was negligible. The standard medium had an ionic composition (in mmoles): sodium chloride, 129; potassium chloride, 5·6; calcium chloride, 2·2; magnesium sulphate, 0·5; sodium orthophosphate, 1·1; sodium bicarbonate, 11·9; and glucose, 10.

When we undertook our experiments, it was already known that liver slices and the liver *in situ* lose about 50 per cent of their potential within 1 h of the death of the animal[1–4]. In our experiments, these results were confirmed. We found a membrane potential of 50·69 ± 1·33 mV (mean ± standard error) in eighty-three measurements on four animals. 30 min after clamping the trachea of the animal the potential had dropped to half its original value. It was now of interest to determine whether this decrease in membrane potential after the death of the animal was characteristic for the membrane of the liver cell or was a general characteristic of all rat cells. To decide this question, simultaneous measurements of the membrane potential of liver cells and of fibres of a superficial abdominal muscle were made before and after the death of the animal. Fig. 1 shows the results of these measurements. While the potential of the liver cells drops within 20 min from 56 mV to 27·5 mV, the potential of the muscle stays constant over the same period. This difference in the time course of changes in the membrane potential of liver and muscle indicates a difference in the membrane properties of both kinds of cells.

Measurements of the membrane resistance were made with double-barrelled micro-electrodes[5], using one barrel as polarizing electrode and the other as recording electrode. The common resistance of both barrels was determined in the bathing solution before every measurement. This was then subtracted from the total measured resistance. The diameter of the rat liver cell was determined from cells in the smear and it was assumed that the cells were spherical with a diameter of 50μ. On the basis of these data, a value of 37 Ωcm² was obtained as a mean for the membrane resistance (R_m) of the rat liver cells. This resistance is much lower than the membrane resistances known from excitable cells. However, there is a good agreement with the value of 30 Ωcm² published for rat thyroid cells *in situ*[6] and the values of 3–10 Ωcm² for glial cells in tissue culture[7]. A rectification of the membrane of the liver cell could not be detected in the current range of ± 10^{-7} amp. With the low membrane resistance found in the rat liver cell, the expected time constant cannot be

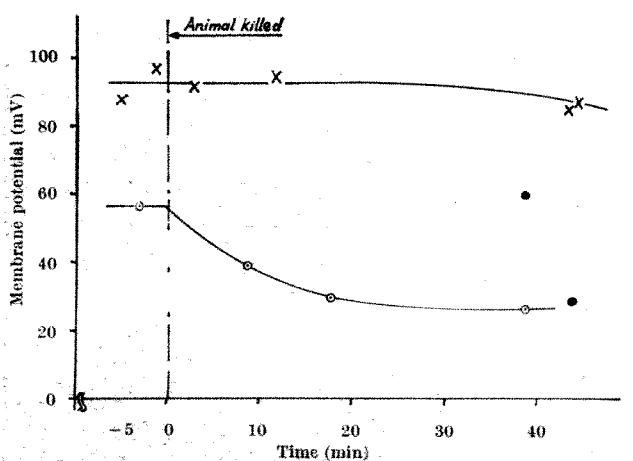

Fig. 1. Simultaneous recording of membrane potentials of the liver (○) and an abdominal muscle (×) of the rat. At the time $t = 0$ the animal was killed by clamping the trachea. Each point is a mean from four to twenty-two measurements

detected with double-barrelled micro-electrodes, even if a compensatory network is used[8]. For this reason, no data about the membrane capacity were obtained.

Preliminary experiments were carried out to determine the relation between the membrane potential and the ionic composition of the bathing solution. It is already known that the potential of the thyroid cells of the rat scarcely responds to an increase in the concentration of external potassium[6]. In the case of liver, increase in $(K)_0$ to 40 mM reduced the membrane potential by 7·2 mV; reduction of the sodium concentration to 70 mM raised the membrane potential by 7·1 mV. Substitution of the chloride by sulphate and reduction of the sodium concentration to 70 mM resulted in a decrease of 1·7 mV. Although the reports of the internal ionic concentration of the rat liver are not consistent, a rough approximation to the measured potential changes could be obtained by assuming the following values for the relative permeability constants in the Goldman equation: P_K, 1; P_{Na}, 0·3; and P_{Cl}, 1·5. These coefficients were calculated by means of the estimated intracellular ion concentrations: (K), 180 mM; (Na), 20 mM; and (Cl), 5 mM. The most impressive feature of these permeability constants is the high sodium permeability. For the cells of the rat thyroid, a similar high value for P_{Na} of 0·12 has been reported[6]. It is possible that the high sodium permeability and the low membrane resistance are characteristics of inexcitable cells.

We thank Prof. J. Leyden Webb for his encouragement throughout this investigation and Miss Elaine Majeski for her valuable technical assistance.

Distribution of Colloidal Particles in Extracellular Space and Synaptic Cleft Substance of Mammalian Cerebral Cortex

ADJACENT plasma membranes of neurones and glia in the central nervous system are separated by a 150–200 Å space which has been estimated to represent 3–5 per cent of brain volume[1,2]. Recent electron microscopic investigations using freeze-substitution methods[3] and perfusion with aldehydes[4] indicate that a great variability in the amount of extracellular space can be obtained in central nervous tissue. The functional significance of this intercellular space in the movement of ions and small molecules between vascular and neuronal elements has been a subject of considerable controversy. However, investigations of changes in brain volume leading to cerebral oedema or dehydration have not revealed significant alterations in the dimensions of the intercellular gap at a time when marked changes in glial cell volume can be demonstrated[5]. These and other investigations[6,7] have been viewed as evidence that the extracellular compartment of brain is represented largely by glial elements which are immediately involved in exchange of ions and metabolites between blood and neurones. In contrast to this, investigations of the mechanisms of ionic transport in the leech central nervous system have indicated that changes in spike potentials of neurones subsequent to removal of environmental Na^+ are attributable to rapid diffusion of administered solutions by way of extracellular spaces[8]. No evidence for participation of glial elements in neuronal effects of administered low Na^+ solutions was obtained in these investigations of the leech nerve cord.

We have investigated the functional properties of the extracellular space in the mammalian cerebral cortex by following the sequential passage of saccharated iron oxide particles (about 80–100 Å in diameter) from small sub-pial, intracerebral depots to intravascular locations. Experiments were performed on adult cats under pentobarbital anaesthesia. Quantities of saccharated iron oxide contained in volumes less than 0·1 ml. were injected into the most superficial portions of suprasylvian neocortex at several sites. Samples of tissue at the site of injection or a few millimetres away were removed at different times up to 20 min following injection. Samples were fixed for 1 h with cold 1 per cent osmium tetroxide at *p*H 7·3 buffered with Millonig's solution[9] and embedded in 'Epon 812' (ref. 10).

As might be expected, distortion of tissue and tissue spaces was found at the site of injection of marker particles. However, tissue examined from sites 1–3 mm from points of injection appeared intact in all respects. Elements and interneuronal relationships were entirely comparable with those described in previous electron microscope investigations of adult cat neocortex[11]. In these locations marker particles were found exclusively in the intercellular spaces (Fig. 1) It is of interest that in many instances particles were preferentially located at the synaptic clefts of typical axo-dendritic synapses (Fig. 2). Particles of saccharated iron oxide appeared to concentrate

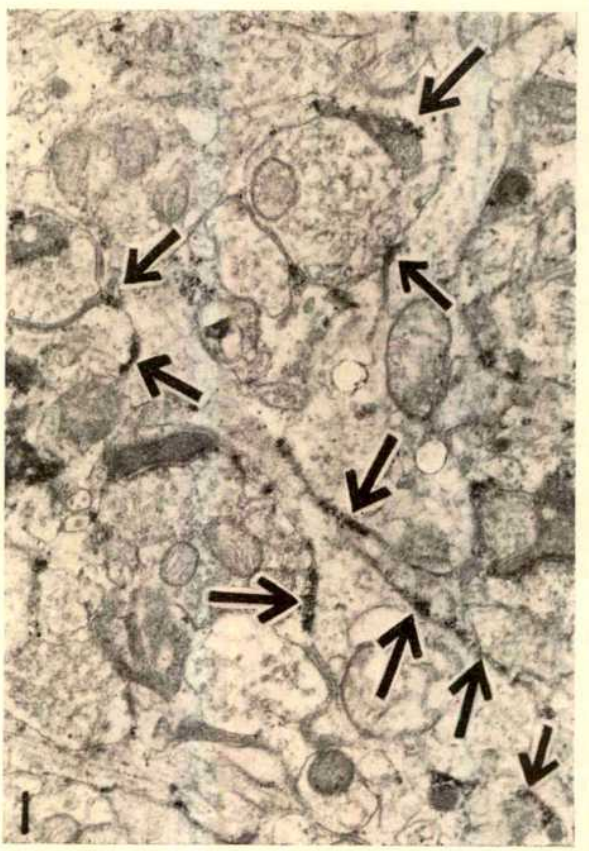

Fig. 1. Electron micrograph of a section of neuropil in the superficial neocortex of the cat. Twenty minutes before fixation, saccharated iron oxide was injected directly into the cortex and formed a small bleb. This tissue was removed about 2 mm from the bleb. Accumulations of marker particles (at arrows) are present in the intercellular spaces of the neuropil. (× *c.* 20,000)

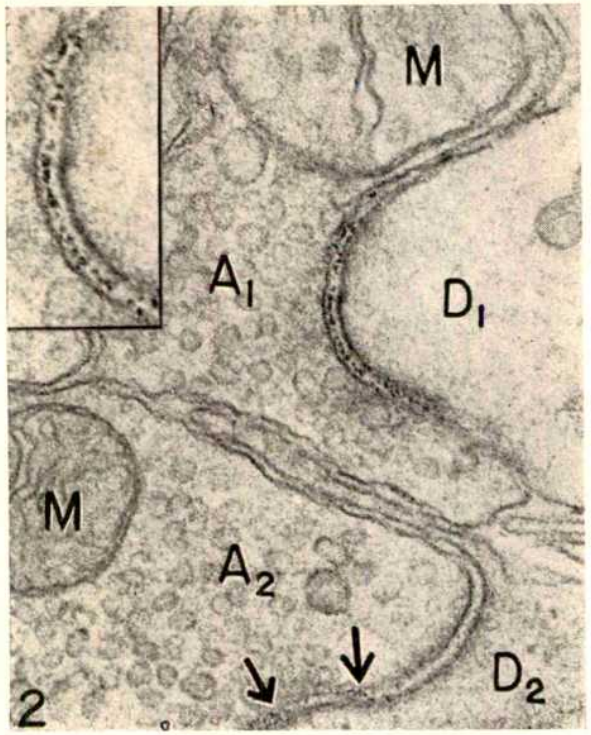

Fig. 2. Electron micrograph of portions of two axo-dendritic synapses (A_1-D_1 and A_2-D_2) taken from a preparation similar to that described in Fig. 1. In many instances marker particles were preferentially located at the synaptic clefts. In a typical axo-dendritic junction formed by axon A_1, filled with synaptic vesicles, and dendrite D_1, the synaptic gap contains particles which are concentrated in linear array. (See higher magnification in the inset on the upper left.) While particles are also present in the synaptic cleft (at arrow) of the junction formed by axon A_2 and dendrite D_2, the linear arrangement is not apparent in this tangential profile. *M*, Mitochondria (× *c.* 56,000, inset = × *c.* 111,000)

in a linear array in the synaptic cleft equidistant from pre- and post-synaptic membranes (Fig. 2 and inset). Within a period of 20 min, marker particles were also observed in intravascular locations. None was noted in the cytoplasm of glial or neural elements during this period.

The results described here provide direct evidence that the extracellular space of the mammalian cerebral cortex is patent to the passage of colloidal particles. Similar findings have been reported in spinal ganglia of the toad[12]. A somewhat different situation is encountered at synaptic sites where marker particles are concentrated by the sub-synaptic cleft substance. Similar adherence of marker particles on to cell surfaces was originally demonstrated with the polysaccharide-rich coated membranes of amoeba[13] and is now recognized to be a general property of cell surfaces that have an 'extraneous coat'[14] or 'glycocalyx'[15]. The synaptic cleft substance at the neuromuscular junction has properties characteristic of mucopolysaccharides—periodic acid–Schiff-positive, diastase-resistant material has been demonstrated there[16]. Furthermore, Birks[17] has observed adherence of thorium dioxide particles to this material. Hess[18] has suggested that periodic acid–Schiff-positive material represents the 'ground substance' or the interstitial component of the central nervous system. Our results do not permit inferences concerning the possible nature of the intercellular material at non-synaptic sites. However, the observations that marker particles adhere to synaptic cleft substance suggest that there is a relatively high concentration of mucopolysaccharide material at these locations in the mammalian brain. If the synaptic cleft substance is indeed rich in mucopolysaccharides, it is reasonable to expect that this material is of functional significance in synaptic transmission. Such specialized sites of glycocalyx formation might provide a suitably structured matrix for effecting cohesion between pre- and post-synaptic membranes[19] as well as provide a basis for immuno-chemical 'sensing' of functionally related synaptic pathways. The presence of mucopolysaccharide material at synaptic sites could explain the affinity of immunologically active substances for synaptic loci in tissue culture preparations of mammalian cerebral cortex[20].

RADIOBIOLOGY

Induction of Lung Tumours by the Action of Radiation and Urethane

IN a recent paper, Foley and Cole[1] reported some investigations of the incidence of lung tumours in mice exposed to different doses of X-rays, followed by an injection of urethane. They assumed that the lung tumours are induced by the urethane and that the X-rays have an inhibitory effect on the tumour incidence. On this basis they interpreted their results as showing a dependence of this inhibitory action on radiation dose with a threshold of about 300 rads.

It seems to us that these results can also be interpreted in an entirely different way, that is, that the main action of urethane is not to induce tumours but to promote, or to speed up, the appearance of potential tumours induced by radiation or other causes.

Foley and Cole present their results as two sets of data: the mean number of tumours per tumour-bearing animal, and the percentage of animals in which tumours were observed. Actually, these two are not independent but closely related end-points. The number of animals with zero, one, two, etc., tumours follows a Poisson distribution based on the mean number of tumours per animal from the whole population. Using this latter criterion, the results of Foley and Cole were recalculated and are presented in Table 1.

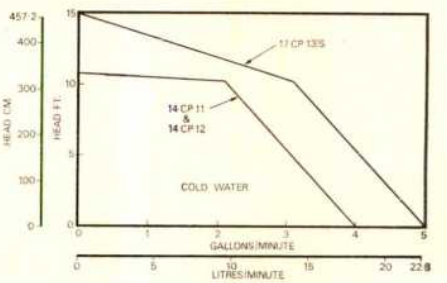
Quickfit

Portable Glass Circulating Pumps

MANY INDUSTRIAL USES

These 90mm bore, portable, low-speed centrifugal pumps provide compact units for pumping a wide range of corrosive and high-temperature liquids. Their rates of flow against head make them suitable for laboratory use and for a wide variety of applications throughout the general engineering, chemical and chemical engineering industries.



A NEW SEAL DRIVE GIVES STRENGTH and RELIABILITY

The pumps incorporate a new form of seal drive. The glass loaded P.T.F.E. face of the seal is spring-loaded and revolves against a static alumina ceramic disc to ensure leak-proof joints, maximum corrosion resistance and minimum wear.

CORROSION & HEAT RESISTANCE

Only heat and chemical resistant borosilicate glass, P.T.F.E. and alumina ceramic come into contact with liquids being pumped. The polyurethane paint finish on bases and covers ensures a high degree of chip and corrosion resistance.

Table 1. MEAN NUMBER OF TUMOURS PER MOUSE

1 Dose (rads)	2 X	3 $X+U$	4 $\frac{X}{C}$	5 $\frac{X+U}{U}$	6 $\frac{X+U}{X}$
0	0 27	3·1	1	1	11·5
100	(0·11)	3·1	(0 41)	1 0	(28·2)
300	0·30	3·5	1·11	1·13	11 7
500	0·10	1·2	0·37	0·39	12 0
700	0 08	0 8	0 30	0·26	10 0

The second column in Table 1 gives the mean number of tumours in mice which were exposed to X-rays only (X); the first line in this column represents the spontaneous incidence in the control population (C). It will be noted that the value for the incidence after an exposure to 100 rads is comparatively low; considering that this figure is based on the observation of only one tumour, an incidence more than twice this value could easily be within the experimental error. Column 3 gives the tumour incidence in mice which were exposed to X-rays and then injected with urethane ($X + U$); the first line represents the incidence in mice which received urethane alone (U). In columns 4 and 5 we give the ratios $\frac{X}{C}$ and $\frac{X+U}{U}$, and it is seen that, with the foregoing exception, the corresponding values in the two columns are practically identical. The last column shows that the ratio $\frac{X+U}{X}$ is constant within the experimental error, with an average value of 11·3, if the 100-rad data are omitted.

Although the errors in an experiment using a small number of animals are necessarily large, the figures in columns 4 and 5 give an indication of an initial increase in tumour incidence with radiation dose, followed by a decrease. This is as expected from the variation of the incidence of radiation-induced tumours with dose[2]; it shows a "turnover" point at a certain dose, which is the result of the interaction between the processes of tumour induction and cell killing by radiation. Combined with the observation that for each dose the figures in columns 4 and 5 are the same, this may be taken as evidence that in both cases the same potential tumour population was involved, and that the action of urethane was simply to promote the appearance of tumours already induced by radiation or resulting from other causes. The mean value of 11·3 from column 6 is a measure of the promoting action of the urethane; naturally, it depends on the amount of urethane used.

It should be mentioned that a study of the combined action of chemical carcinogens and radiation has been carried out in this laboratory for the past three years[3]. The results of these investigations fit in well with the model proposed here. The possibility that urethane acts as a promoting agent has been discussed before[4], particularly in relation to leukaemogenesis[5].

The accuracy of the experimental data is not sufficient to exclude a direct tumour-inducing action by urethane, and a combination of both types of action is possible. It is hoped that work now in progress will help to clear up this point.

Apart from the fundamental significance of the proposed model, the promoting action of urethane can be utilized to facilitate the study of the effects of radiation on lung tumour incidence, by using urethane as a means of increasing the number of tumours observed.

Degradation of Ribonucleic Acid in Dilute Solution by Ionizing Radiation

So far, no absolute figure has been available for the sensitivity of ribonucleic acid to ionizing radiation in dilute solution. Ginoza and Norman[1] were able to show that tobacco mosaic virus (TMV) RNA is sensitive to ionizing radiation such that one ionization within its structure renders it inactive. However, their work was not designed to investigate the action of active radicals formed in water by radiation.

This report describes experiments in which the degradation of RNA in dilute solution was observed and the number of breaks produced in a unit of molecular weight 10^6 estimated by comparison with the thermally induced scission of RNA. It is found that 0·8 breaks are produced for each 100 eV released in solution. Direct comparison shows RNA to be about twice as sensitive as DNA to this type of action.

The technique for observing the degradation of RNA was the measurement of the turbidity of the precipitate produced by 10 per cent trichloroacetic acid (TCA). Large hydrogen-bonded macromolecules form a precipitate with 10 per cent TCA and the resulting turbidity develops to a maximum in a matter of a few minutes at 37° C. The amount of undegraded RNA can be measured by observing the turbidity in a simple spectrophotometer at 425 mμ wave-length. Calibration in terms of different concentrations of the original RNA sample makes it possible to convert any figure into concentration of undegraded RNA. In order to estimate the number of scissions produced the thermal degradation of RNA was first measured. This has been investigated by Ginoza, Hoelle, Vessey and Carmack[2]. Using 10^6 as the reference molecular weight of RNA, the number of breaks per unit time can be derived from their data for any temperature. We investigated the loss of TCA precipitate turbidity at 85° C, 100° C and 125° C and, using the figures for RNA scission derived from Ginoza *et al.*, the results given in Fig. 1, relating residual undegraded RNA to number of

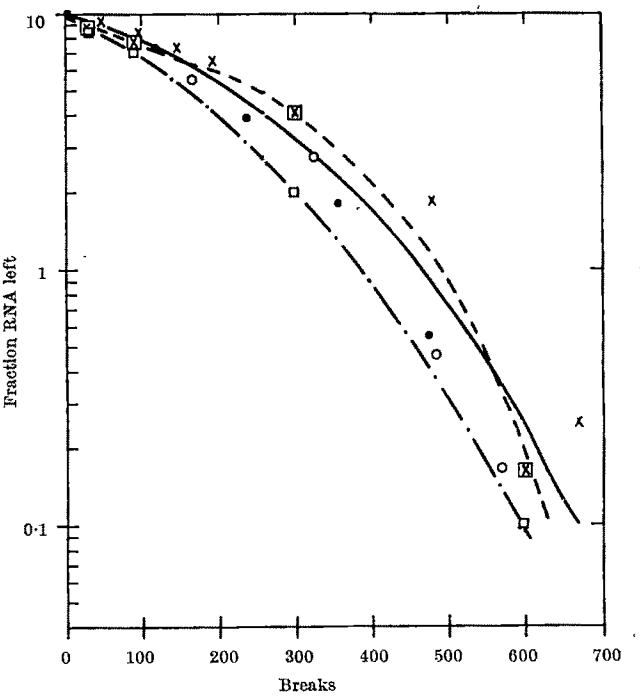

Fig. 1. The effect of heat applied at three different temperatures on the fraction of RNA which is insoluble in trichloroacetic acid. The number of breaks per million molecular weight unit is estimated from Ginoza *et al.* Approximate theoretical values for ten (– – – –) and fifteen (– – ·–) nucleotides remaining in the precipitate are shown for comparison. ×, 85° C, ○, 100° C, ●, 125° C

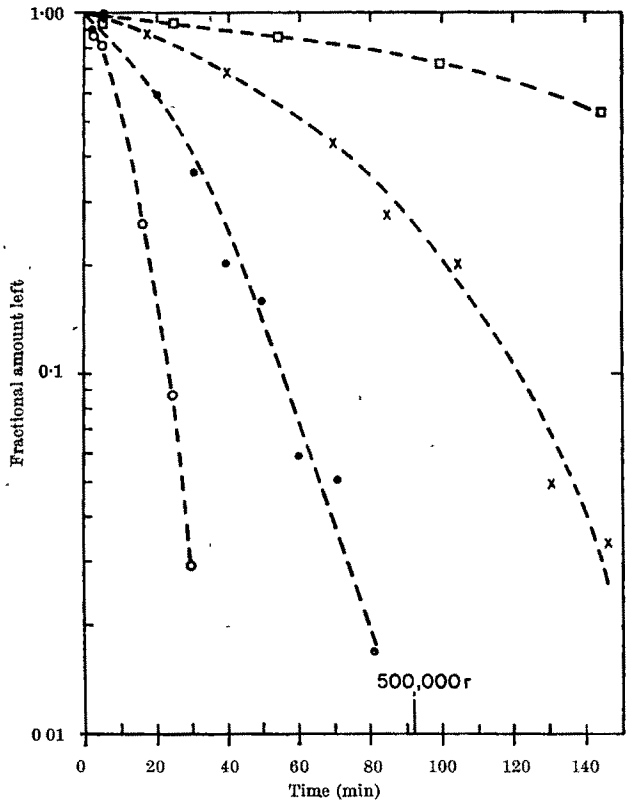

Fig. 2. The effect of exposure to cobalt-60 γ-radiation on RNA in dilute solution. Four concentrations are shown and the fraction left in the TCA precipitate is shown as a function of time in the source. From Fig 1 the breaks produced can be estimated and a yield of breaks per 100-eV radiation energy calculated ○, 0 25 mg/ml., ●, 0 5 mg/ml.; ×, 1·0 mg/ml ; □, 2·0 mg/ml.

breaks, were obtained. An approximate theory for the amount of residual precipitate can be devised as follows.

Let us suppose that the RNA is a long chain of nucleotides, and let us suppose also that the average number of breaks per nucleotide is X. Then if we are to have an intact chain of n nucleotides, starting from one end, we must fail to break the first n nucleotides, for each of which the probability of miss is e^{-x} or a total probability of e^{-nx}, and we must succeed in breaking the $(n + 1)^{th}$. This is a probability of $(1 - e^{-x})$ or, because x is small, X. So both events together have a probability of xe^{-nx}. The weight of precipitate is proportional to n, so the function describing the weight of chains of length n is nxe^{-nx}. If graphs of nXe^{-nx} are plotted versus n, the proportion of chains can be estimated for each value of X. Doing this, and recalling that in Fig. 1 the number of breaks is given for 10^6 molecular weight, so that the actual number of breaks plotted is 3,000 X, we find theoretical curves shown as dotted lines in Fig. 1. The upper curve is for ten nucleotides as the smallest number to yield a precipitate. The lower is for fifteen. It seems likely that ten fits better and it is suggested that TCA precipitates polynucleotides of chain-length exceeding ten.

To observe radiation degradation four concentrations of RNA, 2, 1, 0·5 and 0·25 mg/ml., were exposed to radiation from a cobalt-60 source delivering 5,500 r./min. The fractional amount left in each case after various times of exposure is shown in Fig. 2. From Fig. 1 the number of breaks can be determined. The number of breaks for various doses and various concentrations of RNA is shown in Table 1. The number of breaks produced in a unit of 10^6 molecular weight per 100-eV energy released, the G-value of radiation chemistry, is found to be $0{\cdot}8 \pm 0{\cdot}1$.

In order to observe the effect of this type of radiation on DNA by this method, a comparable experiment was

Table 1. BREAKS INDUCED IN RNA AND DNA IN PHOSPHATE BUFFER, *p*H

performed on heat-denatured (and presumably single-stranded) DNA and normal DNA. The results are shown in Fig. 3. For the single-stranded form the behaviour is very much like that of the RNA with the difference that the G-value for a break is less by about a factor of two. The figure is in reasonable agreement with 0·45 for the sugar phosphate rupture obtained by Scholes, Ward and Weiss[3]. The behaviour of double-stranded DNA is somewhat different. There is an initial increase in the amount of precipitate formed up to about 130 breaks. After this, the behaviour is very much like single-stranded DNA. The increase in precipitate is not unexpected, as relatively large pieces of DNA would be expected to be detached from the double-stranded condition and give an increase in the DNA bound to the TCA to form the precipitate.

The foregoing figures were obtained in 0·1 M phosphate buffer, *p*H 7. If similar experiments are conducted in

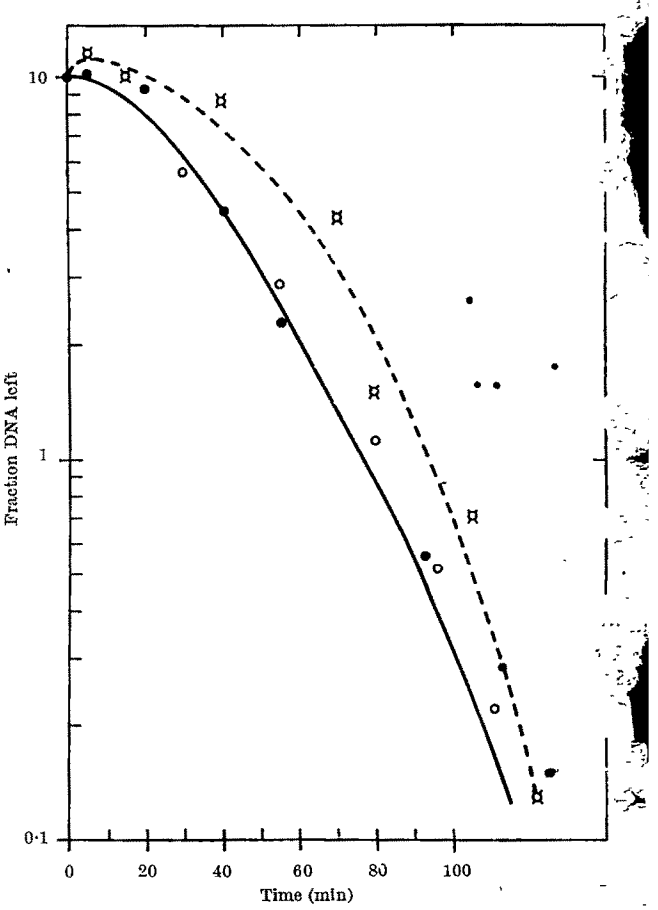

Fig 3. Data similar to Fig. 2 for radiation action on single-stranded and normal DNA. There is a slight increase in precipitate as the random radiation-induced breaks appear in the case of normal DNA but not for the single-stranded DNA. ———, Heat-denatured DNA; – – – – normal DNA

tris(hydroxymethyl)aminomethane-chloride buffer, the *G*-values for both RNA and DNA are reduced by approximately a factor of ten. This is in agreement with the observation by Ginoza[4] of a high X-ray sensitivity for single-stranded virus nucleic acids in phosphate buffer.

I thank Mrs. Carol Duff for performing the assays and Mr. John Swez for discussions and suggestions. The work was supported by a grant from the U.S. Atomic Energy Commission.

Metabolic Dissociation of the Parent and Daughter Radionuclide Pair, Barium-140 and Lanthanum-140

BARIUM-140, one of the γ-ray emitting isotopes in fall-out, has a physical half-life of 12·8 days. It decays to lanthanum-140 which emits γ-rays and has a physical half-life of 40·3 h. Barium-140 contributes approximately 10 per cent of the total fission product activity at 10 days and 30 days after production. About 12 per cent of the total radioactivity of fission products aged for 10 or 30 days after production is lanthanum-140 (ref. 1). Therefore, barium-140 and its daughter contribute significantly to that portion of the fall-out radiation dose caused by radionuclides of short or intermediate half-lives.

In view of the close proximity of barium and lanthanum in the Periodic Table (barium, Group 2*a*, atomic number 56; lanthanum, 3*b*, atomic number 57), one would reasonably expect similarities in their physicochemical properties and physiochemical behaviour. Therefore, it is generally considered that the distribution of the radionuclides of barium and lanthanum is similar, and the parent radionuclide (barium-140) is present in transient equilibrium with its daughter (lanthanum-140) after administration of barium-140–lanthanum-140. Although there is close resemblance in the excretion, distribution and retention of barium and lanthanum in mammals, quantitative differences have been reported in the metabolism of the radionuclides of barium and lanthanum[2,3]. Therefore, a question arises whether the parent and daughter radionuclides are selectively metabolized by cells and tissues.

A knowledge of the metabolism of the parent (barium-140) in relation to that of the daughter (lanthanum-140) is essential in order to estimate the total internal radiation hazard due to barium-140–lanthanum-140, because the parent and daughter decay at different rates. Furthermore, the photopeak energies of barium-140 (0·304, 0·539 MeV) are so close to those of lanthanum-140 (0·329, 0·489 MeV) that it is not possible to resolve and identify the photopeaks of both parent and daughter isotopes simultaneously by γ-scintillation spectrometry[1]. Lanthanum-140 is measured by its characteristic gamma radiation at 1·6 MeV, which is used to assay barium-140–lanthanum-140 in the present experiments. The physical decay patterns of (1) barium-140–lanthanum-140 excreted in the urine in the first 4 days, and (2) barium-140–lanthanum-140 accumulated by rat tissues (bone, kidney, blood) in 4 days after intraperitoneal administration of barium-140–lanthanum-140 have been determined to evaluate the metabolic dissociation of the parent and daughter radionuclides *in vivo*.

The period of 4 days after the intraperitoneal administration of barium-140–lanthanum-140 was selected for our investigations for the following reasons. The experiments on whole-body retention of barium-140–lanthanum-140 after intraperitoneal injection indicate that: (1) rats excrete no barium-140–lanthanum-140 after the fourth day; (2) the parent and daughter radionuclides are in transient equilibrium in the barium-140–lanthanum-140 which is retained by the animals after the fourth day of administration; and (3) the peak concentration of the gamma activity is found in the bones (critical organ) on the fourth day after the injection of barium-140–lanthanum-140.

White male rats of Sprague–Dawley strain weighing between 317 and 342 g were injected (intraperitoneally) with 1·52 μc./kg of carrier-free barium-140–lanthanum-140 as chlorides in normal saline. The sample of barium-140–lanthanum-140 was aged until transient equilibrium was attained between the parent and daughter radionuclides. At the end of 4 days, the animals were decapitated and the blood was drained into a heparinized beaker. The bones (humerus, ulna, radius, femur, tibia and fibula) and the kidneys from each animal were dissected immediately. The same tissues from all animals were combined and dissolved in a nitric acid–dioxane–water system as described elsewhere[4]. The physical decay patterns of the nuclide pair, in various tissues, and in a standard sample of barium-140–lanthanum-140, administered to the animals were determined simultaneously by standard γ-scintillation spectrometric methods[5]. The gamma activities of the standard sample, as well as the solutions of tissues on various days, were expressed as a percentage of their gamma activities on the first day, the day of death. Each value in Figs. 1 and 2 is obtained from a pooled sample of at least five animals.

The physical decay patterns of the standard sample of barium-140–lanthanum-140, and barium-140–lanthanum-140 accumulated by bone and kidney, are shown in Fig. 1. The decay pattern reported for pure lanthanum-140 is shown in the same figure for comparison. The physical half-life of barium-140–lanthanum-140 found in the kidneys (48 h) is considerably shorter than the 'effective physical half-life' of administered barium-140–lanthanum-140 (14 days). The amount of gamma activity in the blood at the end of the fourth day is very small and has an effective physical half-life of about 48–52 h. The effective physical half-life of barium-140–lanthanum-140 in the bone (15 days) is nearly equal to that of the injected barium-140–lanthanum-140 (14 days). These observations suggest that (1) the parent and daughter radionuclides in the bone are in transient equilibrium and (2) the blood and kidney retain the daughter (lanthanum-140) preferentially.

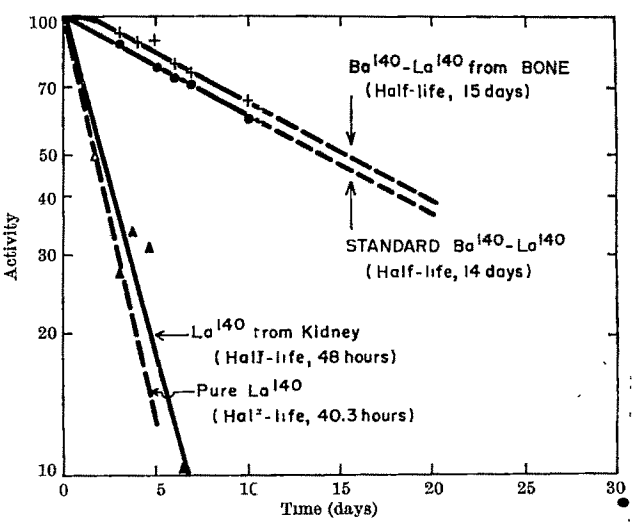

Fig. 1. Decay patterns of barium-140–lanthanum-140 accumulated by rat tissues in four days after intraperitoneal administration. Dose, 1·52 μc./kg

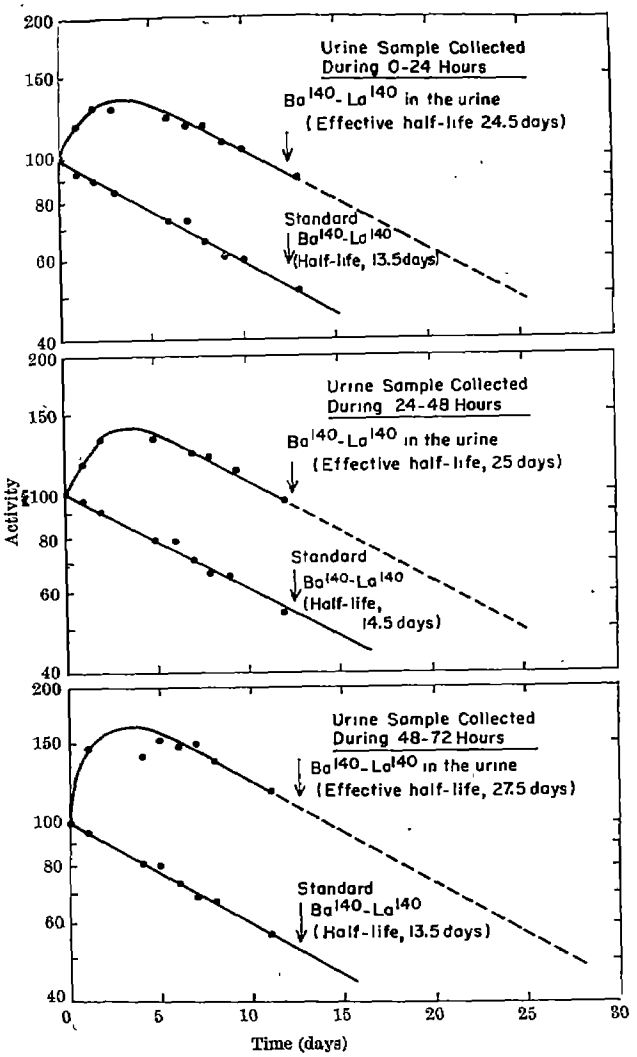

Fig. 2. Decay patterns of barium-140–lanthanum-140 excreted in the urine by the rat after intraperitoneal administration. Dose, 1·52 μc./kg

The decay patterns of barium-140–lanthanum-140 excreted in the urine are plotted in Fig. 2. The effective physical half-lives of barium-140–lanthanum-140 (24·5–27·5 days) in the urine samples collected during 0–24, 24–48, 48–72 h after the administration of the isotopes are longer than the physical half-life of injected barium-140–lanthanum-140. The increase in the activity of barium-140–lanthanum-140 in urine samples during the early period of the decay curve is due to the accumulation of the daughter lanthanum-140 due to the disintegration of the parent barium-140. This behaviour corresponds to the increase in activity of barium-140 separated chemically from the daughter. The amount of barium-140–lanthanum-140 in the urine over the period of 3–4 days is very small and it has an approximate physical half-life of 25–28 days. On the fourth day the gamma activity in the blood is small (see above). These observations suggest that the parent is preferentially eliminated in the urine.

Our results indicate that although barium and lanthanum occupy adjacent positions in the periodic table and resemble each other in many of their physicochemical properties, some rat tissues show differential transport between barium-140 and lanthanum-140. Selective metabolism of closely related parent and daughter radionuclides is an important and interesting technique for the investigations of cell and tissue transport systems.

This work was supported partially by contracts with the U.S. Army and the U.S. Atomic Energy Commission. I was supported in part by faculty fellowships from Mead Johnson and Co., and the Squibb Institute for Medical Research during the period of this investigation. I thank Mrs. L. K. Owens for technical assistance and Drs. G. R. Meneely and R. M. Heyssel for the use of facilities at the Radio-isotope Center.

Effects of Fast Neutrons on Eye Colour Mutations in *Dahlbominus*

VERY little information is available on the effects of neutrons on mutagenesis in female germ cells. In mice, published work with fast neutrons at high and low intensities has been confined to the irradiation of spermatozoa for the induction of dominant lethals[1], and to spermatogonia for specific locus mutations[2,3]. In insects, however, relative biological effectiveness (RBE) of 2–4 has been demonstrated in *Mormoniella* adult females for recessive eye colour mutants following high doses of fission neutrons[4], and higher values for low doses. Similarly, acute doses of 14 MeV neutrons have an RBE of 1·2 for recessive visible mutations in silkworm oogonia[5], while fission neutrons have RBEs of 2·5–3 (ref. 6). This communication presents data on the mutagenic effects of 14 MeV neutrons as compared to cobalt-60 gamma rays in adult females of *Dahlbominus fuscipennis*.

The numbers of four classes of eye colour mutants (carmine, claret, chestnut and russet) were scored following exposure of *Dahlbominus* adults to cobalt-60 gamma rays and 14·6 MeV neutrons. Unmated females of this species produce haploid male progeny in which all mutations induced in the germ plasm of the mother are expressed in her sons[7,8]. Groups of adult females were irradiated each day in small gelatine capsules, with neutrons and with gamma radiation, at average ages of 12, 60 and 108 h from emergence. Monochromatic neutrons, from the deuterium–tritium reaction, average energy 14·6 MeV, were obtained from a 150 keV accelerator at a dose-rate of approximately 80 rads per min (at 3 cm from the target). The neutron dose was determined from measurements of the sodium-24 activity produced in thin aluminium strips placed in front of and behind the gelatine capsules during the exposures. In converting neutron flux to dose, the hydrogen content of the insects was assumed to be similar to that of soft tissue. The total dose, whether of neutron or of gamma rays, was about 750 rads; for each experiment the gamma-irradiated flies received their exposures as soon as the neutron doses had been measured (that is, 1 h later) so that the gamma dose could be adjusted to the same number of rads. A 1,500-c. cobalt-60 source furnished gamma radiation at 100 r./min., measured with a calibrated '*EIL* Model 37*A*' portable electrometer. Following irradiation, the females were confined in small shell vials with host cocoons, and eye-colour mutants were scored in the male progeny.

The neutron exposures produced about 30 per cent more mutations (see Table 1 and Fig. 1). As the age of the insects at the time of exposure was increased from

Table 1. FREQUENCIES OF EYE COLOUR MUTATION IN *Dahlbominus* ADULTS FOLLOWING IRRADIATION WITH 750 RADS OF GAMMA RAYS (COBALT-60) AND NEUTRON (14·6 MeV) RADIATION

Age (h)	Gamma rays Mutants/ total sons	Mutants/ 10^5 sons	Clusters	Neutrons Mutants/ total sons	Mutants/ 10^5 sons	Clusters	Ratio of effect
12	29/24 948	116	—	52/32 712	159	—	1·4±0·4
60	52/29 176	178	—	69/32 699	211	—	1·2±0·3
108	58/21 753	267	2	99/29 958	330	5	1·2±0·3

12 to 108 h, the frequency of mutations rose about two-fold. This was so for both neutrons and gamma rays, but the relative effectiveness of the neutrons did not change detectably with age. The overlapping of the standard limits for each age group demonstrates that no significant differences were detected between the results with gamma rays and with neutrons. Only one eye colour mutant was found among 19,824 males in non-irradiated controls. "Clusters" of mutant offspring from gametes that had arisen by cell division following a single mutational event were observed in seven separate instances. Each consisted of two eye colour mutants (Table 1). It was interesting that all clusters occurred among the older (108 h) females. Each mutant in the clusters was counted in calculating the mutation frequencies. Sterility levels in the irradiated insects were almost identical with those found in controls (that is, 8·2 per cent unparasitized cocoons with neutron irradiation as compared with 9·3 and 8·1 per cent for gamma irradiation and for controls).

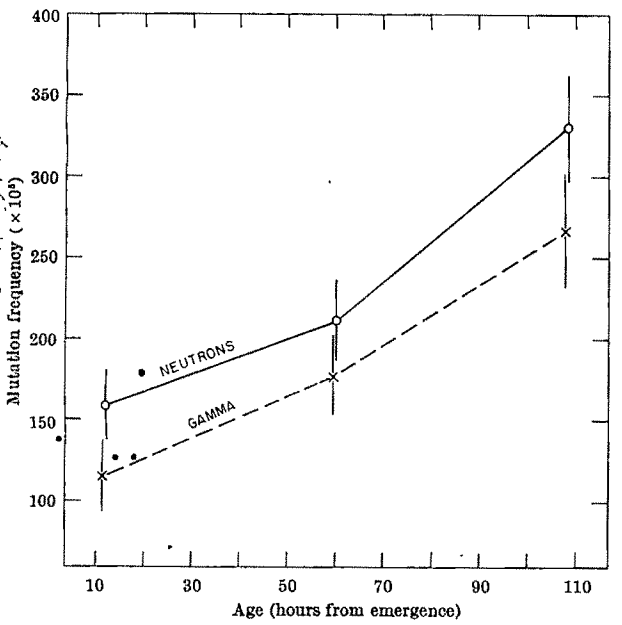

Fig. 1. Frequency for eye colour mutations in *Dahlbominus* oocytes following exposure to 750 rads of 14·6 MeV neutrons and cobalt-60 gamma rays

The ratios for neutron/gamma effects in *Dahlbominus* (1·2 : 1·4) agree with the corresponding RBEs for silkworm oogonia mentioned previously, and also with the value of 1·23 found by Edington and Randolph[9] for sex-linked recessive lethals in *Drosophila* sperm following exposure to 14 MeV neutrons. In *Mormoniella*[4] and silkworm oogonia[9], slightly higher RBEs (2–4) were found for fission neutrons, which have a lower average energy (about 1 MeV) and higher average linear energy transfer. In all these investigations with insects, high dose rates were used, whereas, in mice, RBEs for mutagenesis of 5–6 (ref. 3) and of 19 (ref. 4) have been reported following chronic exposures to fission neutrons.

The increase in both gamma and neutron induced mutation with age from emergence in *Dahlbominus* is probably associated with high sensitivity in mature oocytes.

VIROLOGY

Phenotypic Mixing between Group *A* Arboviruses

WHEN two different viruses infect the same cell some of the progeny may exhibit phenotypic mixing: that is, the genome of one parent may be enclosed in a coat determined, at least in part, by the genome of the other parent. Thus the phenotype may not correspond to the genotype. This anomaly disappears after one cycle of growth if further mixed infections are avoided. Phenotypic mixing was first detected in bacteriophage[1] and has subsequently been observed in polio viruses[2] and myxoviruses[3]. We shall describe a double mutant of Sindbis virus (a group *A* arbovirus) that can be used in a simple test for phenotypic mixing with other wild-type arboviruses. Such a test for phenotypic mixing may be useful in confirming or suggesting relationships among these viruses. The methods used for the growth and titration of arboviruses in primary chick embryo cultures have been described[4].

A Sindbis virus mutant with high resistance to thermal inactivation was selected by several cycles of alternately heating at 60° C for 5 min and regrowing the survivors. In this way a strain was obtained (designated HR) which, after heating at 60° C for 5 min, yielded 10^5 times more viable virus than the wild type under identical conditions (Fig. 1). This heat-resistant mutant retained the growth temperature requirements of the wild type: both were able to make plaques over the temperature range 27°–40° C. This property of the cloned heat-resistant mutant was next altered by selection of a temperature sensitive conditional-lethal (CL) mutant[5]. The resulting mutant (HR–CL) grew in liquid medium and produced plaques normally at 27° C but was unable to reproduce at 39° C. This double mutant thus multiplied only at low temperatures but produced virus that was very resistant to heating.

The HR–CL mutant was examined for phenotypic mixing with three group *A* arboviruses: wild-type Sindbis, Western equine encephalitis (WEE) and Eastern equine encephalitis (EEE). These three viruses had a similar high sensitivity to heating (Fig. 1) and were able to grow well over the temperature range 27°–39° C (Table 1). Chick embryo fibroblasts in monolayers were infected by adding 25 plaque-forming units (P.F.U.) per cell of HR–CL virus together with 25 P.F.U. per cell of a second virus in a small volume of phosphate-buffered saline. After an adsorption period of 1 h at 0° C, the monolayers were drained, rinsed, and then incubated with fresh medium at 27° C for an additional 8 h to permit growth of both viruses. Since

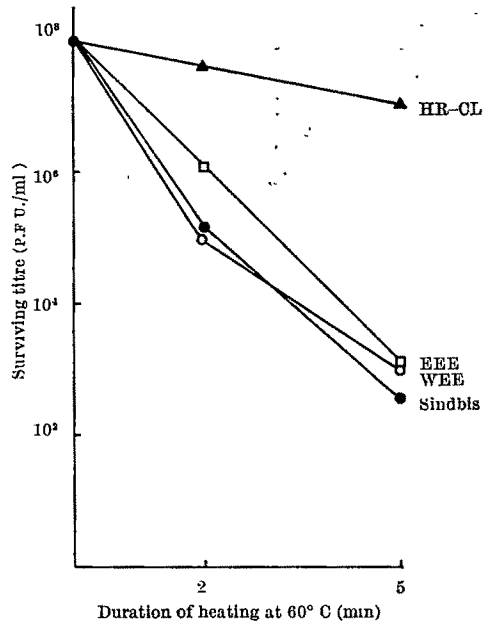

Fig. 1. Heat inactivation of wild-type group *A* arboviruses and heat-resistant mutant of Sindbis (HR–CL). Survival of all viruses was measured by plaque-forming ability at 27° C

viruses of the HR–CL genotype are unable to form plaques at 39° C, the plaques produced at 39° C by fluids collected after mixed infection provide a count of the genomes of the second virus (wild-type Sindbis, EEE, WEE) present. If these genomes were enclosed in their own protein-lipid coats, their survival after 5 min heating at 60° C would be predicted by the curves in Fig. 1. If, however, these viruses included in their coats protein determined by the HR–CL mutant, some protection from heat inactivation should be afforded.

Table 1. PLAQUING EFFICIENCY OF GROUP *A* ARBOVIRUSES AT 27° C AND 39° C

Virus	Titre in P.F.U /ml. with incubation at 27° C	39° C
Sindbis	$1{\cdot}5 \times 10^8$	3×10^8
WEE	3×10^7	3×10^7
EEE	3×10^7	1×10^8
HR	1×10^8	2×10^8
HR–CL	7×10^7	3×10^3

Virus was collected after 9 h growth at 27° C on chick fibroblast monolayers. Plaquing efficiency of the infected fluids was determined by measuring plaque formation at the two incubation temperatures.

Table 2. HEAT RESISTANCE ACQUIRED DURING MIXED INFECTION

Progeny of mixed infection with HR–CL and:	Titre of virus able to make plaques at 39° C	Titre after 5 min at 60° C	Predicted* titre after 5 min at 60° C
Sindbis (wild-type)	$1{\cdot}5 \times 10^8$	7×10^6	5×10^2
WEE (wild-type)	4×10^7	$1{\cdot}5 \times 10^6$	4×10^2
EEE (wild-type)	5×10^7	1×10^6	6×10^2

* Titres are predicted from the heat-inactivation curves of Fig. 1, which also records the heat inactivation characteristics of HR–CL.

Each wild-type arbovirus was grown in mixed infection with HR–CL at 27° C. Viral titres were measured by plaque formation at 39° C and are expressed in P.F.U./ml.

Table 2 records the yield of virus able to make plaques at 39° C, the actual sensitivity of these particles to heating, and the sensitivity expected if these virus particles were phenotypically wild type. Substantial protection was observed, whereas, in contrast, no protection was seen when artificial mixtures of the viruses were examined. (The protected particles have less resistance to heating than the HR–CL parent, as would be predicted from similar experiments with myxoviruses[3].)

The protected virus particles might have been recombinants that had inherited the ability to make plaques at 39° C from one parent, and resistance to heat from the other. To test this possibility, plaques produced by t of these 'protected' particles were cloned and regrow at 27° C. All clones had regained the sensitivity of the wil type virus to heat inactivation. Furthermore, in t mixed infection with HR–CL and EEE, several protecte particles, cloned and regrown, were all serological demonstrated to be EEE. Therefore, we interpret th observed protection as evidence of extensive phenotyp mixing between wild-type arboviruses and the HR–C mutant.

The three viruses used in this experiment are known t be serologically related[6] and undoubtedly have structura features in common. To discover if this was an essenti factor in phenotypic mixing, we then examined a serolog cally and morphologically unrelated virus. Vesicula stomatitis virus (VSV) is at present unclassified[7] and i in gross morphology[8], quite different from Sindbis virus Nonetheless, these viruses have certain characteristi in common. Both are RNA viruses and contain lipid[4] that is probably acquired as they pass through a cellul membrane. Both have been isolated from insects[11], When heat inactivation of VSV grown in mixed infectio with HR–CL was compared with inactivation of VS grown in single infection, no protection was observe (Fig. 2).

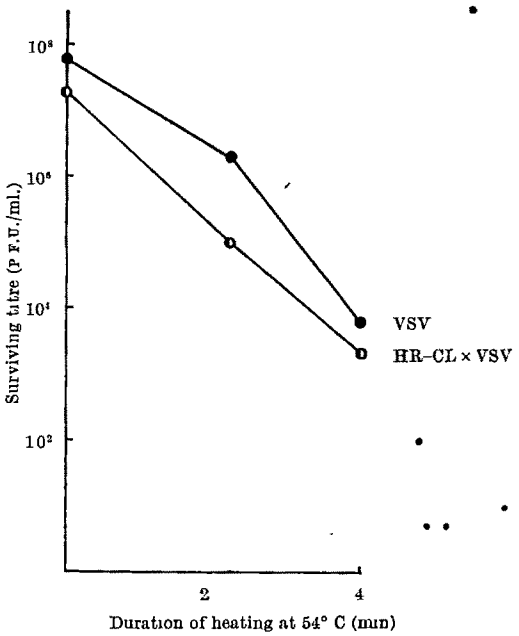

Fig. 2. Heat inactivation of vesicular stomatitis virus (VSV) grown in single infection (●), and grown in mixed infection with HR–CL (○)

It may be that no phenotypic mixing was observe between these two viruses because they are structural so dissimilar that their coat components are not inte changeable. However, this result would also have be obtained if true mixed infections had not been establishe and each cell in the culture was releasing only one speci of virus. This possibility will be tested by examining the progeny of single cells.

We conclude that extensive phenotypic mixing occurs during mixed infections with certain group *A* arboviruses, but does not occur when VSV and a group *A* arbovirus simultaneously infect the same tissue culture. Regardless of its basis, the presence or absence of phenotypic mixing appears to correlate with the serological classification of these viruses. The extent of this correlation is being examined with a greater variety of arboviruses of groups *A*, *B* and *C*.

VETERINARY SCIENCE

An Epizootic of Equine Sarcoid

JACKSON[1] first recognized and described equine sarcoids, hich are locally aggressive, fibroblastic tumours of quine skin. They are often multiple, frequently recur ollowing surgical excision or radiotherapy, and generally ave fibropapillomatous features. Horses, donkeys and ules are susceptible. Neither a seasonal incidence nor an ge distribution of equine sarcoids has been detected[2]. ackson pointed out that the gross and microscopic ppearance of the tumours, the predilection sites, and the attern of spread to secondary sites on affected animals ere suggestive of viral aetiology. Auto- and homo-ansplantation have been reported[2-6]. Voss recently ported that several tumours were produced in horses ith centrifuged sarcoid extracts which probably were ll-free although they had not been filtered[5]. Intrader-al inoculation of bovine papilloma virus in horses oduced localized, fibroblastic growths similar to equine coid which suggests the interesting possibility of a sal relationship to equine sarcoid[7]. Equine sarcoid has known relationship to Boeck's sarcoid in man.

An epizootic of equine sarcoids occurred in the spring of 35 in a herd in Eastern Washington, United States. Fig. gives details of the important features of this herd from s beginning in 1961 until the end of 1965. The herd

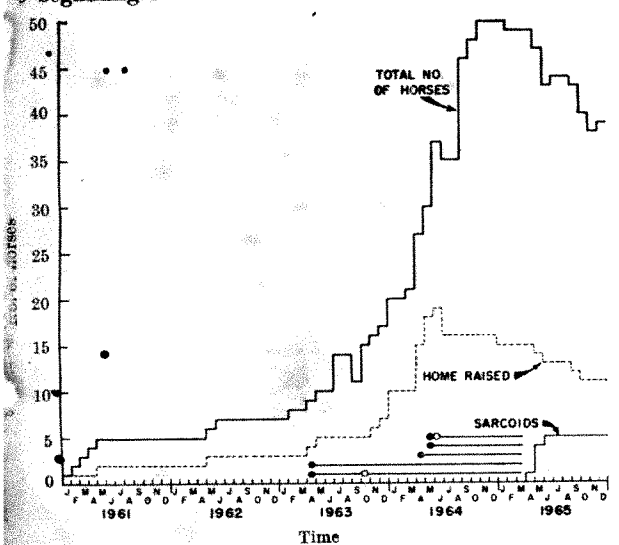

Fig. 1. The occurrence of sarcoids in a herd of horses. The total number of horses at risk for any month is given by the top solid line. The number of these horses born in the herd is designated by the broken line. The number of sarcoid cases is given by the bottom solid line. Horses less than 6 months of age are not included. The solid circles indicate when each of the five affected horses was born. Two of the affected horses were not born in the herd. The dates they were introduced into the herd are designated by open circles

was made up of Appaloosa, Quarter, Pony of the Americas, and mixed breed horses. The entire herd was at risk but was free from sarcoids until April 1965 when one case was observed. There were three additional cases in May and a fifth case in June of that year. All five cases occurred in a six-week period.

One horse was a mixed breed and the other four were Ponies of the Americas. There were four fillies (two yearlings and two 2 year-olds) and one 15-month-old colt. Four cases had solitary tumours (right upper forearm, left foreleg just above the carpus, right distal thigh, or the anterior right stifle). One case had multiple sarcoids located on the right mandible, base of the right ear, and on the right shoulder. The herd was maintained under close observation so that all the cases were detected early and presented for treatment while the tumours were still small (the largest was 3 cm in diameter). The tumours were removed by surgical excision and the diagnosis was confirmed by histopathological examination. Microscopically the tumours appeared to have been adequately excised, and none has recurred.

An estimate of the incidence of equine sarcoids in the Pacific Northwest, based on equine accessions at the Washington State University Veterinary Hospital for a 140-week period, was 0·0049 per hundred per week. The true incidence is undoubtedly lower. The attack rate in this herd during the 6-week outbreak was 1·8 per hundred per week.

The most striking feature of the history of the herd was the addition of a large number of horses 8–12 months before the appearance of equine sarcoids. If it is assumed that equine sarcoids are caused by a virus, the incubation period was probably less than 1 year because three of the affected individuals were yearlings. Sarcoids have been observed in 6-month-old foals[2]. If a sarcoid-evoking virus had been present in the herd early in 1963, one might have expected that the two affected 2-year-olds would have developed sarcoids at an earlier date. Since these two individuals developed tumours at about the same time as the other three, it seems reasonable that they were all infected at about the same time. Thus, we believe that a sarcoic-evoking virus might have been introduced into the herd with the horses added to the herd 8–12 months before the tumours appeared.

There was also a familial pattern in this epizootic as four of the five affected individuals were members of a highly inbred family. The herd husbandry made it difficult to explain this pattern on the basis of environmental factors. The elucidation of a genetic factor would require a prospective study.

While the epizootiologic picture in this herd was compatible with a viral aetiology, it will be necessary to isolate and characterize a sarcoid-evoking agent by appropriate procedures. The relationship of such a virus to bovine papilloma virus should be determined.

This investigation was supported in part by funds provided for biological and medical research by the State of Washington Initiative Measure and in part by the U.S. Public Health Service.

SOIL SCIENCE

Optical Microscopy and Soil Structure

USE of a photometer in conjunction with a polarizing microscope has yielded useful information regarding the structural anisotropy of soil mechanics test specimens.

Kaolin was thoroughly remoulded at 100 per cent moisture content and divided to form three specimens. One specimen was consolidated in a shear box to 4 kg/cm², allowed to rebound to 2 kg/cm², sheared at 1 mm/min and finally unloaded completely. For the second specimen shearing was omitted. The third specimen was left in the remoulded unconsolidated state.

Using a cheese wire, undisturbed samples were cut from the sheared and from the consolidated specimens. Samples were taken from the unconsolidated specimen with a spatula. After impregnation with 'Carbowax 6000', without an intermediate drying stage, thin sections were prepared by grinding and polishing.

Between crossed-polars the thin sections showed a mottled appearance. Fig. 1 is typical. The shades of the light and dark patches changed as the angle between section and polars was altered. A parallel electron-microscopical examination suggested that each patch is a domain of almost parallel particles.

For microphotometry, an auxiliary lens, mounted above the microscope eyepiece, imaged the section in the plane of a variable iris diaphragm. Light passing through the diaphragm was filtered to 5420 Å wave-length, and collected by a photocathode. An auxiliary viewing system made possible both visual control of the measurements and calibration of the diaphragm setting.

The polar diagram (Fig. 2*a*) illustrates a series of measurements made on a circular area of 0·1 mm diameter. The intensity of light transmitted by this area (I) was measured as a function of angle while thin section and microscope stage were rotated together. In the diagram the intensity is plotted as radius at the corresponding angle. The symmetrical four-lobed figure is as might be expected from an anisotropic area.

An anisotropy index (A) has been defined as:

$$A = \frac{I_{max} - I_{min}}{I_{max} + I_{min}}$$

Fig. 2*b* shows the dependence of anisotropy index on radius of area of measurement for observations made on three series of concentric circles. The locations of the observations were judged by visual examination to be typical of the specimens in the unconsolidated and in the consolidated cases. Increases of anisotropy due to consolidation and to shear are in accordance with observations made elsewhere[1–8] and with preliminary electron microscopical observations made on other samples of these specimens.

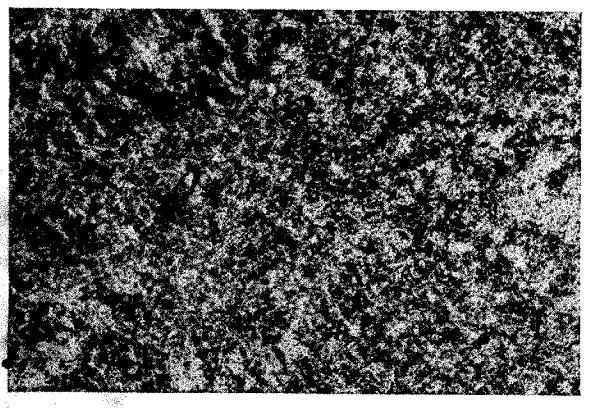

Fig. 1. Remoulded kaolin between crossed-polars. (× *c.* 100)

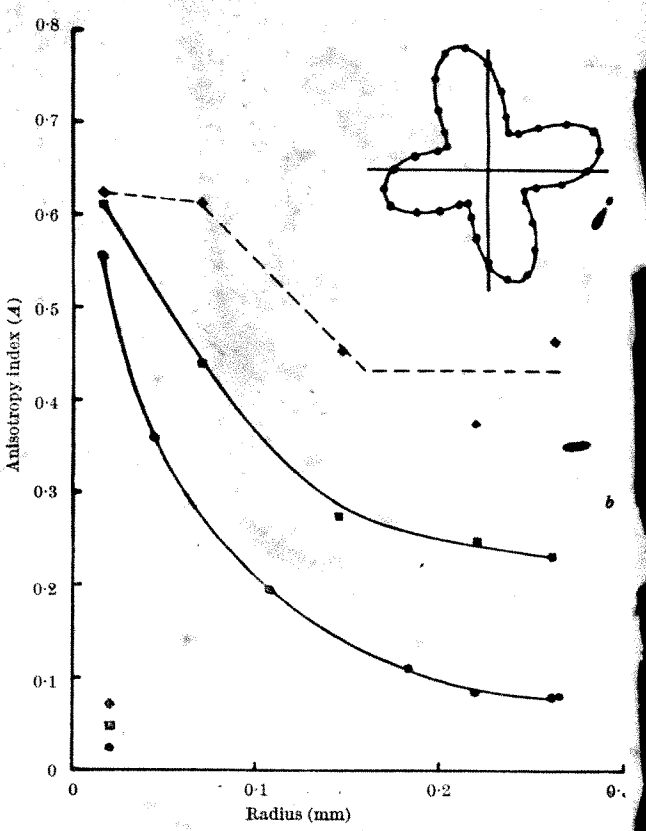

Fig. 2. (*a*) Polar diagram: intensity of light transmitted: inclination of polarizing system. (*b*) Anisotropy index: radius. ●, Unconsolidated; ■, uniaxial consolidation; ◆, sheared

In any interpretation of the results, the nature of the optical phenomena involved, the statistical variation inherent in the specimens, and the thickness of the sections studied must all be considered.

The results available are of sufficient extent only to illustrate the methods. I thank Ernst Leitz *G.m.b.h.* the Soil Mechanics Laboratory of the Department of Engineering, University of Cambridge, and the Nuffield Foundation for their assistance.

GENERAL

Giorgi: a Proposed New Name for the Kilogramme

THE rapidly increasing acceptance of S.I. units by physicists, other than nuclear physicists, by chemists by electrical engineers, and by mechanical engineers has led to the expression in several quarters of the desirability of a single symbol and a simple name to replace the kilogramme. I suggest the symbol G and the name Giorgi The reasons for this are obvious.
